vmbgs	vertical metres below ground surface
wt. %	percent weight

1.0 INTRODUCTION

This Site Characterization Plan (SCP) has been prepared to meet the requirements of an application for a Quartz Mining License for the Coffee Gold Mine. It follows the guidance in the Plan Requirement Guidance for Quartz Mining Projects (Yukon Water Board and EMR 2013).

The proposed Coffee Gold Mine (the Project) is an open-pit gold mine owned by Goldcorp Kaminak Ltd, a subsidiary of Newmont, located on the south side of the Yukon River in the White Gold District of west-central Yukon, approximately 130 km south of the City of Dawson, 140 km west of Pelly Crossing, 95 km north-east of Beaver Creek, and 340 km northwest of Whitehorse. The Project is located wholly within the traditional territory of Tr'ondëk Hwëch'in, partially within the traditional territory of Selkirk First Nation and First Nation of Na-cho Nyäk Dun, and partially within the asserted territory of White River First Nation. The Project contains several gold occurrences within an exploration concession covering an area of more than 600 km^2. The Mine Site will be accessed by road from Dawson via a 16-km stretch of Klondike Highway and 192-km all-season road, referred to as the Northern Access Route (NAR) (Figure 1-1). The NAR will be comprised of 61 km of existing road, 5 km of winter road, and 126 km of road modifications, including approximately 31 km of new single-lane, forestry-type access road. The NAR includes seasonal barge crossings on both the Stewart and Yukon rivers, with ice bridges and a seasonal winter road in the winter months.

The Government of Yukon and the Government of Canada, in partnership with Yukon First Nations, have come to a joint decision to accept the Yukon Environmental and Socio-economic Assessment Board (YESAB) Executive Committee's recommendation that the Coffee Gold Mine project be allowed to proceed. This SCP provides information from the Project Proposal submitted to YESAB as well as information collected during and subsequently to the Project approval process.

Concordance of the SCP to the Plan Requirements Guidance for Quartz Mining Projects is shown in Table 1-1.

Table 1-1 Concordance with Plan Requirements

4.7	Soils and Bedrock	9.0 Soil and Bedrock 9.2 Permafrost
4.8	Seismicity	10.0 Seismicity
4.9	Geochemistry and Geotechnical Information	11.0 Geochemistry and Geotechnical Information

1.1 Project Summary

The Project is comprised of four open pits: Supremo, Latte, Double Double, and Kona. Waste rock is proposed to be permanently stored in the Alpha Waste Rock Storage Facility (WRSF) (Figure 1-2). The ore production rate is proposed to be up to approximately 9.0 million tonnes (Mt) per year, producing an estimated total of 67 Mt of heap leach feed over the 10-year Operation Phase. The conceptual-level estimate for waste material to be moved over the life of mine (LOM) is up to approximately 330 Mt based on an average strip ratio of 5.0:1. The ore will be crushed and transported to the Heap Leach Facility (HLF) via overland conveyor or trucks for nine months of the year. During the three coldest months of winter, run-of-mine (ROM) ore will be stockpiled in the ROM stockpile. Gold will be extracted from gold-bearing leach solution by a six tonnes per day (t/d) adsorption, desorption, recovery carbon plant with mercury retorting to produce a final gold doré product. A total of 2.6 million ounces of gold is planned to be recovered over a 10-year mine life.

The Project phases are defined as follows:

- Construction Phase: Q2 Year –3 to end of Year –1 (30 months)
- Operation Phase: Year –1 to end of Year 9 (10 years)
- Reclamation and Closure Phase: Year 10 to end of Year 21, including a 6-year Post-Mining Closure Stage and a 5-year Active Closure Stage (11 years)
- Post-Closure Phase: Year 21 onwards as determined to be required.

These phases broadly describe the activities occurring within a particular time period; however, some activities will continue from one phase to another as mine site development advances with operational activities (e.g., Open Pits, WRSF). When areas that support mine operations are no longer required, they will be progressively reclaimed. The overall Project schedule is the general expected scenario for mine construction and operation; detailed activities are subject to change depending on detailed mine planning and the timing of receipt of authorizations.

1.2 Scope and Objectives

This Plan is provided in conjunction with several other plans as part of a package to meet the requirements for quartz mine applications for a Quartz Mining License and a Water Use Licence under the *Quartz Mining Act* and the *Waters Act*, respectively. Other applicable plans identified in the guidelines are submitted separately.

This plan addresses the site environmental baseline conditions for the Coffee Gold Mine in sufficient detail to support the required plans within the overall application. It includes descriptions of the footprint areas of the mine and the surrounding environment that may be affected by mine activities. Mitigation measures to avoid and reduce potential effects of the mine on the environment have been approved by YESAB and are included in the scope of other submitted plans.

The Plan includes a description of the pre-disturbance and existing conditions of the Project footprint and reference areas. This description of pre-disturbance and existing conditions following exploration activities is based on scientific data collected during baseline programs conducted by Newmont in parallel to the Project feasibility and advanced exploration activities. These baseline programs include meteorology, hydrology, hydrogeology, geotechnical, soils, air, noise, aquatic, and terrestrial wildlife, and were initiated in 2010 or earlier. The purpose of baseline programs was to collect data to support the assessment of potential effects of the Project and develop mitigation measures, and to describe the pre-Project conditions that will inform the basis for future monitoring programs that will be required as part of required Project authorizations. Environmental baseline programs continue to be implemented at the Project site to collect ongoing environmental information and inform exploration activities.

Reference areas defined as areas within the boundaries of regional study but outside the zones of potential Project-related influence, are also described herein. In this case, the reference areas are defined by water quality monitoring stations located where the proposed Project will not have an influence – on Dan Man Creek and the Yukon River upstream of all Project related discharges (Section 4.2). These reference areas provide local background context for the development of future monitoring programs.

1.3 Summary and Record of Consultation

First Nation engagement and consultation is ongoing, and any feedback that is received or concerns that are heard during consultation will be incorporated into this plan, where applicable.

1.4 Synergies with Newmont Standards and Requirements and Other Project Documents

As an important part of Newmont's internal governance process, Newmont has implemented a Global Policies and Standards (Global Standards), that are reviewed and preliminarily approved by a Global Policies & Standards Committee. The Global Standards provides the framework and standards for Newmont sustainability management and ensures a consistency of approach for implementing these global policies across the Company.

The scope of the Social and Environmental Standards (SER) is global, and they apply to all directors, officers and employees of Newmont Corporation, its subsidiaries, and any other entities that it controls. A variance request process for existing or future conditions is in place for SER standards. The process provides an alternative mechanism for those instances where a Newmont site/operation cannot logistically or feasibly conform to a requirement established in a Standard due to special conditions or unique hardships. The Newmont SER standards is straightforward in design and is capable of being implemented globally. The SER standards is intended to be fully integrated into all core business functions, and it emphasizes sustainability responsibility and accountability at all organizational levels.

The SER contains overarching standards applicable to all sustainability functions (Global Standards), as listed below:

- Air Emissions Management Standard
- Biodiversity Management Standard
- Closure and Reclamation Management Standard
- Community Investment and Development Standard
- Cultural Resource and Management Standard
- Hazardous Materials Management Standard
- Human Rights Standard
- Indigenous Peoples Standard
- Land Acquisition and Involuntary Resettlement Standard
- Local Procurement and Employment Standard
- Product Stewardship Standard
- Social Baseline and Impact Assessment Standard
- Stakeholder Relationship Management Standard
- Tailings Storage Facility and Heap Leach Facility Environmental Standard
- Tailings Storage Facilities Technical and Operations Standard
- Waste Management Standard
- Waste Rock and Ore Stockpile Management Standard
- Water Management Standard.

While this Plan can be reviewed in isolation to inform a review of the specific actions for Project management and monitoring, this plan should be viewed in concert with the management plans listed in Table 1-2 in order to attain a holistic understanding of the Project.

Table 1-2 Management Plans

Plan	Description
Air Quality and Greenhouse Gas Management Plan	This plan intended to identify and demonstrate how appropriate management techniques will reduce the potential for any Project-related adverse effects to air quality and human health, and to describe the measures that will be undertaken to control gas air emissions generated by Project activities.
Access Route Construction Management Plan	Describes the procedures and protocols for construction of the access road, barge crossings, and seasonal ice roads (i.e., the NAR) between Dawson, Yukon, and the Project Site
Access Route Operational Management Plan	Describes the procedures and protocols for use of the NAR. The NAR will be used during both the Construction and Operation Phases to transport fuel, equipment, and other supplies
Cyanide Management Plan	Describes the measures Newmont will implement to minimize the risk to the public, employees, contractors, and the environment from the use of cyanide in the recovery of gold from ore.
Emergency Response Plan	The purpose of this plan is to protect the health and safety of all personnel by ensuring an appropriate response is in place (and sets out guidelines to be followed) in the event of reasonably foreseeable emergencies and incidents.
Erosion and Sediment Control Plan	Erosion and sedimentation associated with ground disturbances such as vegetation clearing, earthworks (cuts and fills), excavations, and slope failures, have the potential to affect the surrounding environment if not properly mitigated. The objective of this Erosion and Sediment Control Plan (Plan) is to provide guidance and protocols that aim to minimize water erosion and prevent sediment mobilization into the receiving environment, specifically areas with fish and aquatic biota values that can be affected by increased turbidity or sediment deposition.
Explosives Management Plan	The purpose of this plan is to provide guidance on the handling, storage, and use of explosives, which is regulated at the federal and territorial level. The objective of the plan is to describe management practices that the Project will employ to ensure the safe storage and use of explosives in mine operations while minimizing the risk to employees, contractors, and the environment.
General Mine Development Plan	This plan serves to describe the development of the mining property to support operational mining. It describes the facilities which will be constructed, and preparations required before the commencement of normal mine operations.
Waste and Hazardous Materials Management Plan	The objective of this plan is to address the responsible handling, storage, transportation, and disposal of all hazardous and non-hazardous waste at the Mine Site.
Heap Leach and Process Facilities Plan	This plan outlines the design and construction information for the Heap Leach Facility (HLF), which is comprised of the crushing plant, heap leach pad (HLP), and process facilities. The Plan also details the procedures and protocols for management of the crushing plant, HLP and process facilities once constructed. The Plan discusses the safety measures implemented to provide safe handling practices, containment requirements, and disposal and treatment of solutions.
Heritage Resources Protection Plan	The objective of this plan is to provide protection measures to reduce any significant or adverse effects for known and previously unrecorded heritage resources throughout the life of the Project.

Plan	Description
Mine Operations Plan	This Mine Operations Plan describes the design criteria, open pit mine design, material scheduling, and general operations of the four Open Pits at the Project.
Noise Management Plan	This Noise Management Plan presents details on the relevant noise effects assessment criteria, compliance procedures and controls relating to Project activities. The objective of the Noise Management Plan is to describe the appropriate management techniques that will reduce the potential for noise-related adverse impacts to human health or the environment
Reclamation and Closure Plan	Newmont will develop and implement a Reclamation and Closure Plan that contains commitments related to: salvageable material, socio-economic aspects of closure, care and maintenance, revegetation, project facilities, social reclamation
Spill Contingency Plan	The purpose of this plan is to minimize the impacts of spills through the establishment of pre-determined lines of response and plans of action, and to protect the safety of workers, contractors and the environment in the event of a spill.
Vegetation Protection Plan	The purpose of the Vegetation Protection Plan (the Plan) is to reduce the effects of Project Construction and Operation-phase activities on vegetation. The Plan outlines measures to maintain the integrity of vegetation and ecological communities and prevent the introduction and spread of invasive plant species.
Water Management Plan	The water management plan describes water management practices and procedures to minimize adverse effects on water resources resulting from mining operations and activities.
Waste Rock and Overburden Management Plan	This plan describes the types of waste rock, soil overburden and ROM stockpiles that will be constructed and how their materials will be characterized, segregated, and stored to ensure long-term stability; and how frozen materials will be handled and stored to support closure and reclamation objectives
Wildlife Protection Plan	The purpose of the Wildlife Protection Plan is to minimize the effects of the Project's Construction and Operation-phase activities on wildlife and wildlife habitat. The Wildlife Protection Plan is intended to ensure that wildlife continue to use habitat in areas adjacent to the Project footprint and within the broader Project area while reducing the potential for Project-related injury or mortality to wildlife and accommodating operational and human health and safety requirements

2.0 GEOLOGY

2.1 Regional Geology

The Project is located in the Yukon-Tanana Terrane (YTT), an accreted pericratonic rock sequence that covers a large portion of the Omineca Belt in Yukon and extends into Alaska and British Columbia (BC). The YTT underlies part of the Tintina gold belt and hosts multiple gold deposits, including the Sonora Gulch gold deposit, the Casino copper-gold-molybdenum porphyry, the Boulevard gold prospect, and the Golden Saddle gold deposit (Bennett et al., 2010; Allan et al., 2013). The YTT also hosts volcanogenic massive sulphide and Mississippi Valley-type deposits (Figure 2-1).

The YTT is composed of a basal metasiliclastic sequence overlain by three subsequent volcanic arcs. The oldest component of the YTT is the Late Devonian Snowcap assemblage, which consists of metasediments including psammitic schist, quartzite, and carbonaceous schist in addition to local amphibolite, greenstone, and ultramafic rocks (Piercey and Colpron 2009). The Snowcap assemblage was deposited on the ancient Laurentian margin in a passive marine setting (Piercey and Colpron 2009). The beginning of eastward subduction of the paleo-Pacific plate led to the formation of a magmatic arc, at approximately 365 million years ago (Colpron et al. 2006a). Rapid westward slab rollback caused significant extension, which initiated the formation of the Slide Mountain Ocean back-arc basin by approximately 360 million years ago (Colpron et al. 2007). Arc volcanism during the Wolverine-Finlayson magmatic cycle (365 to 342 million years ago) deposited submarine mafic and felsic volcanic rocks of the widespread Finlayson assemblage onto the Snowcap assemblage (Colpron et al. 2006b).

A reversal of subduction polarity during the Late Permian resulted in the western margin of the Slide Mountain Ocean back-arc subducting beneath the evolving YTT (Erdmer et al. 1998). This subduction initiated a magmatic arc which was active from 269 to 253 million years ago and formed the Klondike arc assemblage, the youngest member of the outboard YTT (Allan et al. 2013; Colpron et al. 2006a). Closure of the Slide Mountain Ocean, by the Late Permian to Early Jurassic periods, led to the obduction of the YTT onto the Laurentian margin, causing a collisional event responsible for lower amphibolite facies metamorphism in the Project area (Beranek and Mortensen 2011). In addition, collision resulted in the development of a low-angle transpositional foliation, recognized throughout the YTT (Berman et al. 2007).

Following accretion of the YTT onto Laurentia, easterly subduction caused intra-arc shortening and compressional deformation. In the Klondike and the area of the Project, thrust fault-bounded panels of the Slide Mountain Ocean assemblage greenstone and serpentinized ultramafic occur within the tectonic stratigraphy of the YTT (Buitenhuis 2014; MacKenzie et al. 2008). These thrust-emplaced slices are generally less than 100 metres (m) in thickness, dip to the southwest, and persist for tens of kilometres in some areas (MacKenzie and Craw 2010, 2012). The emplacement of these slices is contemporaneous with northeast-vergent, open to tight folding dated between 195 and 187 million years ago (Berman et al. 2007).

Beginning in the early- to mid-Cretaceous, localized rapid uplift and exhumation occurred throughout the YTT in Yukon and Alaska, including the Dawson Range (McCausland et al. 2006). Extension and unroofing of the rocks of the Dawson Range was accompanied by the emplacement of the Coffee Creek granite and Dawson Range batholith (approximately 110 to 90 million years ago; Colpron et al. 2006a). This localized extension and exhumation is recorded by an apparent age-resetting event observed in white mica in western Yukon Tanana at roughly 90 million years ago (Douglas et al. 2002), in rhenium-osmium dates in molybdenite (92.4 million years ago), and uranium-lead dates in monazite (92.5 million years ago) from

plutons in east-central Alaskan YTT (Selby et al. 2002). At the Coffee property, this extension resulted in the activation of the Coffee Creek fault system, a set of dextral strike-slip faults and associated north-to-northeast brittle faults, interpreted as splays, off of the regional Big Creek fault to the southeast (Sánchez et al. 2013; Johnston 1999).

2.2 Coffee Property Geology

The Project area is underlain by a package of metamorphosed Paleozoic rocks of the YTT that was intruded by a large granitic body in the Late Cretaceous. The Paleozoic rock package consists of a mafic schistose to gneissic panel which overlies the Sulphur Creek orthogneiss. Both packages form the southwestern limb of a northwest-trending antiformal fold with limbs dipping shallowly to the northeast and southwest.

The schistose and gneissic mafic rock package comprises a thick panel of biotite (+ feldspar + quartz + muscovite ± carbonate) schist, with rare lenses of amphibolite, which overlies a panel of amphibolite and metagabbro with arc-derived geochemical signatures. Within the schistose panel, slices of 20-m thick serpentinized ultramafic are in tectonic contact with the surrounding rocks. This rock sequence overlies the augen orthogneiss. These rocks are in contact to the southwest with the 98.2 ± 1.3 million years ago Coffee Creek granite. Both the Paleozoic metamorphic rocks and Cretaceous granite are cut by intermediate to felsic dykes of andesitic to dacitic composition.

Due to only rare outcrop exposure on the property (less than 5%), the geological map (Figure 2-2) has been compiled from a combination of geological traverses, bedrock mapping, borehole data, soil geochemistry, and geophysics (magnetic and radiometric). The magnesium number (Mg#) from soil samples (Mg# = Mg/Mg+Fe) was used to discern mafic from felsic units with the granite being the most felsic, followed by the felsic gneiss. The mafic schist unit was further subdivided into felsic-intermediate schist, biotite schist, amphibolite, and ultramafic rocks (Table 2-1).

Table 2-1 Main Rock Units in the Coffee Property

Rock Unit	Description
Felsic Gneiss	Variable quartz + feldspar augen + biotite + muscovite. Typical Mg# 2-28. Low in potassium. Host to gold mineralized zones at Supremo.
Biotite Schist	Biotite +/- feldspar +/- quartz +/- muscovite +/- amphibole. Commonly carbonate-rich. High in potassium. Typical Mg#20 – 40. Locally mylonitic. Host to gold mineralized zones at Latte.
Muscovite Schist	Mainly quartz + muscovite. Typical Mg#10 – 20. Locally mylonitic.
Biotite Amphibolite	Amphibole + feldspar + biotite. Typical Mg# 20 - 40. Biotite and amphibole both iron-rich. Contains up to 20% biotite.
Amphibolite	Found within the lower mafic footwall. Amphibole + feldspar ± biotite. Typical Mg# 30-50, biotite and amphibole more magnesium-rich than biotite amphibolite. Contains up to 15% biotite.
Metagabbro / Amphibolite	Interleaved metagabbro with coarse magnesiohornblende + feldspar, and fine-grained, massive amphibolite with greater than 95% magnesiohornblende. Moderate to strong retrogression to actinolite. High magnesium content of biotite, amphibole.
Ultramafics	Serpentinite, pyroxenite or listwaenite. Typical Mg# 50 - 73, higher than all amphibolites and metagabbro. Very high in chromium and nickel.
Granite	Coffee Creek granite and Dawson Range batholith. Both are phases of the Whitehorse Plutonic suite and are uranium-rich. Dawson Range batholith higher in thorium. Both are identifiable using airborne radiometrics.
Dacite Dykes	Quartz + feldspar phenocryst porphyry. Generally, strongly silicified and sericitized. Strong spatial association with mineralized gold zones.
Andesite Dykes	Feldspar phenocrystic. Aphanitic in gold-bearing structures where all original textures are destroyed by intense silicification and sericitization. Strong spatial association with mineralized gold zones.

2.3 Deposit Mineralization

Exploration drilling completed between 2010 and 2015 identified significant gold mineralization in over 15 separate areas of the Coffee property: Supremo, Latte, Sumatra, Arabica, Double Double, Americano West, Americano, Espresso, Kona, Kona North, Macchiato, Cappuccino, French Press, Dolce, and Sugar. Mineralization textures for the four Project resource and reserve deposits: Supremo, Latte, Double Double, and Kona, are described in Table 2-2 and are further detailed below.

Table 2-2 Main Mineralized Zones of the Project

Zone	Host Rocks	Description
Supremo	Augen Gneiss	Narrow gold-bearing brittle fault structures with gold hosted in intense fracture zones, immature clast supported breccia and in zones of most intense deformation matrix supported breccia. Mineralization commonly on the margin of and within dacite dykes which intruded along the fracture zones pre-mineralization. Gold mineralization and accompanying quartz-sericite-pyrite alteration are associated with later reactivation of structures. Complete oxidation up to 250 m below surface.
Latte	Biotite-feldspar Schist, Augen Gneiss	Gold is hosted in zones of brecciation and strong fracturing as well as areas with pervasive sericite alteration and strongly disseminated sulphides. Some high-grade zones are associated with quartz vein breccias. Dolomite-illite/sericite-arsenian pyrite sulphidizes foliaform biotite laths. Potential remobilization of gold to other structures. Complete oxidation up to 75 m below surface
Double Double	Augen Gneiss, Biotite-feldspar Schist	Narrow gold-bearing brittle structures hosted in matrix-supported breccia including dacite porphyry fragment breccia. Anastomosing quartz vein networks and microbreccia associated with high-grade. Local intense silicification and strong disseminated sulphide mineralization. Complete oxidation up to 350 m below surface.
Kona	Granite	Broad zones of fracture-controlled and disseminated pyrite associated with dacite dykes. Gold hosted in quartz-sericite altered granite. Iron oxides after disseminated pyrite, pyrite veinlets, stockworks and sooty-pyrite rich shear zones.

2.3.1 Supremo Zone

The Supremo zone is hosted in the augen gneiss package and consists of a number of interconnected north-to-northeast trending, steeply dipping structures (T1 to T8). The structures are variably spaced and are known to splay and merge into one another over their strike length. The geometry of the structural zones is defined by linear gold-in-soil anomalies, topographic lineaments, and magnetic linear breaks, and ultimately subsurface via extensive drilling and three-dimensional interpretation of lode geometries supported by core-oriented structural measurements.

The gold mineralization at Supremo is generally characterized by two distinct styles: brecciated mineralization and biotite replacement mineralization. The highest grades are associated with polyphase hydrothermal breccias. Breccia textures range from mature matrix-dominant phases with rounded fragments to immature wall rock crackle breccias. Matrix compositions range from incompetent limonite-clay material to strongly silicified material. Angular-to-sub-rounded clasts range from 0.5 centimetres to 3 centimetres in diameter and consist predominantly of highly silicified fragments and subordinate altered wall rock and dacite porphyry fragments. Brecciated lasts occur locally, indicating multiple phases of brecciation. The lower grade gold mineralization is associated with pervasive hydrothermal alteration of

non-brecciated gneissic host rock. Biotite is pseudomorphously replaced by pyrite and the hydrothermal alteration is characterized by an overall removal of potassium and aluminum with the addition of sulphide, carbonate, and silica. Andesite and dacite dykes appear to have utilized the same structures as mineralizing fluids, but they are themselves altered and locally auriferous, therefore they predate mineralization. In other cases, altered dykes with elevated arsenic and antimony are barren. Some dyke margins appear to focus brecciation, potentially due to rheological contrast. The relationship between dykes and the auriferous hydrothermal system remains poorly constrained.

2.3.2 Latte Zone

Drilling across an east-west trend of gold-in-soil anomalies at Latte has intersected gold mineralization 0.5 m to 1 m below surficial colluvium and soil. Latte zone consists of a stacked set of moderately to steeply south-southwest dipping, east-southeast striking brittle ductile structures, whereas the Latte North structure splays off from the main Latte structure and dips moderately to steeply to the southeast with a north-easterly strike. No shear fabric or observable high strain indicators are visible in association with the steep and mineralized Latte structures. Drilling has intersected mineralization at depths of up to 450 m below surface, and all structures remain open at depth.

The western portion of the Latte zone is dominated by broad regions of disseminated mineralization found throughout a wide panel of biotite schist. The western structures strike approximately 100˚ and contain five or more mineralized shoots which merge and separate along strike. The structures continue to the east and eventually merge into the connector zone, where the Supremo north-south structures and the east-west Latte and Double Double structures converge. Total traceable length of the mineralized Latte structure is currently in excess of 2,100 m. Latte North displays identical mineralization textures as the main Latte structure. However, the structures strike at approximately 045˚ and dip approximately 60˚ to the southeast. Latte North splays away from the main Latte corridor for a minimum strike length of 275 m. Mineralization at Latte consists of disseminated gold-bearing arsenian pyrite, overprinted by later brecciation and late fluid ingress. Mica-rich rocks are the main host for gold, with a three-phase mineral reaction resulting in gold precipitation. Gold-bearing mineralizing fluid, rich in carbon dioxide-arsenic-antimony and sulphur, reacted strongly with iron-bearing biotite within the biotite schist at Latte. A sulphidation reaction proceeds, in which iron within the biotite is leached to form fine-grained arsenian pyrite, illite, and dolomite which pseudomorphously replace the parent biotite grain. Titanium within the parent biotite is removed and incorporated within hydrothermal illite and rutile. In high-grade intervals, this reaction has run to completion with no biotite preserved. Areas which did not experience the same levels of fluid-rock interaction retain relict biotite laths.

2.3.3 Double Double Zone

The Double Double zone trends east-northeast with a known strike length of 600 m. It dips steeply to the north and consists of a number of discrete, high-grade strands of mineralization up to several metres wide. Host rocks are augen-bearing gneissic rocks with interleaved biotite-feldspar-quartz (± muscovite ± amphibole) schist. The gold mineralization at Double Double is structurally controlled and may be associated with a north-easterly trending splay off the main Latte structure. Gold-rich intervals at Double Double are characterized by relict schistose to mylonitic textures overprinted by mottled silica and sericite alteration in addition to limonite-filled micro fracture networks and oxidized pyrite cubes. Breccia domains locally exceed 50% by volume within gold zones, characterized by silicified fragments as well as strongly altered wall rock and porphyry dyke clasts. Some of these fragments exhibit rounding and imbrication in

addition to textures consistent with re-fragmentation of earlier breccia events (i.e., polyphase breccia). Networks of anastomosing chalcedonic silica veins with local microbreccia domains within the veins have been noted in the high-grade intervals. Similar to the Supremo zone, gold at Double Double is micron-scale, and illite has been detected by infrared spectroscopy within the mineralized intervals. Other alteration minerals observed at Double Double include sericite, epidote, leucoxene, hematite, and carbonate.

2.3.4 Kona Zone

Drilling in the Kona zone encountered both biotite replacement and breccia hosted mineralization within the Coffee Creek granite. The Kona zone is hosted within coarse grained equigranular biotite monzogranite, and consists of one to three east-northeast trending, steeply south-dipping fault structures. The gold structures are associated with narrow, less than 5-m-wide, sparsely feldspar phenocrystic to aphanitic andesite to dacite dykes. Alteration typically consists of sericite, clay, and limonite, with illite being detected during reconnaissance work at Kona. Sulphide is dominated by sooty arsenian pyrite, which typically replaces ferromagnesian minerals, and also occurs as veins, veinlets or fracture fill, and in sulphide-matrix fault breccias.

2.4 Geotechnical Considerations

Mine planning considered the northern climate environment, permafrost, and the physical characteristics of the ore and waste rock in the geotechnical considerations for Project design. Newmont carried out field investigations and analyses designed to characterize geotechnical and hydrogeological conditions required for feasibility-level open pit designs. Based on the location and characteristics of the geomechanical domains and the pit shells, design sectors were identified for each of the proposed pits.

Geotechnical investigations have been conducted to characterize the subsoil conditions within the Alpha WRSF foundation footprint including sonic core drilling of soils, test pit excavation, diamond core drilling and laboratory test programs. The results of these investigations and subsequent analyses were used to provide the basis for geotechnical design recommendations. The Alpha WRSF will be constructed in mid to upper slope areas which are generally dominated by in-situ residual soils and colluvium derived from weathering of bedrock. Relatively competent bedrock is typically encountered within approximately 3 m of the ground surface. The colluvial material is variable and typically contains mixtures of gravels, sands, and silts with a thin veneer of organics in the upper approximately 20 to 30 cm. The depth of soil beneath is typically between 0.5 m and 2 m on the slopes with depths of up to approximately 10-m deep in the valley bottoms. Foundation soils are typically ice-poor. The thickness of the strongly weather bedrock is variable but is generally less than a metre. In general, the foundation conditions are considered conducive to construction of the Alpha WRSF.

Permafrost is deep beneath the Alpha WRSFs. The active zone is generally shallow across the site (less than 2 m), except in areas where vegetation has been stripped (i.e., road cuts) (Tetra Tech 2017). Additional details regarding permafrost conditions can be found in Section 9.2. The Alpha WRSF will be constructed on permafrost soils. Permafrost soils are expected to provide suitable foundation conditions for the Alpha WRSF, provided the foundation soils remains frozen.

Pit slope design involves analysis of the three major components of an open pit slope, i.e., bench configuration, interramp slope angle and overall slope angle. The overall slope angle consists of interramp slope sections separated by wide step-outs for haul roads, mine infrastructure or geotechnical.

2.4.1 Overburden Test Pitting

Surficial materials exposed in the testpits at the Coffee Mine Site revealed several surficial units which were described in detail and sampled. The testpits were infilled immediately following logging and sampling. A total of fifty-seven testpits were logged and representative samples of various overburden types were collected during Phase 1 for analysis in Tetra Tech Canada Inc.'s geotechnical laboratory in Whitehorse. Thirty additional samples of surficial deposits and fractured bedrock from selected testpits were taken during Phase 1 for Lorax Environmental Services Ltd. These were sent to ALS laboratories in Vancouver, B.C., for geochemical analysis. Phase 2 commenced upon completion of Phase 1. Various types of overburden were identified within the testpits. These include loess, weathered bedrock, colluvium, peat, and surface moss cover. Approximate volumes of each were calculated for various site facilities. Permafrost conditions, including ground ice, were identified in many of the testpits.

2.4.2 Surficial Geology

Colluvial blanket and veneer (thick and thin deposits) are dominant. The colluvial apron/muck deposits cannot be identified definitively from air photo interpretation alone. As a result, at slope breaks near valley bottoms, units mapped as Ca (colluvial apron), may in fact contain some amount of eolian material. Colluvial aprons are generally poorly to very poorly drained due to the presence of permafrost. It is also possible that silt-dominated colluvial deposits also contain some component of wind-blown silt. Although colluvium dominates the mine site area, a few other units are present as well. Weathered bedrock is exposed in places, mainly on the ridge tops, while limited areas of fluvial and organic deposits are found in valley bottoms. In some tributary valleys, thin fluvial deposits are present, but are too small to map. The mapping for surficial geology is shown in Appendix A.

3.0 CLIMATE

3.1 Site Meteorological Data

The locations of automated weather stations, standalone tipping bucket rain gauges and snow courses at the Coffee Gold Mine Project are summarized by Figure 3-1 and Table 3-1. At present, there are two active- and continuously recording climate stations, and two standalone tipping bucket rain gauge stations, the latter two gauges being in operation until 2018. There is also a comprehensive network of snow course stations at the property, positioned to capture variability in snow accumulation across a range of elevations and aspects.

Newmont intends to operate the Kona weather station in parallel with the original baseline climate station for several years. Overlapping climate data from these two weather stations, as well as any supplementary precipitation data collected at standalone rain gauges and snow courses, will be used to update the characterization of the site climatic regime as it becomes available, and refine the water balance models accordingly.

Details related to the automated weather station installations at the Coffee Gold Mine Project can be found in Appendix B (Coffee Gold Project 2021 Hydro-meteorology Baseline Report).

Key climatic variables recorded at the two Project site weather stations includes:

- Air temperature and relative humidity
- Wind speed and direction
- Incoming solar radiation
- Precipitation
- Atmospheric pressure
- Snow depth and snow water equivalent.

With the exception of the occasional winter riming event which affects the anemometer, the instrumental record for Km 11 climate station now exceeds 9 years in duration and is essentially continuous, while the Kona climate record is approximately 3-years in duration.

3.2 Air Temperature

Mean annual air temperature (MAT) recorded at the majority of the regional climate stations near the Coffee Gold project range from -5 to -2°C. At the Km 11 station, record period MAT is -2.2°C, and -2.6°C at the Kona climate station. On a monthly basis, average air temperatures for the Project site also show similar patterns and magnitude as the nearest regional climate stations (Figure 3-3). Minimum (maximum) recorded temperatures are - 38.2°C (29.7°C) and -36.2°C (23.7°C) at the Km 11 and Kona climate stations, respectively (Table 3-2). Average monthly air temperature ranges are as follows (with reference to Figure 3-2):

- Minimum monthly air temperatures range from -32.6 to 6.0°C at the Km 11 station, and -31.6 to 4.1°C at the Kona station.
- Mean monthly air temperatures range from -16.8 to 13.9°C at the Km 11 station, and -15.4 to 11.7°C at the Kona station.
- Maximum monthly air temperatures range from -2.0 to 25.3°C at the Km 11 station, and -1.8 to 22.9°C at the Kona station.

Note: All values calculated from hourly data.

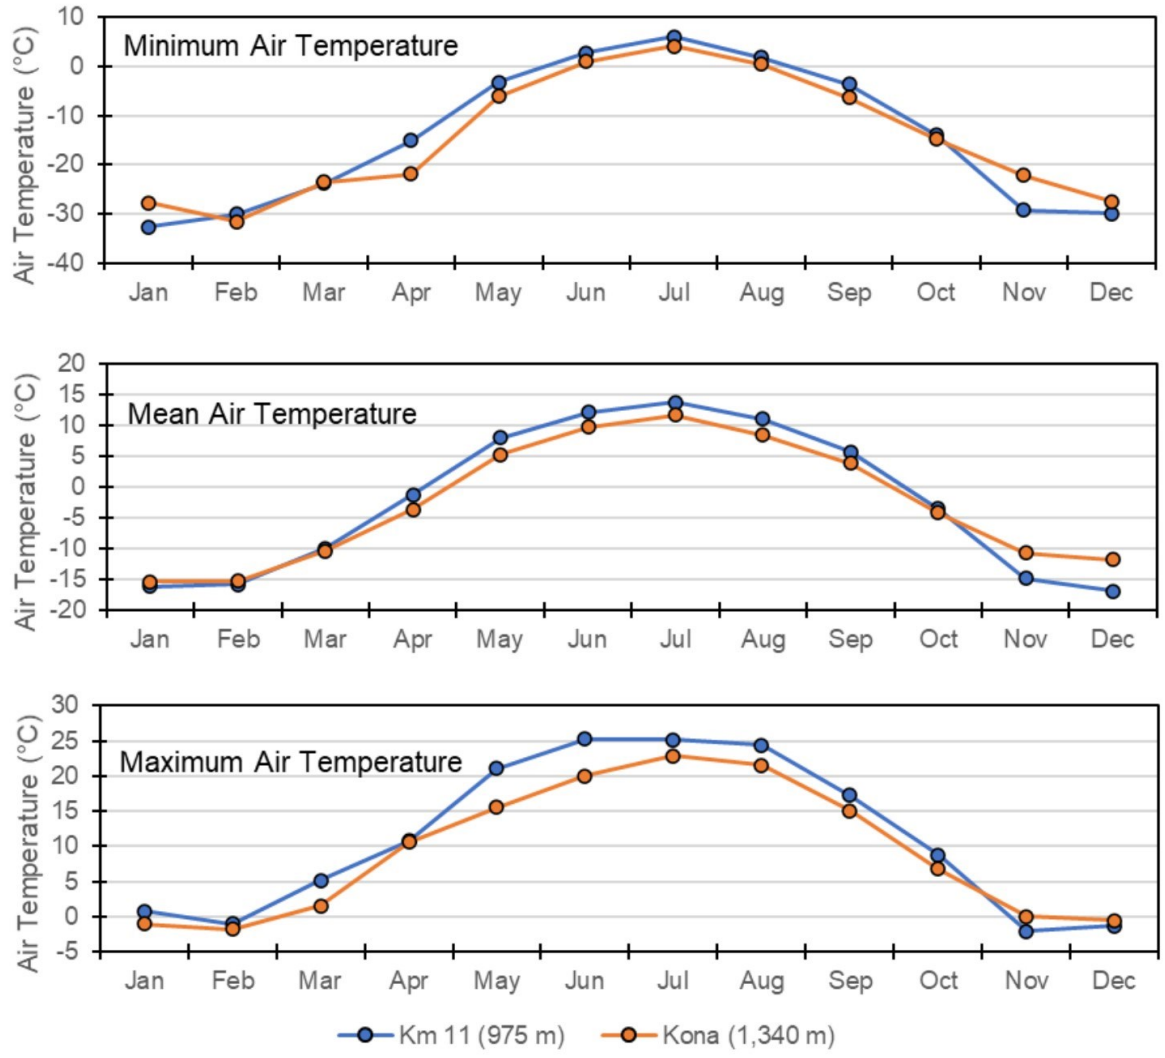

Figure 3-2 Mean Monthly Minimum (top panel), Mean (middle panel) and Maximum (bottom panel) Air Temperature Records for the Km 11 and Kona Climate Stations.

The lowest air temperatures are often experienced in December through February, while the highest air temperatures usually occur in July at both stations, noting that there is evidence of inversion events during the winter months. Detailed information on air temperature inversions can be found in the 2021 Hydro-meteorology Baseline Report (Appendix B)

3.3 Precipitation

Precipitation has been measured on-site since July 2012 at the Km 11 climate station, and at several snow courses located at various elevations around the Project site. Tipping bucket precipitation gauges were also installed at the camp (425 m) and at ridgetop (>1,200 m) in 2015 and operated until 2018 to refine assumptions related to precipitation accumulation with elevation at the Project site. The Kona climate station was installed at an elevation of 1,340 m in October 2018 to gather data representative of the planned HLF location and has a reliable precipitation record.

Precipitation and snow course data gathered during the baseline study indicate mean annual precipitation (MAP) averages 331 mm at 975 m and 398 mm at 1,340 m, with approximately 30% of this amount falling as snow between October and April, and 70% falling as rain from May to September (Table 3-3 and Table 3-4). These measured MAP values for the Project site do not necessarily account for the effects of gauge under-catch or sublimation, which will result in measured precipitation values (winter values in particular) being lower than actual values. These are well-documented issues in northern regions (e.g., Yang et al., 2005 and Pomeroy et al., 1999) and corrections are required to obtain a true MAP estimate. Detailed information can be found in the 2021 Hydro-meteorology Baseline Report (Appendix B)

Figure 3-3 also shows regional precipitation data from nearby climate stations. Overall, site and regional precipitation measurements show similar magnitudes and monthly patterns. Like air temperature, the local precipitation signature closely approximates the patterns returned by regional climate station. Further, the seasonal precipitation distribution calculated from valley bottom climate records also strongly resembles the proportions measured during the baseline study (i.e., regional data return proportions of snow and rain to be 35% and 65% of total annual precipitation respectively).

Table 3-3 Summary of Measured Precipitation Data for the Km 11 Climate Station (July 2012-June 2019).

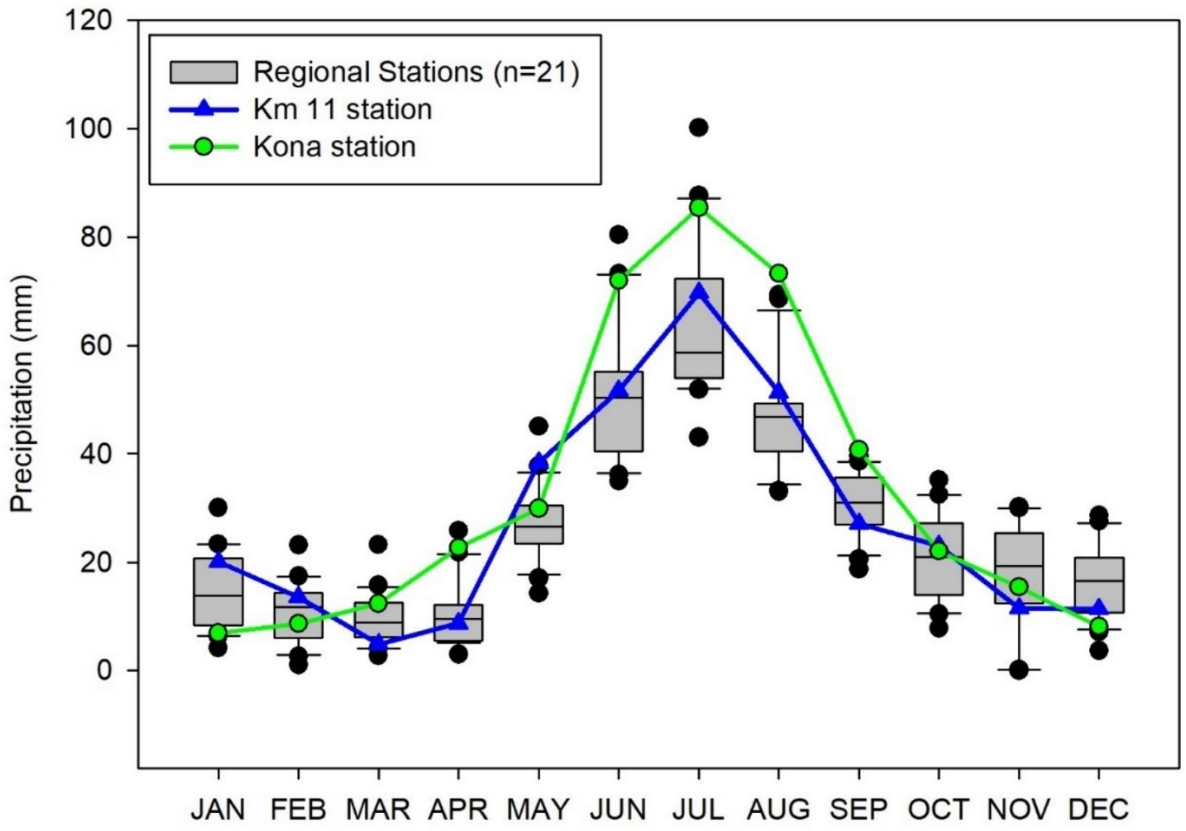

Figure 3-3 **Comparison of the Monthly Precipitation Signature for the Coffee Gold Km 11 and Kona Climate Stations to Nearest Regional Stations (n = 21) with Long-term Records**

Note: The box and whisker plots show the following statistics for the regional stations: median and quartiles (grey box), 5th and 95th percentile values (tails) and outliers (black circles).

3.4 Relative Humidity

Relative humidity generally varies between 50% and 85% on an average monthly basis, with March to October values showing close correspondence between the two climate stations at site (Figure 3-4). At a monthly time-step and on average, relative humidity values are highest in the winter at the Km 11 station and range from 76-83% between November and February. The relative humidity signatures at Km 11 display a notable departure at the Kona station, with winter values at Kona tracking lower than the Km 11 values by approximately 10%. This is due in part to the noted temperature inversions at site. Detailed information on air temperature inversions can be found in the 2021 Hydro-meteorology Baseline Report (Appendix B)

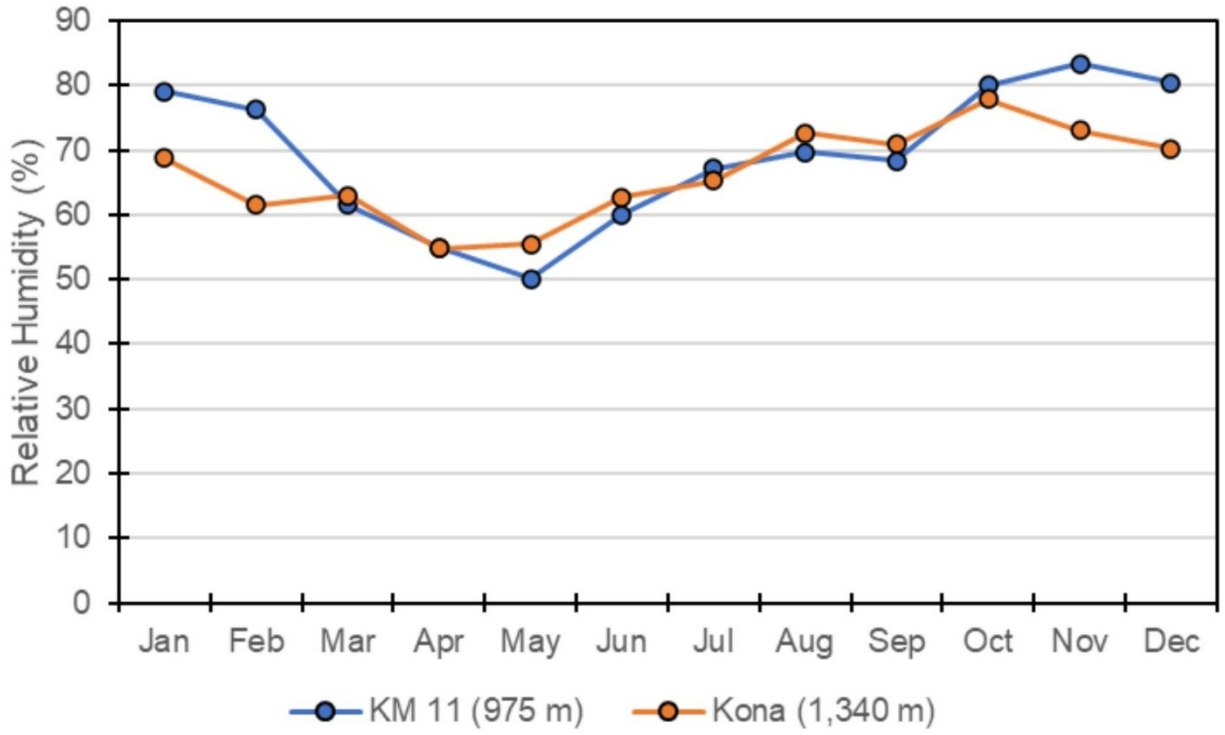

Figure 3-4 Average Monthly Relative Humidity for the Km 11 and Kona Climate Stations

3.5 Wind Speed and Direction

Monthly average wind speeds range from 0.9 to 2.8 m/s at the Km 11 station, with maximum recorded wind gusts of > 14 m/s occurring in all months. Wind speeds are higher in the months of April through September compared to October through March (Table 3-5, Figure 3-5). By comparison, the higher elevation Kona station experiences monthly average wind speeds of 3.7 to 5.1 m/s, gusting in excess of 20 m/s in all months, with a similar seasonal pattern as noted for the Km 11 record, although maximum wind gust speeds are more often noted in the winter and spring months. The dominant annual wind vector at the Km 11 station is from the south (blowing from), with secondary vectors from the northwest and northeast. At the Kona station, the dominant annual wind vector is from the southwest, with secondary vectors from the southeast through east.

Table 3-5 Measured Wind Speed (average and gust) Data for the KM 11 and Kona Climate Stations

Station	Years	Parameter	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual

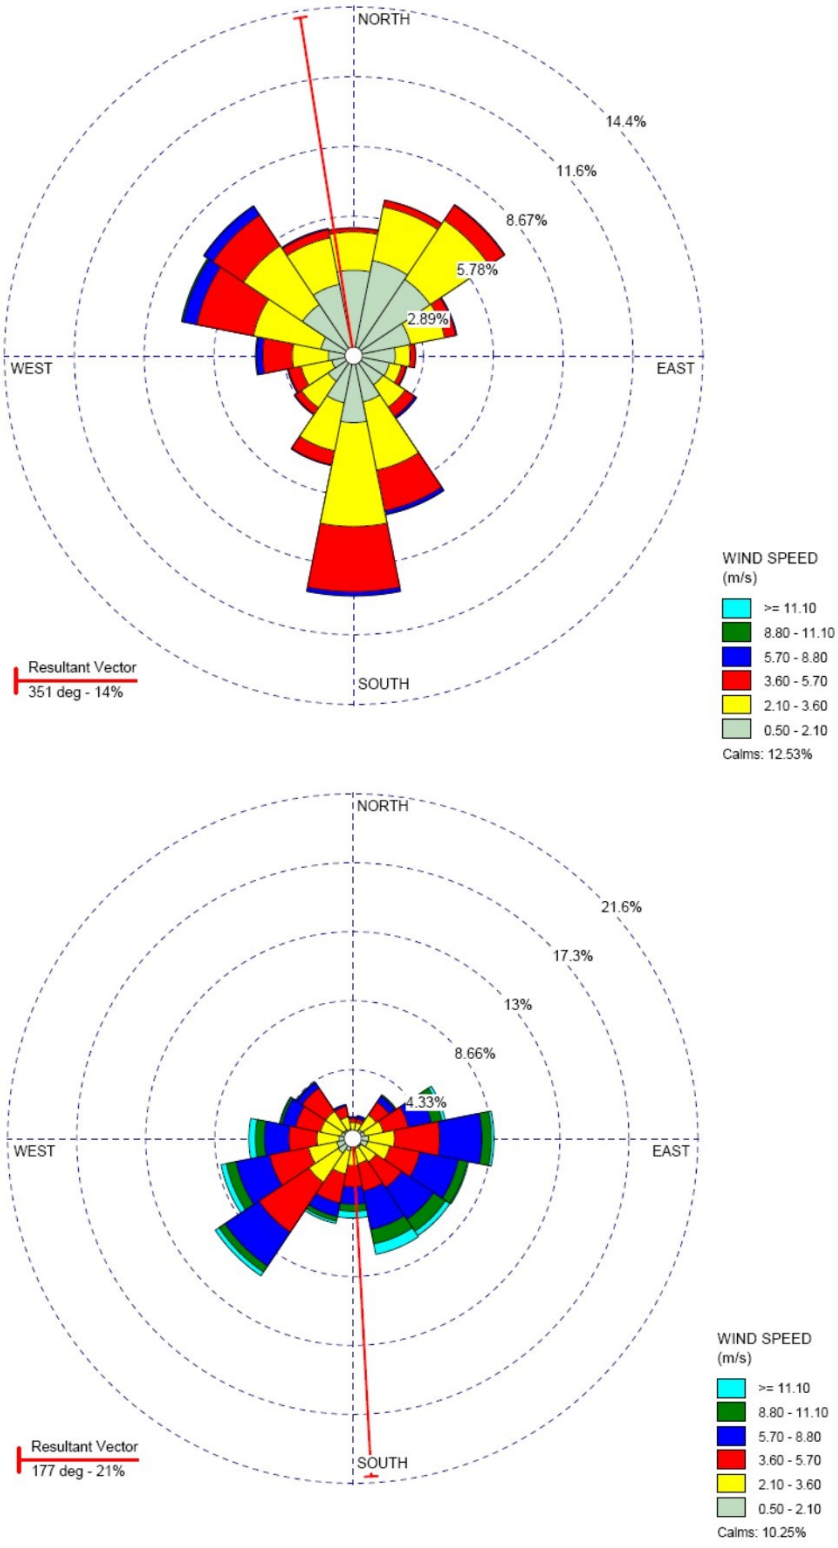

Figure 3-5 Annual Wind Roses for the KM 11 (top panel) and Kona (bottom panel) Climate Stations. Wind directions are 'blowing from'.

3.6 Potential Evaporation and Evapotranspiration

Potential evapotranspiration estimates for both the Km 11 and Kona climate stations were derived using the Penman-Monteith and Priestly-Taylor methods and show average April-October totals of 469 mm and 452 mm, respectively (Table 3-6). The estimates are 10% and 20% higher for the Kona station over the common period of record (2019-2021), due to elevated wind speeds and higher solar radiation at the upper station.

As a point of comparison, potential evapotranspiration (PE) estimates for Coffee Gold derived using Km 11 and Kona weather station data and the Hargreaves-Samani method are reported in Table 3-7. Processing of the data returned average PE estimates on the order of 463 mm at 975 m, and 425 mm at 1,340 m, which are slightly higher than those derived from the ClimateWNA software package (2021 Hydro-meteorology Baseline report Figure 3-7). Like evapotranspiration, monthly PE rates are highest in May, June, and July each year, compared to other months of the year.

As a final comparison, the Km 11 estimates for April to October derived using the three methods are plotted in Figure 3-6 for the 2013-2021 period. Overall, there is close correspondence between the more data intensive formulations (Penman-Monteith and Priestly-Taylor) and the simpler temperature-based method (Hargreaves-Samani).

3.7 Climate Change

3.7.1 Climate Change Scenario Data for State of Alaska and the Canadian North

Climate change scenario data from Scenarios Network for Alaska and Arctic Planning (SNAP) was used as the basis of the climate change assessment presented in detail in the 2021 Hydro-meteorology Baseline Report (Appendix B).

The influence of a changing climate on the hydrologic regime of the discontinuous permafrost zone is well documented in Appendix B of the 2021 Hydro-meteorology Baseline Report (Appendix B) for a detailed summary of historical climatic trends and projected changes in temperature and precipitation). Average annual temperatures are projected to rise significantly in the region over the next century. Present day annual average temperature is approximately -2°C at the Project site, and the annual average is forecasted to rise by 2.5 to 5°C by the end of the century (Table 3-8). Net precipitation in the vicinity of the Coffee Gold Mine is projected to increase by 20% to 35% over the course of this century (Table 3-8), where summer and winter can be expected to be slightly wetter in the future, and spring and fall seasons are projected to see little net change in precipitation abundance.

A trend analysis conducted on the regional historic climate records (Appendix B1 of the 2021 Hydro-meteorology Baseline Report) indicates that recent climate trends are in line with future projections. Average winter temperatures are increasing by 1°C/decade, while the trend in summer temperatures is of

lower magnitude at 0.3°C/decade. Seasonal precipitation trends show a mixed signal in summer, and a strong regional trend towards increased autumn precipitation (4-6 mm/decade). Streamflow metrics are consistently increasing in the Yukon, with significant trends noted for winter low flows (increasing), and the timing of freshet onset (moving earlier).

Table 3-8 Decadal Statistics for the Coffee Gold Project (mean annual air temperature and precipitation) for the RCP4.5, RCP6.0 and RCP8.5 Climate Change Scenarios

Decade	Mean Air Temperature (°C)			Precipitation (mm)		
	RCP4.5	RCP6.0	RCP8.5	RCP4.5	RCP6.0	RCP8.5

4.0 SURFACE WATER

Hydrological and water quality information has been collected at the Project site since fall 2010 at stations shown in Figure 4-1. Data collected from the Project site is compared to regional monitoring programs available from federal and territorial hydrometric programs. Hydrological and water quality information is used to inform the water balance and water quality model. Monitoring during construction and operation will be used to confirm model predictions.

Local patterns of streamflow are dominated by a snowmelt freshet that typically occurs between late April and early June. Following freshet, patterns of streamflow are punctuated by several rainfall-induced runoff events which occur throughout summer and autumn. In general, these high flow events are short duration, persisting usually for a one or two-day time period. Flows in local creeks and streams abate in October in response to freezing temperatures, and it is notable that local watersheds typically experience zero flow conditions throughout the winter (i.e., November through end March). Aufeis (i.e., frozen groundwater seepage that accumulates within- and adjacent to local watercourses) is pervasive in creeks and streams at the Project site and melts during the freshet but may persist into the early summer.

Water chemistry in Project drainages is influenced by varying proportions of snowmelt-driven surface runoff and groundwater inputs to surface flow, based on the seasonal water balance. This seasonality in water chemistry is more pronounced higher in catchments. Surface water quality is characterized by soft to moderately soft water that is low in major ions during freshet periods, and hard to very hard waters, with high levels of major ions during winter low-flow periods. Lower in catchments, water chemistry shows a similar seasonality, though annual minimum and maximum amounts are less pronounced. Dissolved major ion levels during the open water period of May to September are generally low. During low-flow periods, water chemistry is dominated by hard to very hard waters with high levels of dissolved solids. In contrast, pH remains relatively uniform throughout drainages on an annual basis (7.0 to 8.0). Peak summer flows typically coincide with annual maximum amounts of total suspended solids (TSS), dissolved organic carbon, dissolved aluminum, total iron (Fe), and particulate-bound metals; however, mean monthly concentrations of total and dissolved trace elements are generally low. During winter low-flow periods, the total uranium (U) concentration is consistently well above its Canadian Council of Ministers of the Environment (CCME) long-term guideline on an annual basis. Total arsenic (As) and total selenium (Se) are typically below their water quality guidelines (WQG) year-round, although sporadic increases are observed in association with high-TSS events.

In the Yukon River, water chemistry is characterized by moderately soft to moderately hard waters with low to moderate levels of major ions. Measurements for pH are generally circumneutral to slightly basic. The strong seasonal water quality signature evident in Project drainages is largely absent from the Yukon River, presumably due to its large catchment. The Yukon River shows concentration peaks for certain organic parameters during summer high flows. Despite annual concentration peaks for certain parameters during summer high flows, mean monthly concentrations of total and dissolved trace elements are typically low, falling below CCME and BC long-term guidelines.

4.1 Surface Water Local Study Area

The immediate local study area (LSA) includes Latte Creek, Halfway Creek and YT-24 – basins that contain project mining components. In addition, the LSA also includes sampling stations in Coffee Creek (located

immediately upstream and downstream of the confluence with Latte Creek) and selected reaches of the Yukon River (from upstream of the Coffee Creek confluence to immediately downstream of the Independence Creek confluence) (Table 4-1, Figure 4-1, Figure 4-2).

4.2 Baseline Water Quality

This section presents a characterization of baseline water quality in the drainages of Latte Creek, Coffee Creek, Halfway Creek, Yukon River, and the Independence Creek (reference stream). The Baseline Water Quality Report 2010 to 2020 is provided in Appendix C. Compiled raw water quality results data for all stations sampled during the period of 2010 to 2020 is provided electronically in excel format (Appendix C).

Baseline water quality characterization is presented and described by catchment:

- Section 4.2.1 characterizes baseline water quality in Latte Creek utilizing monitoring data primarily from stations LC-15.5 for upper Latte Creek and stations LC-11.4 and LC-0.2 for mid-reach and lower-reach of Latte Creek
- Section 4.2.2 provides a summary of water quality in Coffee Creek at locations both upstream and downstream of the project area. Data from station CC-11.6 (upstream of project influences) and CC-3.2 (downstream of confluence with Latte Creek) are utilized to characterize baseline conditions in Coffee Creek
- Baseline water quality in the Halfway Creek drainage (Section 4.2.3) is characterized using data from stations HC-6.8 and HC-1.0
- Section 4.2.4 provides a brief description of water quality in Yukon River upstream of the project area at YUK-51.3 and downstream of project influence at YUK-26.1
- Section 4.2.5 provides a description of water quality in the Independence Creek catchment using data from station IC-2.7 (mainstem) and KT-0.4 (tributary to Independence and downgradient of Kona deposit).

Monthly summary statistics for each catchment area are briefly discussed below and fully compiled in Appendix C.

4.2.1 Latte Creek

Background water chemistry in Latte Creek can be divided between upper Latte Creek and mid to lower Latte Creek. In general, upper Latte Creek water chemistry is dominated by surface runoff whereas mid to lower Latte Creek water chemistry is influenced by both groundwater discharge, as well as surface runoff during the ice-free periods. No measurable flow has been observed in upper Latte Creek during winter sampling campaigns (e.g., November to March), suggesting little to no groundwater baseflow contributions during these periods. Conversely, mid to lower Latte Creek monitoring stations LC-11.4 and LC-0.2 are more routinely sampled during low-flow periods of the winter owing to groundwater baseflow discharge to these reaches of Latte Creek.

4.2.1.1 Upper Latte Creek- Station LC-15.5

Upper Latte Creek is characterized by water quality samples taken at Station LC-15.5 (Figure 4-3), which includes contributions from two small tributaries (represented by stations CC-5.5 and CC-5.0) in the headwaters. Upper Latte Creek sampling locations were established in 2014 in the baseline surface water quality monitoring program due to adjustments in mine planning. As previously mentioned, flow is not observed during winter months in this section of the creek, therefore limited water samples have been collected at these locations. Given that seasonal variability in Latte Creek has been well characterised, the water quality dataset is considered reliable and robust. More details on major ions, nutrients (mean monthly values), trace elements in Upper Latte Creek can be found in Appendix C.

4.2.1.2 Mid and Lower Latte Creek- Stations LC-11.4 and LC-0.2

Water quality in mid-reach and lower-reach Latte Creek is distinctly different from the conditions previously described for upper Latte Creek. Groundwater baseflow contributions produce a more pronounced seasonal signature in water chemistry. In addition, with more significant groundwater contributions, periods with little to no surface flow still result in measurable streamflow within Latte Creek. As a result, monitoring of water quality has been possible through all months of the year. Mid-reach Latte Creek is characterized by water quality data collected at station LC-11.4 for the period of October 2010 to December 2020 (Figure 4-3). This station in Latte Creek is located approximately 50 m downstream of the confluence of a small ephemeral tributary that has been monitored at station LCT20-0.1 since June 2014. Lower Latte Creek is characterized by water quality data collected at station LC-0.2 for the period of October 2010 to December 2020. More details on major ions, nutrients (mean monthly values), trace elements in Mid and Lower Latte Creek can be found in Appendix C.

4.2.2 Coffee Creek

Background water chemistry in Coffee Creek can be divided between upper Coffee Creek (e.g., above the confluence with Latte Creek) and lower Coffee Creek (Figure 4-4). Upper Coffee Creek is represented by data collected from CC-11.6 and lower Coffee Creek is represented by data collected at station CC-3.2. Station CC-10.9 located immediately downstream of the confluence with Latte Creek was added in 2017 to evaluate mixing with Coffee Creek. Monthly water quality monitoring at both stations commenced in October 2010 and continues to present. More details on major ions, nutrients (mean monthly values), trace elements in Upper Coffee Creek, Lower Coffee Creek and CC-10.9 Coffee Creek can be found in Appendix C.

4.2.2.1 Upper Coffee Creek- Station CC-11.6

Upper Coffee Creek is characterized by water quality measured at Station CC-11.6 (Figure 4-4) which reflects contributions from a large watershed of approximately 385 km^2. This compares to the Latte Creek watershed area at LC-0.2 of approximately 70 km^2 described in Section 4.2.1.

4.2.2.2 Lower Coffee Creek- Station CC-3.2

Lower Coffee Creek is characterized by water quality measured at Station CC-3.2 (Figure 4-4) which reflects contributions from Latte Creek that enters Coffee Creek immediately downstream of previously described station CC-11.6 on upper Coffee Creek.

4.2.2.3 CC-10.9 Coffee Creek

This station reflects the contributions from Latte Creek that enters Coffee Creek immediately upstream of this station (Figure 4-5).

4.2.3 Halfway Creek and YT-24

Halfway Creek contains two water quality monitoring stations at HC-6.8, approximately mid-way down the watershed, and at station HC-1.0, at the mouth of Halfway Creek prior to entering the Yukon River (Figure 4-5). Water quality in YT-24 is characterized by data collected at YT24-0.1 at the mouth of the creek prior to entering the Yukon River (Figure 4-5). More details on major ions, nutrients (mean monthly values), trace elements in Halfway Creek Stations HC-6.8 and HC-1.0, and YT-24 can be found in Appendix C.

4.2.4 Halfway Creek – Stations HC-6.8 and HC-1.0

Water quality at stations HC-6.8 and HC-1.0 has been collected since October 2010 and continues to present. Data for HC-6.8 represents a nearly continuous monthly record for the period of October 2010 to December 2020. For station HC-1.0, monthly sampling in the winter period has proved sporadic as a result of freezing conditions and during the low flow periods, the lower reaches of Halfway Creek do not contain flow.

4.2.5 YT-24 Stations

A relatively small, ephemeral drainage named YT-24, drains the northern slopes of the Coffee Project area and enters the Yukon River. Monitoring of this drainage occurs at two stations YT24-4.9 (mid-creek) and near the mouth at station at YT24-0.1.

4.2.6 Yukon River Stations

The baseline water quality results for the Yukon River in the immediate vicinity of the proposed project is summarized for stations YUK-51.3 and YUK-26.1 (see Figure 4-1) that are located immediately upstream of Coffee Creek and downstream of Independence Creek, respectively. More details on major ions, nutrients (mean monthly values), trace elements in YUK-51.3, YUK-26.1, YUK-49.3 and YUK-37.6 can be found in Appendix C.

4.2.7 Independence Creek

Independence Creek is not affected by proposed mining operations and therefore serves as a reference monitoring watershed. Independence Creek is characterized by water quality measured at Station IC-2.7 (Figure 4-7) which reflects water quality conditions in lower Independence Creek and downstream of contributions from three small catchments that drain the east slope of the drainage divide between upper Latte Creek and Independence Creek (IC-16.1 and IC-14.6) and the eastern slope of the drainage divide of Halfway Creek and Independence Creek (KT-0.4) in Kona Creek (see Figure 4-1 and Figure 4-7). Results are presented for station IC4.5 (mainstem of Independence Creek) and KT-0.4 in Kona Creek, a tributary to Independence Creek (Figure 4-6); complete results for all other stations are presented in Appendix C along with summary statistics for all stations. More details on major ions, nutrients (mean monthly values), trace elements in Station IC-2.7 and Station KT-0.4 can be found in Appendix C.

4.3 Surface Water Hydrology

Streamflow monitoring at the Coffee Gold Project site has been in progress since 2010, with significant network upgrades completed in 2014 and 2016 to increase the spatial coverage of monitoring. Streamflow data consist of a combination of manual measurements made using current meters or salt dilution techniques, and continuously recording stations with water level sensors and fully developed rating curves.

Table 4-2 and Table 4-3 summarize station nomenclature and drainage characteristics for the sixteen stations which comprise the existing baseline hydrology network for the Coffee Gold Project. Figure 4-7 shows the location of these monitoring stations with respect to proposed Project infrastructure and mine site footprints. Detailed information on drainage basin characterization and hydrometric data collection methods are described fully in Appendix B.

Table 4-2 Cross Reference Table Summarizing New and Previous Names for Streamflow Monitoring Stations at Coffee Gold*

Drainage Basin	Watercourse	New Station Name	Previous Station Name
Coffee Creek	Coffee Creek (CC)	CC-3.2	CC-4.5
		CC-11.6	CC-0.5
	Latte Creek (LC)	LC-0.2*	CC-3.5

* This table is referenced from the 2021 Hydro-meteorology Baseline Report which erroneously labels Station LC-0.2 as LC-0.1. This Station ID is corrected to LC-0.2 here.

Notes:

Station nomenclature for tributaries is as follows: numbering begins at confluence with next larger stream and moves upstream with even numbers on river left, and odd numbers on river right (looking downstream).

All numerical designations for stations are the distance in kilometers upstream from the confluence with the next largest stream.

Table 4-3 Coffee Gold Project, Surface Hydrology Stations, and Drainage Basin Characteristics

TITLE:

Flow Monitoring Locations

PROJECT #: A362-3 *FIGURE:* 4-7

P:\@Drafting\Coffee Gold\Drafting Figures\MxDs\Baseline Report\BaselineFlowMonitoringLocations.mxd

4.3.1 Hydrometric Monitoring

Gauged watersheds at the Coffee Creek site range in size from ~3 to 500 km^2, with nine of these having drainage areas of less than 25 km^2. In addition to capturing a range of drainage areas, the watersheds gauged for the baseline hydrology study differ in elevation characteristics (i.e., mean catchment elevations range 800 to 1,300 m asl) and represent varying aspects as well. Mean elevation, basin area, a detailed basin map, aspect and hypsometry information are presented per hydrometric station in (Appendix C of the Hydro-meteorology Baseline Report 2021 (Appendix B).

Twelve of the surface water monitoring stations at the property are instrumented with metric staff gauges and continuously recording water level recorders set in stilling wells. These stations allow high-resolution (i.e., 15-minute) data records at each site. Streamflow was measured several different ways for this study, including wading with a current meter, salt dilution gauging, using an acoustic Doppler current profiler, and slope-area approaches. Rating curves are well constrained, with all but one of the stations (YT24-4.9) based on 10 or more paired stage: discharge measurements, and a site-wide average error of -2%.

Based on measurements at Coffee Creek hydrometric stations, average unit yields across the Project site are 10.6 L/s/km^2 for the open water season (May to October) and range from 4 to 16 L/s/km^2, with specifics of the runoff regime for each monitoring station being dependent on drainage characteristics (i.e., basin area, shape, mean elevation, extent of permafrost, etc.). Unit yields range from 2.0 - 5.1 L/s/km^2 in October and decrease steadily to annual minima in March (i.e., 0 - 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rains. At Coffee Creek, instantaneous peak flows, expressed as unit yields, are typically between 120 and 200 L/s/km^2, but measurements vary widely across the site (from 60 to >300 L/s/km^2).

In similar fashion to the derivation of the synthetic climate dataset, the site hydrometric data were extended using a piece-wise ranked regression approach, based on the Big Creek (WSC; 09AH003) streamflow record. This allowed daily streamflow time-series to be derived for eleven of the Project site stations, which were then used to generate recurrence interval estimates of mean annual runoff and summer low-flows.

4.3.2 Mean Annual Runoff

Based on the measured streamflow data and the synthetic streamflow records, MAR varied by roughly a factor of four in Project site basins (from 48 mm to 205 mm) and when regressed against mean basin elevation (m), basin area (km^2) and dominant aspect within the drainage, showed strong correlation with elevation, and indicate that MAR increases an average of 7%/100 m, which is comparable to the average annual orographic precipitation gradient of 6%/100 m. Results of the annual runoff recurrence interval analysis indicate that the spread between the 1:200 dry- and wet-years is substantial in the Project area drainages, and generally, an extreme wet-year are expected to produce ten times more runoff than an extreme dry-year.

4.3.3 Instantaneous Peak Flows

At the Project site, instantaneous peak flows, expressed as unit yields, are typically between 120 and 200 L/s/km^2, but measurements range widely across the site (from 60 to >300 L/s/km^2). Recurrence interval estimates of annual instantaneous peak flows from a suite of regional records were plotted against drainage

area, and an enveloping power law function was then fit to the data. The enveloping power law functions derived from the regional data for each recurrence interval (e.g., 1:100-year peak flow) were used to estimate the corresponding peak flow for all Project drainages. The results of this analysis indicate that the 1:100-year instantaneous peak flow is expected to generate unit yield flows of 327 L/s/km^2 for a basin of 100 km^2.

4.3.4 Summer and Annual Low Flows

Following freshet, baseflows in the lower reaches of the Project site creeks are enhanced by active layer melt and soil moisture recharge. At the upper elevation stations (e.g., LC-15.5) and those situated in alluvial deposits (e.g., LCT20-0.1) effective yields can drop to near zero flow conditions. Summer (June-September) low flow estimates were derived based on a combination of regional and synthetic site records. Based on the regional stations assumed most representative of Project site conditions, the analysis returned summer 7Q10 yields that range from 0.7 to 1.11 L/s/km^2. A parallel analysis conducted using the synthetic streamflow data returned estimated summer 7Q10 values for the Project stations ranging from 0.04 to 0.78 L/s/km^2. The summer 7Q10 low flow value based on an average of the eleven Project station synthetic records is 0.34 L/s/km^2.

Site data show that yields range from 2.0 – 5.1 L/s/km^2 in October and decrease steadily to their annual minima by March (0 – 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rainfall. Based on the site data alone, winter low flows are expected to range from 0 to 0.7 L/s/km^2.

An important component of the winter flow regime at the Project site is the extensive icing of the local channels. This ice growth, or aufeis, is the result of shallow groundwater discharge and/or baseflow in the stream channel freezing. This ice impedes subsequent flow, which is forced on top of the existing ice sheet, where it freezes. This process repeats continuously throughout the winter, and results in laminated ice sheets that can approach 2 m in thickness and 50+ m in width in the Project channels.

4.4 Water Balance Model

The water balance model (WBM) is a detailed interpretation of the mine and water management plans, with consideration of baseline climate, hydrometric, water quality and hydrogeological data collected for the Project. The WBM overlays the mine plan and all associated major Project footprints (e.g., open pit, heap leach facility and waste rock storage facility footprints) and water-related activities (i.e., pit dewatering, diversions, storage, and release of water (and loads) from sediment control ponds) associated with the Construction, Operation, Reclamation and Closure and Post-closure phases of the Project onto calibrated local watercourse streamflow and water quality conditions.

The WBM is strongly informed by hydrological and climatological monitoring data and modelling exercises, including:

- Seven to ten years of baseline streamflow data (11 stations)
- Nine years of site climate record
- Reconstructed site climate record (30 years in length) and daily discharge records (33 years in length)
- Regional climate change analyses to inform closure water balance scenarios.

The WBM is configured to represent all relevant physical processes at the Project site that drive streamflow and water quality, which are closely linked. Surface runoff, baseflow, aufeis formation, snowfall and snowmelt processes are represented, as are the elevational dependence of the temperature and precipitation inputs. The watershed model used to predict Project area streamflows on a daily basis was calibrated to both the measured and synthetic streamflow datasets as described in the 2021 Hydrometeorology Baseline Report. Potential evapotranspiration is included as a function of daily mean temperature, plus a stochastic adjustment to represent the observed variability of potential evapotranspiration at the site. The current configuration of the site-wide water balance predicts flows at the 10 receiving environment monitoring stations, accounting for variability based on a 30-year synthetic climate record and the effect of climate change on air temperature and precipitation.

With respect to the Yukon River, the WBM assumes flow from Coffee Creek, YT24-0.1 and Halfway Creek to the Yukon River is partially mixed at each respective monitoring station. Given the measurable dilution afforded by the Yukon River relative to Project area creeks, this approach yielded a conservative estimate of potential water quality in creek mixing zones within the Yukon River. The WBM therefore assumes water discharging from each creek into the Yukon River mixes with only 2% of the Yukon River flow at the modelled downstream locations. Full mixing is assumed to occur in the Yukon River between Coffee Creek's confluence and YT24-0.1's confluence, and partial mixing (25%) inferred between YT24-0.1 confluence and Halfway Creek's confluence.

4.5 Water Quality Model

The water quality model (WQM) developed for the Project predicts water quality for key locations within the receiving environment throughout all phases of the Project. The model generally employs a mass balance approach that combines the loadings associated with background flows and mine-affected flows for a series of climate realizations (i.e., climate scenarios that were developed based on a 30-year climate record and described more fully in Appendix B). The WQM was developed in GoldSim, and accounts for background water quality, runoff volumes reporting from undisturbed portions of watersheds, and regional groundwater, as well as chemical loads emanating from mine-related facilities (e.g., Open Pits and Waste Rock Management Facilities) and Site Water Management Infrastructure (e.g., contact water ponds and ditches). The WQM incorporates the site-wide mitigation strategies developed for the Project, in the sense that intended mitigation has been considered in deriving source terms for specific mine components. The WQM accounts for mine-related activities associated with four distinct phases of the Project: Construction, Operation, Reclamation and Closure, and Post-closure. It is assumed that the mine will be fully reclaimed with no active treatment or mitigation required during the Post-closure Phase (commencing Year 24 onwards as determined to be required). The modelled Post-closure Phase incorporates the effect of a conservative climate change scenario (RCP-8.5) as defined by the Intergovernmental Panel on Climate Change.

5.0 GROUNDWATER

The baseline hydrogeological assessment of the Project was detailed in 2017 Coffee Gold Baseline Hydrogeological Assessment (Lorax, 2017c) and submitted in support of the Project Proposal. Physical and chemical hydrogeological data collected up to August 2019 are summarized. An updated Coffee Gold Baseline Hydrogeological Assessment 2019 Update report is presented in Appendix D. Collection of baseline groundwater quality and water levels is ongoing and will be continued through the licensing process.

5.1 Groundwater Study Area

Groundwater flow systems occur on various scales. At the largest scale, deep groundwater drains towards major regional water bodies. At smaller scales, groundwater that originates in local catchments will drain towards local creeks and streams which ultimately feed into larger surface water systems.

The study area for groundwater includes areas directly underlying mine units and nearby reaches of downgradient creeks where changes to groundwater may result in measurable changes to the surface water regime (Figure 5-5). It was determined that Project-related development and use of the NAR would result only in minor interactions with groundwater and these interactions would be limited to localized shallow groundwater in seasonably active groundwater systems. Therefore, baseline groundwater data along the proposed NAR was not collected.

Multiple hydrogeological and geotechnical field programs have been undertaken at the Mine Site between 2013 and 2017 (Table 5-1).

Table 5-1 Hydrogeological Monitoring Locations Showing End of Mine Layout

Date	Study Objective	Installation	Hydraulic testing
Fall 2013	Preliminary hydrogeological data collection to support a detailed workplan for the hydrogeological baseline assessment	• Four vibrating wire piezometer installations in the Supremo and Latte Pit footprints	Yes
Summer 2014	Geotechnical site investigations and laboratory testing to assess: • Subsurface conditions within the footprint of the HLF, and stockpile; and • Geotechnical engineering material properties of the materials encountered	• Two thermistor strings in previously proposed valley HLF footprint area	No
Summer/Fall 2014	First phase of detailed hydrogeological baseline program establishing groundwater sampling locations in and around the proposed Open Pits	• Conventional monitoring wells and thermistor in pit area • Thermistor/vibrating wire piezometer in former valley HLF footprint	Yes

Date	Study Objective	Installation	Hydraulic testing
March 2015	Second phase of detailed hydrogeological baseline program establishing ground conditions, permafrost conditions, and groundwater pressures downgradient of waste facilities ahead of a larger field program	• Thermistor/vibrating wire piezometer installation downgradient of Alpha WRSF and former South WRSF	No
May – June 2015	Third phase of a detailed hydrogeological field program establish remaining groundwater quality, groundwater pressure and ground temperature stations downgradient of mine facilities	• Thermistor/vibrating wire piezometer, Westbay groundwater monitoring systems (sub-permafrost), and shallow monitoring wells (overburden)	Yes
June – July 2015	Hydrogeological investigation targeting principal geologic structures that will be mined in the open pits, combined with a geotechnical program characterizing permafrost in proposed facility footprints	• Thermistor/vibrating wire piezometer installations in proposed WRSF and stockpile footprints	Yes
August-September 2016	Hydrogeological field program aimed at establishing groundwater quality, groundwater pressure and ground temperature downgradient of the HLF.	• Thermistor/VWP installation along NW margin of HLF.	Yes
Spring-Fall 2017	Geotechnical site investigation to acquire geotechnical and permafrost data, including frozen and unfrozen overburden and bedrock conditions, to inform design of the mine infrastructure	• Thermistor installations in and around Alpha WRSF, Alpha Pond; Beta WRSF; Frozen Soil Stockpile, HLF; Organics Stockpile; and other surface infrastructure	Yes
August 2017	Hydrogeological field program aimed at establishing depth of permafrost, depth of overburden, groundwater pressures, and groundwater occurrence NW of the proposed Kona Pit, as part of the larger 2017 geotechnical investigation.	• Thermistor/VWP installation downgradient of the proposed Kona Pit.	Yes

Note: masl – metres above sea level, mbgs – metres below ground surface

Many of the drilling programs have incorporated hydraulic testing of bedrock, predominantly through a combination of packer testing and airlift testing. Limited slug testing has also been conducted. In conjunction with monitoring well installations, multiple groundwater sampling events have been undertaken to characterize baseline groundwater quality and its range of variability.

Groundwater monitoring events were conducted in September/October 2014, and three to four times annually from 2015 to 2019 (Table 5-2). The monitoring events occur between April/May and October. This modified quarterly sampling frequency is often employed in the Yukon to capture the range of seasonal variability accounting for extended winters and compressed spring/summer/fall season.

Notes:
BP = bladder pump, IP = inertial pump actuated with a Hydrolift-II, PP = peristaltic pump, WB = Westbay sampler; D/S = downstream
1. Water inside monitoring well had started freezing at time of well development.
2. Monitoring well riser pipe collapsed near surface, likley due to freeze/thaw action in the active layer. Consequently, well screen could not be accessed.
3. Monitoring well decommissioned by Kaminak.
4. Monitoring wells MW15-01AZ and MW15-05AZ were damaged in July 2019 due to channel and stream bank erosion caused by a summer precipitation event in the Project area.
5. True Count - reflects the number of samples believed to be representative, collected at each station (samples screened-out due to drilling and well installation artifacts discussed in Lorax (2017c) and in Appendix 5-D of this report are not included in this count, and are highlighted in yellow).
6. At MW15-03WB, Port 6 (~47 m) was sampled between June 2015 and May 2016, and Port 4 (~82 m) was sampled thereafter between July 2016 and August 2019. Groundwater quality results corresponding to the two sample depths indicate that there is no apparent difference in the major ion compositions, and concentrations of field parameters, redox parameters, trace element parameters, and stable isotopes.

5.2 Groundwater Environmental Setting

A combination of hydrogeological, geotechnical and geocryological field programs have established a robust network of hydrogeological monitoring installations in, around and downgradient of major mine facilities. The instrumentation includes eleven conventional monitoring wells, seven Westbay multilevel groundwater monitoring systems, nine combination vibrating wire piezometer (VWP)/thermistor strings, plus twelve stand-alone thermistor strings, twenty-five stand-alone shallow thermistor beads, and four stand-alone VWP strings. Groundwater level information is available from selected sites from as early as 2013, with all installations recording high frequency (sub-daily) water level and ground temperature information from mid-2015 onward.

Ground temperature data obtained from thermistors, as well as observations from drilling and monitoring well sampling indicate that permafrost is discontinuous but extensive across the project area. The thickest permafrost at site is measured on the north-facing slopes, a thermistor string at the north end of the proposed Supremo pit reports ~168 metres of permafrost. Permafrost appears to decrease in thickness with declining ground surface elevation. Permafrost in the project area is relatively warm (between 0 and -2°C) and is coolest (-1.4^{o}C to -1.9^{o}C) on north-facing slopes.

At several higher elevation installations, the water table resides below the base of permafrost. The deepest water level at site, more than 220 meters below ground surface is found along the northwest extent of the proposed Supremo pit. At high elevation installations near the proposed Kona and Latte pits, water levels are on the order of 110 to 150 m deep. A high elevation installation on the margins of the proposed heap leach facility, however, registers artesian pressures in a faulted area confined by permafrost.

Artesian groundwater pressures are reported at many lower elevation installations in both permafrost and permafrost-free areas. While groundwater pressures may be artesian adjacent to creek traces, often vertical gradients are downwards, suggesting groundwater is under-drained by the intercepted faults. This is particularly true at installations along Latte Creek. Upward hydraulic gradients are measured in the lower reaches of Halfway Creek near the intersection of a crosscutting fault.

Most groundwater hydrographs are smooth and broadly sinusoidal with one annual maximum that occurs weeks to months after freshet. A few recorded hydrographs from low elevation installations adjacent to creeks show flashier records that respond to rainfall events. Groundwater hydrographs fluctuate from less than 2 meters per year to over 30 metres at one location. Drier-than-average conditions in 2017 manifest as a smaller annual fluctuation compared to other years.

5.3 Hydraulic Conductivity

Sixty successful measurements of bedrock hydraulic conductivity (K) have been collected during field programs executed between 2013 and 2017. Most measurements were acquired through packer testing, but airlift yield recovery tests and slug tests were also performed. Slug tests were performed on two overburden wells (MW15-03AZ and MW15-02AZ), however, the tests recovered so quickly (i.e., within seconds) that they could not be interpreted.

Bedrock K values are plotted versus vertical depth below ground surface in Figure 5-1 and are color coded according to lithology. Ranges in bedrock K values for different depth intervals are also shown in a box and whisker plot in Figure 5-2 with median values summarized in Table 5-3. The hydraulic conductivity data

range over several orders of magnitude with values exceeding 1E-06 m/s and others below the resolution of the testing method. A broad range in K values is typical of a fractured bedrock system (Golder, 2010). A regression line though the data points (Figure 5-1) indicate a broad trend of decreasing hydraulic conductivity with depth.

Median K values decrease by an order of magnitude or more below 150 m depth and again below 250 m depth (Figure 5-2, Table 5-3).

Rock type does not appear to play a large control on hydraulic properties (Figure 5-1). Rather, structural features, which crosscut all lithologies, impart the dominant control on hydraulic conductivity. Hydraulic tests performed on pit structures (SRK, 2015), along valley traces and in the currently proposed HLF footprint (MW16-01T/WB) have been grouped together as ‘structures’. Some of these test results comprise the cluster of the higher hydraulic conductivity values between 150 m and 300 m depth (Figure 5-1). While not mapped as such, the YT-24 and Halfway Creek drainages are inferred to coincide with fault structures. Reverse circulation drillholes advanced below permafrost in these drainages returned airlift yields on the order of 30 US GPM (~1.9 L/s). Latte Creek coincides with the mapped Coffee Creek Fault.

The two boreholes advanced near the proposed HLF (MW16-01T and MW16-01WB) happened to intercept a previously identified NNW-SSE trending magnetic anomaly. Ground conditions and the hydraulic response of this feature (K values exceeding 5E-7 m/s) suggest that this is a fault structure. The median K of structures is 2E-07 m/s with tests ranging up to 275 m depth. This K value is one to two orders of magnitude higher than other bedrock tests over the same depth interval (Figure 5-2, Table 5-3).

Tetra Tech (2017) conducted packer tests on shallow, frozen bedrock in the Halfway Creek to determine foundation conditions in a proposed sediment pond location. Nine out of thirteen tests had no discernible flow and were assigned maximum values based on the resolution of the test. The median K value estimated for shallow, frozen bedrock is 2E-08 m/s (Figure 5-2, Table 5-3). Field and analytical methods for hydraulic testing have been provided in Appendix D along with detailed results.

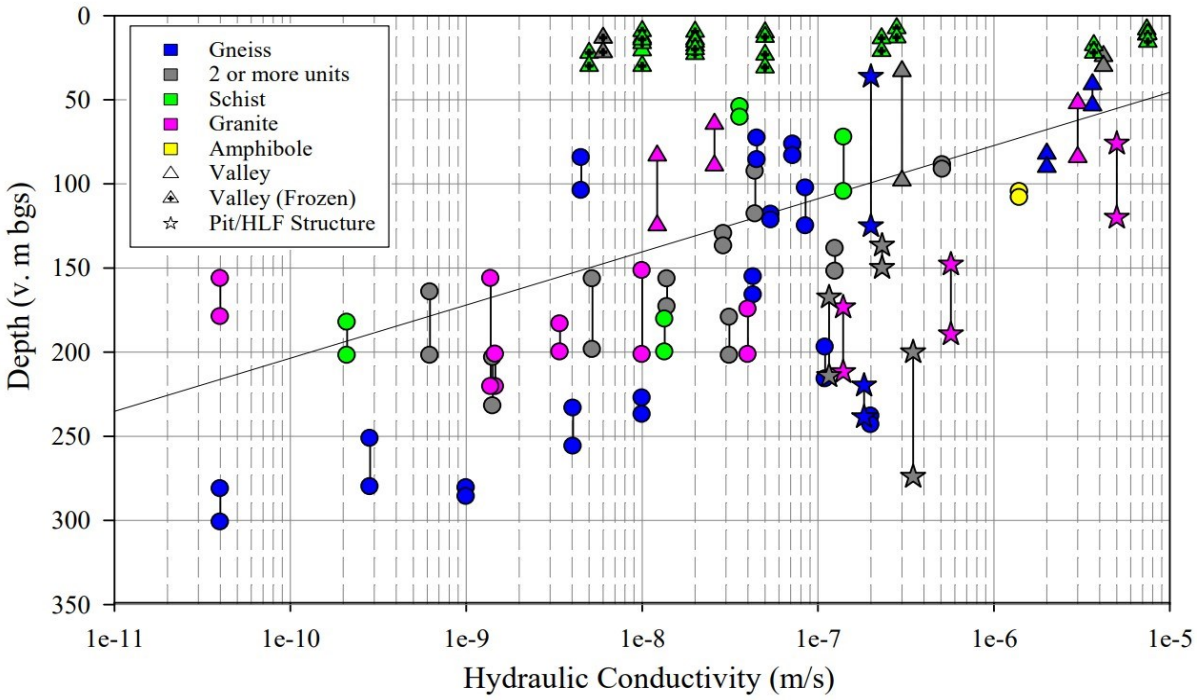

Figure 5-1 **Bedrock Hydraulic Conductivity versus Vertical Depth Below Ground Surface at the Coffee Gold Project (organized by lithology)**

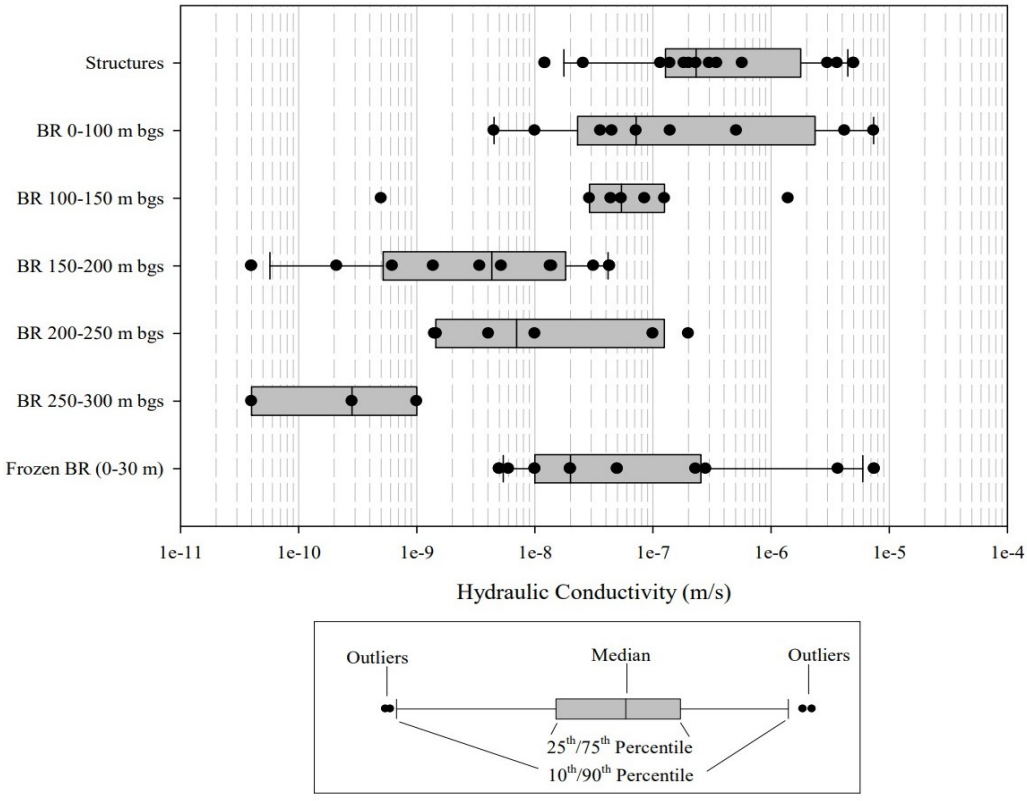

Figure 5-2 **Box and Whisker Plot of Hydraulic Testing Results with Legend in Bottom Panel**

Table 5-3 Median Bedrock Hydraulic Conductivity

Bedrock Unit	Median K (m/s)
Structures & Valley Traces	2E-07
0-100 m deep	7E-08
100-150 m deep	5E-08
150-200 m deep	4E-09
200-250 m deep	7E-09
250-300 m deep	3E-10
Frozen (0-30 m deep)	2E-08

5.4 Water Levels and Gradients

Groundwater sampling was conducted on nineteen occasions between 2014 and 2019 (see Table 5-2). Sampling was conducted at monitoring wells installed by Lorax between 2014 and 2016 and covers the period from September 2014 to August 2019. Data from these sampling events are included in the evaluation of groundwater quality, although several results were discounted due to potential influences from drilling and well installation artifacts. Bedrock water levels measured in June 2018 are presented in Figure 5-3. More details on the magnitude of seasonal water level fluctuations, vertical and horizontal hydraulic gradients measured can be found in Appendix D.

Water levels are highly variable across the site with the deepest water levels (from 130 to over 220 metres below ground surface) measured in ridge areas and flowing artesian conditions often measured in the drainages. However, the presence of permafrost and faults/structures can create unexpected hydrogeological conditions. For instance, artesian water levels are measured near the height of land in the Halfway Creek drainage while downward hydraulic gradients are observed near Latte Creek. The transient water level data show distinct responses to seasonal recharge. The first type is a broad sinusoidal response to seasonal recharge with a single water level maximum per annum. The maxima appear as smooth to slightly sharp peaks in the hydrograph record. Seasonal maxima and minima may vary annually in both magnitude and timing on account of the variable climate.

5.4.1 Halfway Creek

There are several installations located within the Halfway Creek catchment. Water level time series for higher elevations stations are MW14-05A/B, MW17-01T, MW16- 01T and MW14-03A/B while lower elevation installations are SRK15D-08AT, MW15-04T, MW15-03T. In 2019, hydrometric and surface water quality monitoring stations underwent a name change. Current station names are referenced, followed by the former station name in parentheses. Groundwater level hydrographs measured in Halfway Creek catchment for each station and its results can be found in Appendix D.

A combination of water level responses is displayed at stations near the proposed Kona pit (MW14-05A/B, MW17-01T) and HLF footprint (MW16-01T). Water levels at MW14-05A/B track closely together and have continuously climbed between 2015 and 2019, gaining several meters over this period. A very subdued seasonal fluctuation is observed in the trend, but annual minima and maxima are difficult to extract given the overwhelming increasing trend. Vertical gradients are minimal.

5.4.2 YT24-0.1

Groundwater is well-confined along the upper reaches of the YT24-0.1 drainage. Thermal data collected from these instruments indicates that groundwater is confined by permafrost in this drainage, with higher confining pressures experienced farther downstream. The groundwater level hydrographs are distinct at each of the installations. The installation at MW15-07T, at the headwaters of YT-24, has two deep water level sensors at 239 m bgs and 267.8 m bgs. Permafrost depth is between 140 to 150 m and confines water levels that range between 120 m bgs and 138 m bgs. The water level hydrographs are broadly sinusoidal, with annual maxima occurring in November or December and annual minima occurring in June or July. Upward hydraulic gradients (<5%) were measured at this station prior to 2017 but have remained consistently downward since then. The hydrograph clearly demonstrates the below average recharge in 2017.

5.4.3 Latte Creek Tributary

The Latte Creek Tributary drainage is instrumented in its upper reaches with a conventional monitoring well pair (MW14-02A/B) on the north fork and VWP CFD0351 on the west fork. Both locations demonstrate a strong response to seasonal recharge. Seasonal water level fluctuations measured at CFD0351 have exceeded 30 metres and are the largest recorded across the site. The water level hydrograph is broadly

sinusoidal with seasonal maxima occurring in September or October. CFD0351 is not equipped with a thermistor string and permafrost conditions are not constrained. The current permafrost map has it located on the margin, but outside of permafrost coverage. Water levels at the single VWP sensor range from 111 m bgs to 153.5 m bgs. Groundwater level hydrographs measured in Latte Creek tributary drainage at each station and its results can be found in Appendix D.

5.4.4 Latte Creek

There are three hydrogeological installations along Latte Creek (Figure 5-1). The highest elevation station, MW14-07T, was established in September 2014. The thermistor string installed in this hole indicates a permafrost depth of approximately 60 metres. The water level recorded at the single VWP is flowing artesian and consistently several metres above ground. While there have been interruptions in data collection at this station, the record indicates that annual maxima occur in the early fall. Groundwater level hydrographs measured in Latte Creek catchment at each station and its results can be found in Appendix D.

5.4.5 Baseflow

Characterization of the baseflow regime at the Project presents numerous challenges. Accurate measurement of winter streamflow is challenging in drainages at the site on account of extensive icing that forms in local channels over the winter months. This icing, sometimes termed aufeis, is the result of shallow groundwater discharge and/or baseflow in the stream channel freezing. This ice impedes subsequent flow, which is forced on top of the existing ice cover, where it freezes. This process repeats continuously throughout the winter, and results in laminated ice layers that have been measured close to 1.5 m in thickness and greater than 50 m in width in channels at the Project.

5.5 Groundwater Quality

Groundwater in the Project area is predominantly circum-neutral (pH 6 to 8), with most groundwater samples between pH 6.5 and 8. Groundwater quality shows variable influence from weathering of sulphide minerals and/or dissolution of sulphate minerals, either from the deposits or other disseminated mineralization across the Project area. Sulphate concentrations range from low to substantial (7 to 1,120 mg/L) and salinity is variable (field specific conductance readings between 28 and 2390 µS/cm).

Major ion chemistry in overburden wells is calcium-bicarbonate-type. The bedrock groundwater in gneiss has a major ion chemical signature which ranges widely from calcium-bicarbonate to mixed magnesium-calcium-sodium-sulphate-type water, reflecting variable influence of sulphide weathering. Groundwater in the granite is calcium-bicarbonate-type but is generally more sodic than other groundwater on site. The groundwater sampled from the hydrothermal breccia and schist tends to be calcium-bicarbonate to magnesium-sulphate-type.

Baseline groundwater quality in the Project area is characterized by the presence of elevated dissolved arsenic and uranium. Dissolved arsenic and uranium concentrations were generally highest in the bedrock groundwater, ranging from 0.12 to 2650 µg/L and 1.2 to 589 µg/L, respectively.

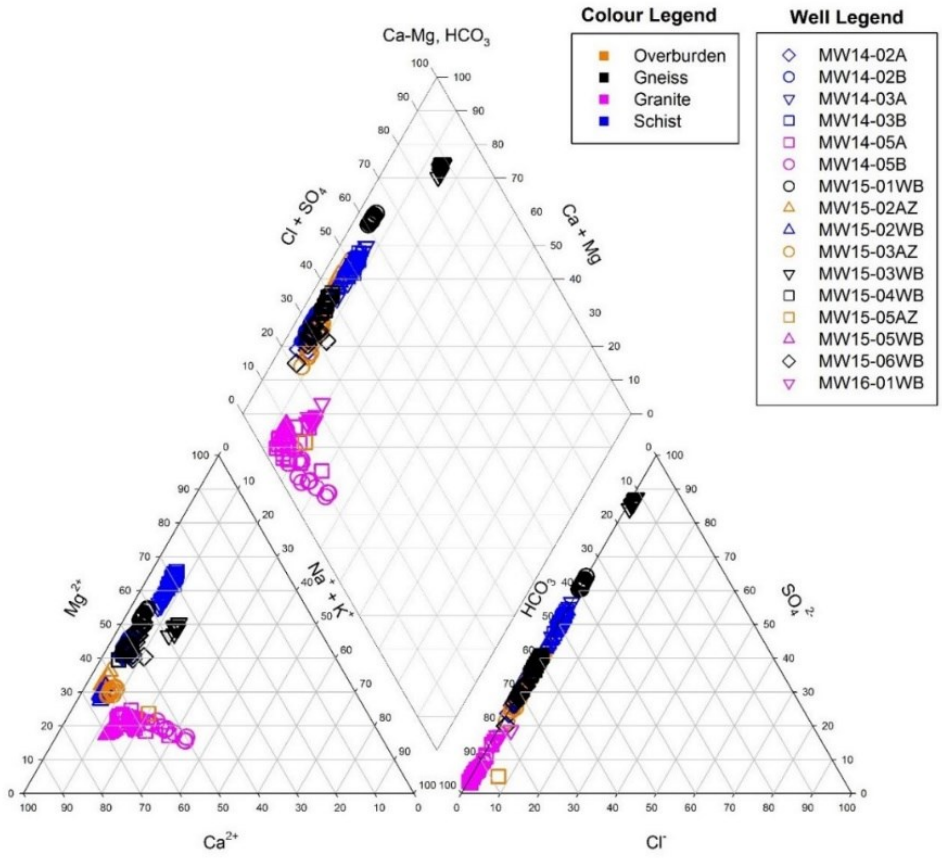

Figure 5-4 Piper Plot of Groundwater Quality Data (2014 and 2019)

5.5.1 Trace Elements

This section presents a review of trace element concentrations across the Project site. Selected dissolved metal parameters of concern (arsenic (As), antimony (Sb), cadmium (Cd), cobalt (Co), copper (Cu), lead (Pb), mercury (Hg), nickel (Ni), selenium (Se), uranium (U) and zinc (Zn)) are discussed in this section. These parameters were selected based on geochemical test results and potential for complexation with cyanide. Dissolved metals are presented and discussed since guidelines, standards and regulations generally apply to dissolved substance concentrations for inorganics in groundwater.

- Overburden groundwater samples were generally characterized by low TSS with concentrations close to or below the method detection limit (MDL) of 1.0 mg/L.
- TSS levels in bedrock groundwater samples were generally higher, ranging from below MDL to 64 mg/L. Dissolved arsenic was measured in all groundwater samples.
- Concentrations of dissolved arsenic were generally lowest in overburden groundwater (0.43 to 2.3 µg/L) and higher in bedrock groundwater (0.27 to 1860 µg/L). The highest concentrations of dissolved arsenic were in granite (1480 to 1860 µg/L).
- Concentrations of dissolved antimony were generally below 1 µg/L in overburden and bedrock groundwater. Dissolved antimony was highest in schist (3.3 to 6.6 µg/L).

- Dissolved cadmium measured in overburden and bedrock groundwater was predominantly in the 0.006 to 0.06 µg/L range. Dissolved cadmium concentrations in overburden were quite variable (<0.005 to 0.125 µg/L), while concentrations in gneiss were more consistent (0.04 to 0.01 µg/L).
- Dissolved cobalt concentrations were generally higher in bedrock groundwater than in overburden groundwater. Concentrations of dissolved cobalt were highest in schist (6.1 to 7.6 µg/L). Dissolved cobalt concentrations in overburden groundwater were generally below 0.25 µg/L.
- Concentrations of dissolved copper was generally highest in overburden groundwater (0.95 to 2.0 µg/L). Concentrations in bedrock groundwater ranged from below MDL (0.05 µg/L) to 2.5 µg/L.
- Dissolved lead concentrations were low in the overburden and bedrock groundwater. Concentrations were lowest in the overburden (<0.005 to 0.033 µg/L) and more variable in bedrock, ranging from below MDL (0.005 µg/L) to 0.34 µg/L.
- Dissolved mercury concentrations were below MDL in the majority of overburden and bedrock groundwater samples. All wells with measurable dissolved mercury were characterized by concentrations <0.01 µg/L, in gneiss (0.02 to 0.10 µg/L) where the highest concentrations were detected.
- Concentrations of dissolved nickel in groundwater were generally below 5 µg/L. Dissolved nickel concentrations were highest and most variable in schist (17 to 22 µg/L).
- Dissolved selenium was generally low in overburden and bedrock groundwater, with concentrations ranging from below MDL (0.04 µg/L) to 0.5 µg/L. The highest Se concentration of any overburden or bedrock well was recorded as 1.1 µg/L.
- Concentrations of dissolved uranium were consistently elevated (>15 µg/L) at most wells. Dissolved uranium concentrations were highest in gneiss (530 to 589 µg/L). Dissolved uranium levels were lowest in the overburden groundwater (0.90 to 35 µg/L).
- Dissolved zinc was consistently measured across the Project area with higher and more variable concentrations measured in the bedrock. Dissolved zinc levels were lowest in the overburden and bedrock groundwater with concentrations ranging between 0.27 and 16.5 µg/L. In contrast, groundwater concentrations in gneiss ranged between 4.9 and 253 µg/L.

5.5.2 Isotopes

Groundwater, surface water and aufeis samples were collected from the Project area between 2014 and 2019 for the analysis of stable isotopes (2 H, 18O, 13C) and radioisotopes (3 H, 14C) (Table 3-7). Water stable isotopes of hydrogen (2 H) and oxygen (18O) are used to assess groundwater sources and recharge history, while the radioisotopes tritium (3 H) and radiocarbon (14C) are used to estimate groundwater age (i.e., mean residence time), which is an indication of how long water is circulating within a groundwater system. A summary of the key findings is presented herein, with a detailed discussion of the isotopic data and results provided in Appendix D.

5.6 Influence of Permafrost on Groundwater Regime

Permafrost is an important consideration in the conceptualization groundwater systems as it imparts controls on groundwater movement. When ground temperatures fall below the freezing point, the hydraulic conductivity sharply decreases as unfrozen water content drops and pores and cracks are increasingly filled with ice (Woo 2012). Permafrost is considered to behave like an aquiclude (impermeable layer) or an aquitard (semi-permeable layer) and can confine sub-permafrost groundwater such that it exhibits artesian

conditions (Woo 2012). Active groundwater circulation can occur above (supra), within (intra) and beneath (sub) permafrost.

The Project is located in an area classified as extensive discontinuous permafrost with low to medium ice content (NRCan 1995). Extensive discontinuous permafrost is defined as 50% to 90% of the land area underlain by permafrost, while low to medium ice content is defined as less than 10% to 20% by volume of visible ice content. Recharge of sub-permafrost groundwater in discontinuous regions can be directly from adjacent non-permafrost uplands or through supra and intra-permafrost connections (Woo 2012).

Overall, permafrost is widespread across the Project site. It extends to greatest depths in ridge areas and appears to thin towards areas of lower elevation; north facing slopes tend to have thicker permafrost than south-facing slopes. The only drilling locations where permafrost was absent were the two instruments established in the lower reaches of the Alpha WRSF drainage. The thickest permafrost (approximately 165 m) is encountered near the north end of the proposed Supremo Pit. Permafrost in the Project area is relatively warm (between 0 and -2°C) and is coolest (-1.4°C to -1.9°C) on north-facing slopes.

5.7 Hydrogeological Field Investigation

Multiple hydrogeological field programs have been undertaken at the Project between 2013 and 2019 (Table 4-1). The field programs have established a robust network of hydrogeological installations in, adjacent to and downstream of proposed major mine facilities (Figure 5-5). The location and configuration of some mine facilities (e.g., Heap Leach Facility (HLF), WRSF) has evolved since hydrogeological field investigations were initiated, with the mine plan layout shown in Figure 5-5 current to date.

The groundwater field installations are as summarized as follows:

- Eleven conventional monitoring wells (five wells less than 10 meters deep; six wells between 150 and 220 metres deep).
- Seven individual multi-port Westbay installations monitoring groundwater 10 to 286 metres deep.
- Twenty-six stand-alone thermistor strings, 14 multi-bead thermistors strings ranging from 20 to 300 metres deep and 26 single bead shallow thermistor strings installed between 4 and 10 metres deep.
- Four stand-alone VWP installations ranging from 120 to 185 metres deep.
- Twelve combination VWP/thermistor installations ranging from 52 to 268 metres deep.

Completion details of the conventional monitoring wells, Westbay systems, VWP and thermistor are provided in Coffee Gold Baseline Hydrogeological Assessment 2019 Update. Borehole logs and instrumentation documentation are provided in Appendix D.

Many of the drilling programs have incorporated hydraulic testing of bedrock, predominantly through a combination of packer testing and airlift testing. Limited slug testing has also been conducted. In conjunction with monitoring well installations, multiple groundwater sampling events have been undertaken to characterize baseline groundwater quality and its range of variability. The discussion below provides a high-level overview of the field programs with emphasis on those conducted by Lorax.

5.7.1 Previous Groundwater Studies

5.7.2 *Groundwater Sampling*

All monitoring wells were developed after installation and prior to groundwater sampling. Well development was conducted using several methods, including purging with a bailer- winch system, inertial pump actuated with a Hydrolift-II, Westbay sampler, and air-lift pumping. The available well development method(s) depended on the type of well installation and depth to groundwater. Details regarding the development of MW14-series (completed in 2014), MW15-series wells (completed in 2015), and MW16-01WB (completed in 2016) are described in Lorax (2017c).

Groundwater monitoring events were conducted in September/October 2014, and four times annually since 2015, except in 2016 and 2019 when three monitoring events were completed. The groundwater monitoring events have been conducted between April and October annually ; this modified quarterly sampling frequency is often employed in the Yukon to capture the range of seasonal variability accounting for extended winters and compressed spring/summer/fall seasons.

All new monitoring wells installed between 2014 and 2016 have been sampled for groundwater quality with the exception of MW14-06A, MW14-06B, MW15-01AZ, and MW15-04 AZ which could not be sampled due to damage or water limitations (e.g., frozen or dry) (Table 5-2). Table 5-2 presents a summary of the groundwater sampling programs between 2014 and 2019, including sampling methods used at each monitoring well.

Groundwater sampling was conducted in accordance with methods outlined in the BC Field Sampling Manual (BC MOE, 2013). Sampling was conducted using several different types of pumps. The pump employed at each well depended on the type of well installation, permeability of the geological unit being sampled, and depth to groundwater. Inertial pumps actuated with a Hydrolift-II mechanical actuator and peristaltic pumps were used to sample monitoring wells screened in permeable formations. Bladder pumps were used to collect groundwater samples from deep wells screened in low permeability bedrock which would not permit sampling with conventional methods (*e.g.,* inertial pump), while the Westbay sampler was necessarily used to collect groundwater samples from the Westbay installations. In general, low-flow sampling methods were employed, and groundwater samples were collected after water levels in monitoring wells and purge water field parameters had stabilized. Field parameters were continuously monitored with a multi- parameter probe (YSI 556 MPS or YSI Professional Plus) coupled to an in-line flow- through cell during groundwater purging. Field parameters were monitored to ensure collection of representative samples and to provide reliable field-based estimates of temperature, pH, specific conductance (SC), dissolved oxygen (DO), and oxidation- reduction potential (ORP).

De-icing was required at monitoring wells MW14-02A and MW14-02B prior to groundwater sampling. Artesian conditions at both wells resulted in the top of the water column freezing inside the well casing installed through permafrost. De-icing was conducted with a hot water pressure washer equipped with high-pressure hoses and a drain jetting nozzle. Groundwater sampling was conducted after the volume of injected de-icing water plus a minimum of one well volume had been purged and purge water field parameters had stabilized.

Low water levels and low yields at monitoring well MW14-05B challenged the equipment capabilities and sampling procedures. Consequently, a modified purging/sampling procedure was employed to obtain the

most representative formation groundwater at MW14-05B. The water level was drawn down to the lowest possible level (pump elevation) to maximize the amount of purged groundwater. The well was then allowed to recover overnight prior to sampling the next day, to ensure the greatest displacement and the largest buffer between 'new' formation water and 'old' residual standing water.

Since Westbay sample zones are isolated (i.e., not in direct contact) from atmospheric conditions, collecting representative groundwater samples does not require the use of typical sampling methods whereby large volumes of water are purged. Westbay installations MW15-01WB to MW15-06WB were sampled after completion of well development and purging in June 2015, while MW16-01WB was sampled after completion of development in October 2016. Additional well development was conducted at MW15-06WB in July and August 2015 due to the suspected presence of drilling additives observed during sampling in June 2015. Subsequent groundwater sampling of all Westbay installations was conducted after purging a minimum of 4 L. Additional detail regarding groundwater sampling methods is included in Lorax (2017c).

The data record at MW15-03WB consists of samples collected from Port 6 (~47 m bgs) between June 2015 and May 2016, while subsequent sampling was completed at Port 4 (~82 m) between July 2016 and August 2019 due to a transcription error. However, both sampling depths intersect similar geology (i.e., mixed mafic gneiss and mixed felsic gneiss) and a strong upward hydraulic gradient was measured by MW15-03T between VWP sensors at 95 and 49 m bgs. The groundwater quality results corresponding to the two sampling depths indicate that there is no apparent difference in major ion compositions, and concentrations of field parameters, redox parameters, trace element parameters, and stable isotopes.

Groundwater samples were collected and preserved in the field with the appropriate laboratory supplied bottles and preservatives, with the exception of select dissolved samples collected in 2015 which were not preserved in the field when filtered at the lab. Samples analyzed for dissolved parameters were filtered in the field with disposable in- line 0.45-micron filters, except for groundwater samples collected from Westbay installations in 2015 which were filtered in the lab. Quality control sampling was conducted in the field and included the collection of field blank, trip blank, and field replicate samples. After collection, samples were kept cool in the field and during shipping until delivery to the laboratory. Groundwater samples were submitted for chemical analysis to the ALS Environmental (ALS) laboratory in Burnaby, BC in 2014, and to the Maxxam Analytics (Maxxam) laboratory in Burnaby, BC in 2015. In 2016, groundwater samples were submitted to Maxxam for all analyses, except cyanide species analyses which were completed by ALS. Since 2017, samples have been submitted to Maxxam (later becoming Bureau Veritas) for all analyses. Groundwater samples were analyzed for physical parameters, anions, nutrients, organic and inorganic carbon, total and dissolved metals, and cyanide species. Groundwater quality parameters and the corresponding detection limits are presented in Table 3-6.

6.0 FISH AND AQUATIC RESOURCES

Fisheries and aquatic baseline studies (Appendix E) for the Project were conducted from 2013 to 2016; some additional information is available from data collected for other projects prior to 2013. Additional fish and aquatic resource studies (Appendix F) were conducted in 2017 2018, 2019, 2020 and 2021. Studies undertaken to date have included the compilation of existing information, fish habitat assessments, and sampling for fish (summer, fall and winter), environmental DNA (eDNA), benthic invertebrates, periphyton and stream sediments.

6.1 Fish and Aquatic Habitat Study Areas

The study area for Fish and Aquatic studies included a large area around the proposed mine site and NAR. For the YESAB submission, the Local Assessment Area (LAA) was 527 km^2 and includes the area around the Mine Site, including portions of the Yukon River, Coffee, Latte, Halfway, and YT-24 creeks, and a 214-km long corridor along the NAR (Figure 6-1).

The Mine Site Assessment Area includes 17 km of the Yukon River as well as tributaries of the Yukon River comprised of four watersheds (Figure 6-1). These include:

- Coffee Creek
- Latte Creek, which flows into Coffee Creek
- Halfway Creek
- YT-24 Creek.

Other watersheds that have been sampled in the general area and may serve as future reference sites include:

- Coffee Creek, upstream of Latte
- Independence Creek immediately to the west
- Carlisle Creek, to the west of Independence
- SYT, a small unnamed stream to the southeast of YT24
- Dan Man Creek
- Los Angeles Creek (downstream reference) watershed located 27 km to the northwest
- Isaac Creek (upstream reference) watershed located 43 km to the southeast
- Excelsior Creek (east of Coffee Creek).

Baseline fish and aquatic resources studies were conducted from 2013 to 2016 in watersheds associated with the proposed Mine Site, and in 2015, 2016 and 2019 for the proposed NAR. Baseline studies include 18 fish sampling sites; 17 fish habitat sites; and 12 benthic invertebrate, periphyton and sediment sites (Table 6-1). Additional studies were conducted in 2017, 2018, 2019, 2020, and 2021 to add to the baseline and provide additional pre-project monitoring data for future comparisons.

The preliminary baseline study (2013) focused on describing the fish habitat near the proposed Mine Site and documenting potential salmon spawning and the distribution of fish species within the tributary streams of the Yukon River. Sampling included:

- minnow trapping in the tributary streams and collection of standard insitu water quality data (temperature, dissolved oxygen, pH and specific conductivity).
- aerial salmon spawning surveys via helicopter to document any chinook salmon and chum salmon spawning in the Yukon River in the vicinity of the Project.

The 2014 baseline study (Table 6-1) expanded on the previous year's survey:

- August: fish communities
- August: fish habitat; benthic invertebrate; periphyton; and sediment data; and
- October: additional fish community data.

The 2015 surveys (Table 6-1) included:

- March: a winter fish habitat survey
- June: spring fish and fish habitat data
- July and August: summer fish community, fish habitat, benthic invertebrate, periphyton, and sediment data
- September: additional fish and fish habitat data.

The 2016 surveys (Table 6-1) included:

- March: Fish and fish habitat sampling including eDNA
- March and August: benthic invertebrate sampling
- March, July, and August: fish habitat investigations and fish sampling
- August: chlorophyll-a sampling
- August: spawning surveys for chinook salmon on Independence and Coffee Creeks
- August: stream gradient modelling and analysis for small streams within the Mine Site
- July: fish and fish habitat investigations at stream crossings along the NAR
- July: fish sampling and habitat characterization at proposed barge landings and the Stewart River back channel
- October: spawning surveys for chum salmon in the Yukon and Stewart River channels.

The 2017 surveys (Table 6-1) included:

- March, August and October: environmental DNA (eDNA)
- August: fish sampling

- August: fish and fish habitat investigations (Halfway Creek)
- August: drainage assessments for headwater tributaries in the mine footprint
- July and August: spawning surveys for Chinook salmon
- August: fish tissue sampling for metals
- August: benthic invertebrate and periphyton tissue sampling for metals
- August: Canadian Aquatic Biomonitoring Network (CABIN) invertebrate sampling
- August: periphyton sampling and analysis for chlorophyll-a and ash free dry mass
- August: sediment sampling for metals.

The 2018 surveys (Table 6-1) included:

- July: fish sampling
- July: Chinook salmon aerial spawning survey (Coffee and Independence Creeks)
- July: Yukon and Stewart River back channel investigation fish sampling
- August: fish sampling
- August: Chinook salmon aerial spawning survey (Coffee and Independence Creeks)
- August; Yukon River back channel investigation fish sampling
- August: Hess invertebrate sampling
- August: environmental DNA (eDNA) sampling
- August: Fish Habitat Assessment Procedure surveys (Halfway, YT-24, and Latte creeks)
- October: Yukon and Stewart rivers Chum salmon spawning survey.

The 2019 surveys (Table 6-1) included:

- May: fish sampling
- May: fish habitat investigations in a back channel of the Stewart River
- July: fish sampling
- July: Chinook salmon aerial spawning survey (Coffee Creeks)
- July: fish sampling on various creeks in the mine site area (MSA), and within mixing zones of the Yukon River
- July: barge landing fish sampling and investigations
- August: fish sampling
- August: Chinook salmon aerial spawning survey (Coffee Creeks)
- August: Fish Habitat Assessment
- August: fish sampling on various creeks in the MSA, and within mixing zones of the Yukon River.

The 2020 surveys (Table 6-1) included:

- June: Stewart River back-channel investigation
- August: Stewart River back-channel investigation and baseline fish and fish habitat data collection

The 2021 surveys (Table 6-1) included:

- August: fish sampling (Halfway Creek)
- September: fish sampling (Halfway Creek).

Notes:

[1]For sites with multiple years, not all types of sampling listed have necessarily been completed in each year.
[2]Codes: BI = MT = Minnow Trapping, EF = Electrofishing, FN = Fyke Netting, AG = Angling, H = Fish Habitat Assessment, BI= Benthic Invertebrate, P = Periphyton, S = Sediment, UC = underwater camera, AV = aerial video, eDNA = environmental DNA, BS = Beach Sein Netting, HSC = Habitat Site Card investigation, HE = Habitat Evaluation, FHAP = Fish Habitat Assessment Procedure survey.

6.1.1 Fish and Aquatic Habitats Supplementary Study (2017-2022)

6.1.1.1 Fish and Aquatic Habitats Supplementary Study 2019

Fish sampling was conducted on several creeks and rivers within the MSA. Fish sampling occurred during two field events, spanning July 8 to 14 and August 7 to 13, 2019. The objective of fish sampling was to add to existing baseline fisheries information, particularly for fish distribution and assemblages in several select streams within the MSA. The fish sampling method used at each site depended on physical stream features and suitability of the method for the targeted species. The sampling methods used included electrofishing, beach seining, and minnow trapping. Captured fish were identified to species, with the remaining fish enumerated before all fish were released back at their site of capture.

Yukon River Mixing Zones

As suggested by the Selkirk First Nation, fish sampling was completed for the second year at the mixing zones of both Halfway and YT-24 creeks with the Yukon River. Sampling at the Halfway Creek mixing zone occurred on July 12 and August 9, and at YT-24 on July 14 and August 10, 2019. The mixing zone is defined as the immediate area where the creek flows into the Yukon River and the two water masses mix. Sampling involved three successive beach seine hauls, beginning in the Yukon River at the creek mouths and continuing downstream. During each sampling event, three seine hauls were completed, beginning at the mouth of the creek, and going progressively downstream on the Yukon River. Beach seine hauls were conducted with field crews of two members for a length of approximately 15 m, although lengths ranged depending on conditions and riverbed morphology (mean = 15.5 ± 1.5 m; range = 8 – 25 m). Fish captured were enumerated, and a subset of ten fish per species had their length and weight taken from each seine haul. Fish measurement metrics were summarized (fork length and weight, ± SE) for all species captured.

Fish Habitat Assessments

Fish habitat surveys were conducted on three drainages during July and August 2019 following the FHAP survey methodology. The FHAP survey documents the characteristics and frequency of different fish habitats by enumerating different habitat units (e.g., pool, riffle, glide), and measuring various parameters (e.g., average depth, width, length). A detailed methodology is outlined in the FHAP guide (Johnston and Slaney 1996). The length of habitat units was measured using a laser range finder for all creeks assessed, whereas wetted widths, bankfull widths, and depths were measured with a measuring tape and/or metre stick for the unnamed tributary upstream of YT-24 (herein referred to as ‘Unnamed Tributary’) and both Carlisle Creek sites; Coffee Creek used the range finder for wetted and bankfull widths due to its size. Results were considered as average ± standard error (SE).

Chinook Salmon Spawning Surveys

Chinook salmon spawning surveys were completed in areas where Traditional Knowledge indicated past presence (Tr’ondëk Hwëch’in 2012) and in watersheds that appear to have habitat to support spawning Chinook salmon; as such, Coffee Creek and Independence Creek have been investigated and surveyed for spawning Chinook salmon annually since 2014. During the 2019 field season, Coffee and Independence creeks had two aerial surveys completed. Coffee Creek investigations also included a ground survey (stream walk) to record any evidence of Chinook salmon spawning.

NAR Study Area

During the 2019 field season, fish sampling occurred at the proposed barge landings in the Yukon and Stewart rivers. Sampling was completed using a beach seine and several species were captured. Additional opportunistic barge wake investigations were completed to determine the impacts of the wave runout caused by the barge wake at the existing barge landings. The Stewart River back channel was also further investigated for the presence of spawning northern pike. Two adult northern pike were captured in the back channel in May when water levels were high.

6.1.1.2 Fish and Aquatic Habitats Supplementary Study 2020

The June 2020 water levels on the Stewart River were very high at the time (28.505 m) and there was flow through the back channel (WSC 2020). Due to the high-water and associated unwadable conditions, the

crew could not complete the planned fish sampling. In situ water quality measurements and field observations were collected, in situ measurements were collected using a YSI Pro Solo multimeter, Oakton pH Testr pen, and an Oakton T-100 turbidimeter.

The August 2020 water level in the Stewart River was still relatively high (27.493 m; WSC 2020), and the back channel was wetted for its entire length where it parallels the base of the hillside. There was no discernable flow in the back channel during sampling.

In situ water quality measurements were recorded using a YSI Pro Solo multimeter, an Oakton pH Testr pen, and an Oakton T-100 turbidimeter at some of the sampling locations along the length of the back channel. Orange-brown algae was present in the upper half of the back channel. In situ water quality reflected poor habitat conditions in the top half of the back channel (low dissolved oxygen) and conditions improved closer to the mouth of the back channel and the Stewart River. Water clarity (turbidity) improved and then decreased as the influence of the Stewart River backwatering the back channel became more pronounced.

Fish sampling involved seining with a 10 m long by 1.5 m deep beach seine constructed of 5 mm mesh. Seining sampled the wetted width of the Stewart River back channel at regular intervals. A total of eight seine hauls were conducted starting at the top of the back channel, where isolated pools were previously identified (EDI 2019) and working back towards the mouth of the back channel. Northern pike (Esox Lucius), burbot (Lota lota), and lake whitefish (Coregonus culpeaformis) were captured during sampling. Fish were only captured in the lower half of the Stewart River back channel. An adult and juvenile Northern pike were captured in the lower half of the Stewart River back channel. Juvenile burbot and lake whitefish were also captured in the lower half of the back channel. No fish were captured or observed in the portion of the back channel with orange-brown algae.

6.1.1.3 2021 Halfway Creek Fish Investigations

Electrofishing was conducted at three locations in Halfway Creek on August 14 and at two additional locations on September 5. Fish sampling was completed with a Smith-Root LR-24 electrofisher. Electrofishing effort was counted on the electrofisher in total seconds of active electrofishing as well as by the approximate distance from the electrofishing starting GPS point. All captured fish were enumerated and identified to species, and ten of each species were weighed (g) and measured to fork length (mm; Arctic grayling) or total length (mm; slimy sculpin [Cottus cognatus]). A calibrated YSI water quality meter was used to collect in situ water quality parameters (temperature and dissolved oxygen in August; temperature, dissolved oxygen, pH, and specific conductivity in September) at each fish sampling location.

On August 14, photos and measurements were taken at the suspected fish barrier located approximately 1 km upstream of the mouth of Halfway Creek (HC1.0).

Given that no fish had previously been captured this far up in Halfway Creek, additional sampling was completed on September 5 at sites HC2.0 and HC6.8 to investigate fish distribution higher in the watershed; however, no fish were captured nor did the crew make any visual observations of fish. All sampling durations ranged from 1044–1219 seconds.

6.2 Fish and Aquatic Habitat Overview

A total of 14 species of fish can be found in the streams and rivers adjacent to or downstream of the Mine Site, including two species of salmon and 12 species of resident freshwater fish (Table 6-2). The majority of these species are found only in the Yukon and Stewart rivers, with three of these species documented in the small/medium sized streams downstream of the Mine Site. These species include slimy sculpin (*Cottus cognatus*), Arctic grayling (*Thymallus arcticus*), and juvenile Chinook salmon (*Oncorhynchus tshawytscha*). These three species were also the most common species encountered along the NAR (Table 6-3). The Yukon and Stewart rivers are migratory corridors for both Chinook and Chum salmon *(Oncorhynchus keta*) and spawning areas for Chum salmon have been documented within the LAA on the Yukon River and downstream of the LAA on the Stewart River in groundwater fed side channels. = Baseline studies have not found chinook salmon spawning within the LAA Among the tributary creeks, the highest species diversity and abundance of fish have been documented in Coffee Creek, the largest creek in the Mine LAA. Independence Creek, a reference watershed, located just west of the Mine Site has similar species diversity and abundance (Figure 6-2).

Coffee, Independence, and occasionally Halfway creeks are used by juvenile chinook salmon as non-natal rearing habitat, and Coffee Creek provides confirmed overwintering habitat for this species. Arctic grayling use the creeks primarily for summer rearing; eDNA data from March 2016 and 2017 confirmed Arctic grayling overwintering in Coffee Creek and the Yukon River but not in any other streams within the Mine study area. It is common for Arctic grayling to use different streams for important life history periods such as spawning, summer rearing and overwintering. Moderate densities of Arctic grayling have been documented in the lower reaches of Latte Creek during the summer months; however, overwintering habitat for fish within this stream appears poor and eDNA samples collected in this creek in March 2016 and 2017 tested negative for both Arctic grayling and juvenile Chinook salmon. Slimy sculpin are year round residents in Coffee Creek, the lower portion of Independence Creek, and the Yukon River.

The headwater streams within the Mine footprint are small and steep, with poor habitat and are located significant distances from documented fish bearing locations. Lower down in the watersheds, these streams eventually provide fish habitat or flow into areas that are seasonally used by fish (Latee, Halfway and YT24). Along the NAR, fish presence is typically associated with the larger streams that are crossed with likelihood of fish presence decreasing with distance from mainstem habitat.

Table 6-2 Summary of Fish Species Documented in the Streams in the Mine Study Area

Common Name	Scientific Name	Yukon River	Coffee Creek	Latte Creek	YT24-0.1 Creek	Halfway Creek

6.3 Periphyton

Mean chlorophyll-a and ash-free dry mass (AFDM) measured in 2014, 2015, and 2017 were low for all stations, which is typical of northern, nutrient poor aquatic habitats (PECG 2017). There was little variation among the stations and there was no relationship between chlorophyll-a and ash-free periphyton mass; differences in chlorophyll-a content may have been due to varying light conditions, nutrient availability, and periphyton taxonomy, which results in different proportions of photosynthetic and non-photosynthetic organisms that comprise periphyton. In 2014 and 2015 samples missed laboratory holding times and therefore samples may have experienced degradation prior to being analyzed in the laboratory, this combined with the low nutrient status of these streams may have underestimated the chlorophyll-a concentrations. Therefore, all streams within the Project area as well as reference sites were re-sampled for chlorophyll-a concentration in August 2016. The 2016 data indicated higher concentrations of chlorophyll-a throughout the sampling locations when compared with 2014,2015, and 2017 data. This may have been due to a warmer winter season in 2015/2016 followed by an earlier, warmer spring.

Community composition included blue-green algae (Cyanophyta), which comprised approximately 80% of the overall community composition and was the most dominant algal group in the study area; diatoms were the second most dominant group, followed by small percentages of green algae (chlorophyte). Blue-green

algae tended to dominate at higher elevation stations within the Mine Site area, whereas higher proportions of diatoms were present further downstream, at lower elevations. The large diatom *Didymosphenia geminata* (Didymo) was confirmed at station IC2.6 in Independence Creek in 2014; this invasive species has become increasingly prolific in BC and Yukon in recent years and is commonly referred to as rock snot (YISC 2014).

6.4 Benthic Invertebrate Communities

Benthic invertebrate sampling conducted in 2010, 2014, 2015, 2016 and 2017 (see Section 6.1) followed the standardized Canadian Aquatic Biomonitoring Network (CABIN) protocols and focused on total abundance and diversity. The CABIN protocols provide a standardized method to sample benthic invertebrate communities (NWRI 2008) and allows for robust data analysis by leveraging a large, nationwide database of invertebrate community data. The benthic invertebrate sampling conducted in March and August 2016 focused on collecting samples for metals analysis only and was not analyzed for benthic invertebrate abundance and diversity. A summary of results is provided below:

- In 2014 and 2015, Mean total abundance of benthic invertebrates ranged from 247 to 3,885 individuals per kick-net in 2014 and 2015, and from 221 to 5,967 individuals per kick-net in 2017, within watersheds in the Mine Site area.
- In 2014 and 2015 Los Angeles Creek displayed the highest total abundance, followed by Independence Creek, YT24, Coffee Creek, Halfway Creek, and then Isaac Creek. In 2017, total abundance was highest in Los Angeles Creed and Dan Man Creek, and lowest in creek YT24.
- In 2014 and 2015 total abundance generally increased in an upstream direction within watersheds, whereas in 2017 total abundance decreased in an upstream direction on Coffee, Latte, and YT24 creeks, and increased in an upstream direction on Dan Man and Halfway creeks.

Ephemeroptera-Plecoptera-Trichoptera (EPT) abundances within the Mine Site study area demonstrated similar patterns to overall abundance. During 2014 and 2015 samplings, Dipterans were the most dominant benthic invertebrate group, making up approximately 50% of the overall community composition. Conversely in 2017 Dipterans, along with Ephemeroptera and non-insects each comprised approximately 34% of overall abundance. Plecopteran comprised 31% of overall abundance and Trichopteran comprised less than 1% of overall community abundance.In Coffee and Independence creeks, EPT organisms typically dominated stations higher in the watershed; dipteran species dominated further downstream.

- Some stations, such as at IC2.6 in lower Independence Creek, had high between-year variability.
- In 2014 and 2015, after Dipterans, the second most dominant group was the mayflies (Ephemeroptera), followed by the stoneflies (Plecoptera), which contributed approximately 26% and 21% to the overall community composition, respectively.
- Small percentages of ringed worms (Annelids), and caddisflies (Trichoptera) were also present at the majority of stations.
- In 2014 and 2015, benthic invertebrate taxonomic richness was highest in the Coffee Creek watershed and lowest at the Kona Tributary to Independence Creek. In 2017, richness was highest in the Coffee Creek watershed and lowest in Dan Man Creek. There were no apparent inter-watershed patterns for taxonomic richness values in comparison with headwaters.
- Hess sampling results have proved to provide a statistically robust method for project effects monitoring.

6.5 Focal Species

The fish and aquatic baseline program included a broad review of the species and habitats present, as well as more detailed focus on specific species. Focal species selected for field surveys and baseline reporting include both species of conservation concern and species with social, cultural, or economic value. They reflect recommendations received during Project consultation with Environment Canada, Environment Yukon, local First Nations, and other stakeholders, as well as a review of relevant TK. Consideration for the selection of focal species or species groups included:

- Species of conservation concern including both federal and territorial listings
- Species harvested by First Nations or other local harvesters in the region
- Species selected as focal species for previous environmental assessments in Yukon
- Species raised as a concern during Project consultation
- Species with the potential to interact with the Project.

Table 6-5 Fish and Aquatic Habitat Focal Species

Focal Species	Representative of	Rationale for Selection
Arctic Grayling	Non-salmon species; recreational fish species and food species for First Nations	Widespread; important recreational/food fish species.
Chinook Salmon	Salmonids; target species for First Nation fishery. Also targeted by recreational and commercial fisheries.	Importance to local First Nations, present as juveniles in the LAA.
Chum Salmon	Salmonids; important species for First Nation and commercial fisheries	Importance to local First Nations and return to the Yukon River and Stewart River to spawn

6.5.1 Arctic Grayling

Arctic grayling are an important recreational fish species in the Yukon River watershed, and are an important food source for local First Nations (Bates and DeRoy. 2014). Arctic grayling are present within the LAA, and; have only been documented in the lower portions of the streams within the Mine Study area, including YT24 Creek, Halfway Creek, Coffee Creek, and Latte Creek.

- Arctic grayling have been captured in Coffee Creek and in the lower reaches of Halfway, YT24 and Latte creeks
- Along the NAR, Arctic grayling have been captured in Hunker, Maisy May, Ballarat, and Barker creeks, and are known to reside in the Stewart, Yukon, and Indian rivers, and historically in Sulphur Creek
- Smaller tributary streams along the NAR also have potential to provide summer rearing habitat for Arctic grayling.

The temporal characteristics of Arctic grayling life-history include seasonal migrations between overwintering, spawning, and summer rearing habitats with the largest individuals often being found the furthest upstream during the summer months (McPhail 2007). Spawning typically occurs during the spring, shortly after ice-out and typically takes place in larger creeks or small rivers over substrates dominated by

gravels and cobbles (McPhail 2007). Eggs incubate in the gravel for less than a month before hatching. In terms of sensitivities, deposition of fine sediments over the spawning grounds can result in habitat alteration and/or covering or smothering of eggs (mortality) during the incubation period.

Summer rearing habitat for Arctic grayling is typically widespread and includes the use of clear water creeks and rivers, including small tributary streams for summer feeding and rearing. Food items taken by Arctic grayling include a wide variety of aquatic and terrestrial insects and may include small fish and/or eggs (McPhail 2007). Rearing Arctic grayling are sensitive to changes in habitat suitability, accessibility, and stream productivity/food availability. Summer rearing by Arctic grayling was documented in the following creeks:

- Coffee,Latte, Halfway, and YT24 creeks downstream of the mine
- Hunker, Sulphur, Maisey May, Barker, Agate, and Ballarat creeks along the NAR
- Indian, Steward and Yukon rivers.

Arctic grayling typically overwinter in larger streams with groundwater inputs. Winter 2016 and 2017 fish and eDNA sampling in creeks in the vicinity of the Mine Site confirmed Arctic grayling overwintering in Coffee Creek and the Yukon River, but not in any other streams within the vicinity of the Mine Site. Overwintering on the NAR was not investigated; however, is likely limited to the larger streams such as Maisy May Creek, the Stewart River, and the Indian River.

Biomonitoring of fish species provides valuable information about the health of a watershed, as fish are long-lived and have specific habitat requirements that may be sensitive to environmental disturbances. In addition, fish are often positioned at the top of the aquatic food web, allowing them to integrate environmental variability experienced by species at the base of the food web, and increasing the likelihood of detecting environmental impacts (BCMOE 2012). In the baseline program, tissue sampling was undertaken to determine overall health via measurements of metal concentrations. Analysis of Arctic grayling tissue metal concentrations was conducted on samples collected in the vicinity of the Mine Site in the summer of 2014 and 2015 (PECG 2017), 2016, and in 2017. Arctic grayling were captured in Coffee, Latte, YT24 and Halfway creeks, and at reference sites in Independence and Los Angeles creeks.

- In all streams where samples were collected, baseline total mercury concentrations in all muscle tissue samples did not exceed the Canadian Food and Inspection Agency guideline (0.5 micrograms per gram wet weight (µg/g ww)).
- In contrast, estimated methylmercury concentrations (95% of total mercury concentrations, Jewett et. Al. 2003) in nearly all Arctic Grayling sampled in Coffee, Latte, Halfway, Independence, and Los Angeles creeks (both muscle tissue and whole-body samples) exceeded the CCME guideline for the protection of piscivorous wildlife (0.033 µg/g ww). Higher methylmercury concentrations were noted in Coffee and Latte creeks.
- Mean concentrations of methylmercury were lowest in Halfway, YT24, Los Angeles and Independence creeks.
- Selenium concentrations in muscle tissue did not exceed the US Environmental Protection Agency's (US EPA) interim guideline for fish muscle tissue (11.3 µg/g dry weight (dw), US EPA 2016); however, nearly all samples from all sites, with the exception of five samples from Latte Creek exceeded the BC tissue and whole-body guidelines for selenium (4 µg/g dw, BC MOE 2014).

6.5.2 Chinook Salmon

Chinook salmon are an anadromous fish species and an important food source for local First Nations (Bates et al. 2014, DRPC 2013). Juvenile Chinook salmon use the larger streams in the Project area as non-natal rearing habitat:

- Juvenile Chinook salmon were captured during the summer months in Coffee Creek, in the lower Halfway Creek and in lower Maisy May Creek.
- Potential rearing habitat was inferred based on suitable habitat in portions of Maisy May, Barker and Ballarat creeks in the vicinity of the NAR.
- Winter use by juvenile chinook salmon has been confirmed in Coffee Creek through direct fish capture (minnow trapping) and via eDNA sampling in March 2016 and 2017.
- Halfway Creek does not provide overwintering habitat.

In the Yukon River watershed, the temporal characteristics of chinook salmon life-history includes usage of freshwater habitats by young of the year (YOY), juveniles, and adults (spawning only). Chinook salmon spawn from late July to late August in clear, fast flowing streams and rivers, where large and clean cobble substrates are present. Eggs are deposited in stream gravels and hatch in winter as alevin[1]. Chinook salmon alevin remain in the gravels through the duration of the winter and live off stored energy reserves during this time before emerging as fry in late spring (May and June). Juvenile Chinook salmon rear in freshwater streams for up to one year after emerging from the stream gravels. Juvenile Chinook salmon can migrate many kilometres in order to find high quality rearing habitat; this can include the use of both natal and non-natal streams. Chinook salmon generally leave rearing habitats in the early spring of the following year, spend three to five years in the ocean, and return as adults to spawn.

Analysis of juvenile chinook salmon tissue metal concentrations was conducted on samples collected in March and August 2016, and in 2017. Samples were collected from Coffee Creek at CC0.5, CC3., from Halfway Creek at HC0.2 in 2016, and from Coffee Creek at CC6.6 and Halfway Creek at HC0.2 in 2017.

- Samples from Coffee Creek exceed CCME guidelines for the protection of piscivorous wildlife (0.033ug/g ww); samples from halfway creek are below the guidelines for all sampling events.
- The Canadian Food and Inspection Agency tissue concentration guideline for total mercury does not apply to juvenile chinook salmon, as they are not consumed by humans.
- Selenium concentrations in Coffee Creek did not exceed US EPA guidelines for muscle tissue (11.3 ug/g dw: US EPA 2015) or BC MOE selenium tissue guideline (4.0 ug/g dw) for all sampling events.
- One sample form Halfway Creek in 2016 and 2017 had selenium tissue concentrations in excess of the BC MOE guideline.

6.5.3 Chum Salmon

Chum salmon are an anadromous fish species and an important food source for local First Nations (Bates et al. 2014, DRPC 2013; Interview 14, pers. comm. 2016). Chum salmon life-history characteristics restrict their use of the creeks and river around the Project area to spawning and egg/alevin development only. Chum salmon do not rear in Yukon freshwater environments.

[1] A newly spawned salmon still carrying the yolk sac

- Chum salmon spawning has been documented in the Yukon River, with confirmed spawning locations near the Mine Site area in small side channels and sloughs that appear to be groundwater-fed
- Chum salmon spawning in the Stewart River has been documented in similar groundwater-fed side channels, approximately 6, 10 km and 18 km downstream of the NAR crossing
- Chum salmon migrate through the portions of the Yukon and Stewart rivers to reach spawning areas further upstream
- No chum salmon spawning has been documented in any of the smaller creeks (or near these stream mouths) within the Mine Study area, nor has any spawning been documented in the immediate vicinity of the proposed barge crossings or barge landings on the Yukon and Stewart rivers.

In the Yukon River watershed, chum salmon spawning occurs from September to November and is almost exclusively associated with areas of upwelling groundwater discharge. As with Chinook salmon, the eggs hatch as alevin during the winter and remain in the gravel until emergence during the spring. Juvenile Chum salmon migrate downstream to near the ocean after emergence. Chum salmon typically spend three to four years in the ocean before returning as adults to spawn.

6.6 Aquatic Environmental Setting

The Coffee Gold Mine Project mine infrastructure is located along a ridgetop straddling three watersheds (Figure 1-2). Two of the watersheds (Halfway Creek and YT-24), drain directly to the Yukon River. The third watershed (Latte Creek) drains to Coffee Creek, then on to the Yukon River. While all three watersheds have the potential to be influenced by the Coffee Gold Mine Project through changes in water quantity and/or water quality, only Halfway Creek will receive direct discharge of treated water from the Coffee Gold Mine Project. The potential effects of the Project on hydrology, water quality, and aquatic life were evaluated in detail in the Project Proposal and have been the subject of refinement through the YESAB review and screening (e.g., Lorax 2017a, b; EDI 2017a; Minnow and EDI 2017). Briefly, the physical presence of the Coffee Gold Mine Project within these three watersheds will result in modest loss of watershed area and consequent changes in water flow, principally confined to the upper reaches of Halfway Creek, YT-24 Creek, and Latte Creek. Flow changes in Latte Creek are negligible, while those in Halfway Creek are modest (i.e., maximum 15% change in mean annual discharge; Lorax 2017a). Project operations will have some influence on water quality of Halfway Creek, YT-24 Creek, and Latte Creek through erosion and sedimentation, leaching from disturbed mine materials and waste, leaching of nitrogen residues from blasting, discharge of treated camp water, heap leach facility residues, groundwater and surface water interactions and seepage, and atmospheric deposition (Lorax 2017b). Direct discharge of treated water from the WRSF will be limited to Halfway Creek, although small volumes of pit dewatering will be routed to YT-24 Creek, and small volumes of pit dewatering, plant site runoff, and sewage treatment plant effluent will be routed to Latte Creek (Lorax 2019). Detailed evaluation of the influence of the project on water quality indicated some modest Project-associated influences on concentrations of aluminum, chromium, copper, uranium and zinc in Halfway Creek, aluminum, arsenic, and copper in YT-24 Creek, and aluminum, copper, and uranium in Latte Creek and Coffee Creek (Lorax 2017b). Most recent evaluation of water quality under the Coffee Mine Update Study (CMUS) indicated a potential for sulphate concentrations in Halfway Creek to exceed water quality objectives (WQO), but no exceedances for any other parameter (Lorax 2019). This evaluation also indicated no exceedances of any WQO in YT-24 Creek or Latte Creek (Lorax 2019).

Evaluation of the potential influence of the Project on aquatic biology indicated no major expected changes to fish or fish habitat (EDI 2017a), and only very subtle changes in the taxonomic composition and/or productivity of periphyton and benthic invertebrate communities (Minnow and EDI 2017). The latter differ slightly by water body, with changes deemed most likely to occur in Halfway Creek, in the form of subtle changes in periphyton community composition, a modest increase in periphyton productivity (in association with nitrogen input and temperature changes), subtle changes in benthic invertebrate community composition, and a modest increase in benthic invertebrate productivity (Minnow and EDI 2017). In YT-24 Creek and Latte Creek, the only predicted changes are minor, low probability changes in periphyton community composition (Minnow and EDI 2017).

6.7 Aquatic Baseline Studies

6.7.1 Previous Aquatic Baseline Studies (2014-2017)

Baseline aquatic data collections in support of the Coffee Gold Mine Project were initiated as early as 2010. Intensive baseline data collection was completed from 2014 to 2017 in support of the Project Proposal (Table 6-1; Figure 6-1) and submitted with the Project Proposal (Appendix14A Fish Baseline Update, Appendix 14D Fish and Aquatic Resources Baseline). This included focused collection of aquatic biological baseline data in 2014 and 2015 (PECG 2017), and in 2016 and 2017 (EDI 2017a, 2018; Minnow and EDI 2017). Aquatic environmental baseline data collection included:

- habitat and water quality
- sediment quality
- periphyton / primary productivity
- benthic invertebrate community
- benthic invertebrate tissue quality
- fish community and populations
- fish habitat and habitat use evaluations.

With the exception of fish and fish habitat data (which are presented in a separate report), the results of the 2014 to 2017 aquatic baseline studies are briefly reviewed in the Coffee Aquatic Life Baseline Update Draft Report 2021.

6.7.2 Fish and Aquatic Resources Post-Baseline (2017-2021)

Since the submission of the Project Proposal, fish and fish habitat data has been collected on an annual basis to further develop the understanding of baseline conditions as well as provide pre-project monitoring data. The studies are listed below and in Table 6-6, discussed in Sections 7.2.2.1 to 7.2.2.5 and key findings are summarized in Section 7.2.2.6.

- Coffee Gold Mine Project: Fish and Aquatic Resources – 2017
- Coffee Gold Mine Project: Fish and Aquatic Resources – 2018
- Coffee Gold Mine Project: 2019 Fish and Aquatic Resources Studies
- memo addressed to Newmont Corporation from EDI titled Re: Summer 2020 – Stewart River Back Channel Fieldwork

- memo addressed to Newmont Corporation from EDI titled Re: Halfway Creek Fish Investigations (2021).
- Most findings from the 2017 to 2021 field programs are generally consistent with studies completed prior to submission of the baseline report to YESAB. While some new findings were documented they were not expected to have substantial implications to the effects assessment completed as part of the YESAB assessment. The post-baseline studies do provide more in-depth aquatic resource information and provide valuable information on unstudied areas. This additional knowledge will assist monitoring and management programs as they develop throughout future Project operations.

Table 6-6 Fish and Fish Habitat Sampling and Analysis Conducted 2017-2021

Study Area	Survey	Years
Mine	eDNA sampling within various creeks and Yukon River	2017, 2018
Mine	Fish sampling and habitat investigations (FHAP) within various creeks[1]	2017, 2018, 2019, 2021
Mine	Chinook spawning surveys	2017, 2018, 2019
Mine	Fish Tissue Sampling	2017
Mine	Benthic invertebrate and periphyton tissue metals	2017
Mine	Invertebrate community sampling	2017
Mine	Periphyton – chlorophyl and AFDM	2017
Mine	Sediment – texture and metal concentration	2017
NAR	Fish sampling and habitat investigations at barge landings	2017, 2018, 2019
NAR	Fish sampling and habitat investigation in the Stewart River back channel	2017, 2018, 2019, 2020
NAR	Opportunistic barge wake investigation	2018, 2019
NAR	Chum spawning survey	2017, 2018

AFDM = Ash Free Dry Mass

[1]Fish sampling in smaller creeks was primarily completed via electrofishing and in the Yukon and Stewart rivers via beach seining.

6.7.2.1 2017 Studies

During the 2017 field season, EDI conducted: eDNA sampling; fish sampling; fish habitat assessments; Chinook salmon (Oncorhynchus tshawytscha) spawning surveys; fish tissues metal analysis; benthic invertebrate community sampling and sediment analysis. The sampling and monitoring program was conducted on various streams within the Mine Study Area Table 6-7.

Table 6-7 Sampling and Analysis Conducted within the Mine Study Area in 2017

Type of Sampling	Streams Sampled	Results/Analysis
eDNA	Coffee Creek Latte Creek Independence Creek Halfway Creek Yukon River YT-24Creek	Results were generally consistent with past and current fish sampling events.
Fish Sampling	Coffee Creek Halfway Creek Latte Creek Independence Creek YT-24 Creek	Provided a better understanding of distribution, abundance, habitat usage, aging structure analysis, tissue metals, and percent moisture analysis. Fish distribution and species assemblages were similar to previous knowledge.
Fish Habitat Assessments Procedures (FHAP)	Halfway Creek Halfway, Latte, and YT-24 drainages within mine footprint	Pre-project data that can be used for later comparisons.
Chinook Spawning Surveys	Coffee Creek Independence Creek	No evidence of Chinook spawning was found in either creek.
Benthic Invertebrate and Periphyton Tissue Metals	Coffee Creek Independence Creek Latte Creek Los Angeles Creek Halfway Creek	Baseline tissue metals and percent moisture analysis were collected that can be used for future comparisons.
Canadian Aquatic Biomonitoring Network (CABIN) invertebrate sampling	Coffee Creek Halfway Creek Latte Creek YT-24 Creek Dan Man Creek Excelsior Creek Independence Creek Los Angeles Creek Stream South of YT-24 Creek Tributary to Excelsior Creek	BEAST and RIVPACS analyses were completed that can be used for future comparisons.
Periphyton	Coffee Creek Latte Creek Independence Creek YT-24 Creek Halfway Creek Los Angeles Creek	Chlorophyl-a and AFDM were completed that can be used for future comparisons.
Sediment	Coffee Creek Latte Creek Independence Creek Los Angeles Creek YT-24 Creek Halfway Creek	Texture assessment and metal concentration analysis were completed that can be used for future comparisons.

BEAST = Benthic Assessment of Sediment

RIVPACS = River Invertebrate Prediction and Classification Scheme

6.7.2.2 2018 Studies

Additional studies were undertaken in 2018 to add to the baseline and pre-project monitoring data within the study areas. Streams outside of the study areas were also investigated to provide a better understanding of fish and fish habitat in exploration areas.

EDI conducted a sampling program in 2018 to further assess the aquatic habitat and resources within the Project footprint. The 2018 sampling program completed by EDI included: eDNA sampling; fish sampling and habitat investigations; fish sampling in Yukon River confluences (mixing zones) of YT-24 and Halfway creeks; fish habitat assessments and Chinook salmon spawning surveys.

6.7.2.3 2019 Study

Studies completed in 2019 were mainly focused on collection of pre-project monitoring data including trying to find control streams outside of the study areas.

The 2019 program in the Mine Study Area included only fish sampling and habitat investigations, and Chinook spawning surveys. In addition to overlapping sampling and habitat investigations on creeks from previous years, EDI also conducted this on Carlisle, Excelsior, and Los Angeles Creeks. No eDNA sampling was completed in 2019.

6.7.2.4 2020 Study

The works completed in 2020 involved only further investigations in the Stewart River back channel. Similar to previous years, the investigation involved sampling in-situ water quality parameters and fish sampling via beach seining. Northern pike, burbot, and lake whitefish were captured. No sampling or monitoring was conducted during the 2020 field season within the MSA.

6.7.2.5 2021 Study

The works completed in 2021 involved fish sampling in Halfway Creek via electrofishing. Prior to 2021, no fish were captured above an expected fish barrier. A large log jam complex appeared to impede fish from migrating past with inadequate plunge pools for fish to jump over the features; however, two Arctic grayling (Thymallus arcticus) were captured above the log jam during the 2021 field study. In addition to capturing fish in this upper reach, 2021 was also the first year that slimy sculpin (Cottus cognatus) were captured above the downstream confluence. Winter surveys have confirmed that Halfway creek freezes to bed in the lower portions so slimy sculpin will not likely remain in this portion of the stream.

6.7.2.6 Key Findings 2017-2021

Findings from post-baseline data collected between 2017 and 2020 are generally consistent with findings in the baseline studies that were submitted to YESAB. The ongoing data collection programs are collecting new information and knowledge that can support the future licencing and permitting stages as well as setting the stage for future monitoring and adaptive management. Key highlights of the new knowledge gained by the recent studies are summarized in this section.

6.7.2.6.1 Halfway Creek

The extent of fish distribution in Halfway Creek has been dynamic from year to year. The baseline studies conducted prior to 2017 found that fish presence was limited to the lower 350 meters of Halfway Creek and documented a log jam 1 km upstream from the stream mouth that was suspected to be a barrier to fish. The 2017 report found fish presence to up to 600 meters from the mouth and documented many impediments to fish passage between the logjam and the upper watershed/project footprint (approximately 6.8 km upstream from mouth). In 2018, only one Arctic grayling was captured in the stream 200 m upstream

of the mouth. In 2019, grayling were documented up to the log jam but not upstream. The most recent field study completed in 2021 revealed changes to the log jam and resulted in the capture of two Arctic grayling just above the suspected fish barrier but no fish were captured further upstream.

6.7.2.7 YT-24

An Arctic grayling was captured during the 2017 field season in YT-24 Creek beyond the back flooded area at the mouth of the creek (50 m upstream). This was the first fish documented in this creek (beyond the back flooded portion adjacent to the Yukon River), and no fish were captured during the 2018 sampling event. A noticeable change in stream channel morphology was identified on YT-24 Creek and was determined to have been caused by a localized flood event in 2017. Low water was observed during the 2019 field study in YT24 Creek, resulting in loss of aquatic connectivity within regions of the creek and at the confluence to Yukon River. The combined information on YT-24 indicates the stream has limited fisheries values.

6.7.2.8 Mixing Zones

During the YESAB process, Selkirk First Nation expressed interest in the mixing zones at the mouth of Halfway and YT-24 creeks. As such, fish sampling was conducted at the mixing zones of both creeks where they enter the Yukon River. Species diversity and capture numbers were compared to other areas of the Yukon River with variable results.

6.7.2.9 Exploration Creeks

Additional creeks were sampled by electrofishing or eDNA sampling. Sampling determined fish presence in IC tributaries A and B, Dan Man Creek, and Kona Creek. A habitat assessment of IC tributary A indicated that fish presence is likely limited to the lower ~500m of the watercourse.

6.7.2.10 Spawning Surveys

Chum and Chinook spawning surveys were completed in 2017, 2018, and 2019. Chinook salmon surveys were completed on Coffee and Independence creeks, whereas chum spawning surveys were completed on the Yukon and Stewart rivers. No Chinook were observed in Coffee or Independence creeks throughout any of the field study years. Chum were observed spawning in many locations in the Yukon River and a few locations in the Stewart River in all years that the area was surveyed. No spawning has been documented at any of the barge landing or winter road ramp locations.

6.7.2.11 Stewart River Back Channel

The Stewart River back channel was assessed every year from 2017 to 2020 for fish habitat and presence. Although this area is ephemeral and tends to dry up when Stewart River water levels go below approximately 27.0 m, it does provide seasonal habitat for fish species including northern pike, burbot, lake whitefish, and longnose sucker (Catostomus catostomus).

6.7.3 Other Studies

In 2017 fish tissue, invertebrate sampling, chlorophyl-a, Ash Free Dry Mass (AFDM), and sediment texture and metal concentration analyses were conducted. The chlorophyl-a and AFDM confirmed that streams throughout the Project Area are oligotrophic. The sediment metal analysis indicated naturally elevated

levels of arsenic and chromium. Levels of these metals exceed the Interim Sediment Quality Guidelines (ISQG) at many sites and exceed the Probable Effects Level (PEL) at some sites. Although the analysis of sediments at most sites were consistent with baseline data, some sites resulted in significantly different results than baseline which can be found in the Fish and Aquatic Resource Studies - 2017 (EDI, 2018). Minnow Environmental Inc. also has collected additional invertebrate information within the study area. In summary, there has been a substantial amount of fish and fish habitat data that has been collected since the YESAB submission. This data has strengthened the knowledge of fish and habitat within the study area. Please refer to the specific reports for additional information on any of these studies.

7.0 VEGETATION

Detailed baseline studies on the vegetation present within the Project area for Goldcorp Kaminak Ltd. (now Newmont) have been conducted since 2014 in anticipation of regulatory requirements associated with the Project's approval. The Project was submitted to the YESAB Executive Committee for review in 2017.

The summary of vegetation resources for the Project area that may be affected by the mining operations provided below is a summary of the Vegetation Baseline Report submitted for the Project Proposal in 2017 and subsequent updates (Appendix G). The Project area is located within the Klondike Plateau Ecoregion, within the Boreal Cordillera Ecozone.

7.1 Vegetation Study Areas

Vegetation was studied in the Project area and its surroundings. The LSA used for Site Characterization Plan was derived based on the LAA used in the Effects Assessment and is different that the study area described in the baseline study. The LSA includes the proposed mine site and the proposed NAR to the junction with the North Klondike Highway. Around the mine site, the LSA is delineated based on the height of land while encompassing a minimum buffer of 1 km radius around the proposed mine footprint. Along the access route, the LSA includes a 1 km radius buffer from the centreline of the proposed or existing road.

7.2 Vegetation Environmental Setting

According to Yukon bioclimate zone mapping, the study area encompasses four bioclimate zones: the Boreal Low, the Boreal High, the Subalpine, and Alpine zones (Rowe and Sheard 1981). Overall, approximately 90% of the study area occurs within the Boreal Bioclimate zones (Boreal Low and High), while the remaining area occurs predominantly in the Subalpine Bioclimate zone. The Alpine Bioclimate zone is found only in a small area (less than 0.1% of the study area) in the southeastern extent of the study area, along a previously considered road alignment (proposed Casino Connecter) that has since been excluded from the Project.

The vegetation baseline study focused on describing the vegetation near the proposed Mine Site, and along the proposed NAR. Vegetation baseline studies included:

- Ecosystem and Landscape Classification (ELC) mapping (2014 to 2016) using pre-existing data and ELC field sampling within the Mine Site.
- Broad ecosystem Mapping (2016) using existing data and field ELC sampling along the NAR.
- Rare plant surveys (2014 to 2016) focusing on areas with high rare plant potential, based on a desktop review, within 500 m of the Project footprint.
- Invasive plant surveys (2015 to 2016) focused on areas with high invasive plant potential identified during a desktop review.

Within the Project Area, the subalpine landscape is dominated by shrub communities overlaying a well-developed feathermoss and lichen layer. Communities of scrub birch (*Betula glandulosa*), Labrador-tea (*Rhododendron groenlandicum*), bog blueberry (*Vaccinium uliginosum*), lowbush cranberry (*V. vitis-idaea*), and crowberry (*Empetrum nigrum*) are common. The widely distributed dry, shallow hillcrests throughout the Project Area commonly support communities of low-growing shrubs and/or ground shrubs, including scrub birch, mountain avens (*Dryas* spp.*),* crowberry, Arctic white heather (*Cassiope tetragona*), and lowbush cranberry. A sparse conifer canopy (approximately 15% cover) develops over the shrub layer at the lower elevation edges of the subalpine near the treeline and the boreal transition.

Between the treeline of the Boreal High and the valley bottoms of the Boreal Low Bioclimate zone, the vegetation patterns reflect the discontinuous distribution of permafrost throughout the region. Closed canopy pure or mixed stands of hybrid white spruce (*Picea glauca*), black spruce (*Picea mariana*), Alaska birch (*Betula neoalaskana*), and trembling aspen (*Populus tremuloides*) occur on neutral and warm, gentle-to-moderate slopes. Understory species typically include Labrador tea, prickly rose (*Rosa acicularis*), lowbush cranberry, tall bluebells (*Mertensia paniculata*), bastard toadflax (*Comandra umbellata*), and feathermosses. Dry, moderate-to steep, south-facing slopes support grasslands and aspen forests, overlaying kinnikinnick (*Arctostaphylos uva-ursi*), soapberry (*Shepherdia canadensis*), and grasses. In contrast, stunted black spruce forests occur on cold, north-facing slopes with imperfect-to-poor drainage due to near surface permafrost. Understory species typically include Labrador-tea, sedges, cottongrass (*Eriophorum vaginatum*), and cloudberry (*Rubus chamaemorus*). On gentle toe-slopes underlain by permafrost, black spruce communities containing Labrador-tea, sedges, red bearberry (*Arctous rubra*), and lichens predominate. Black spruce forests with high lichen cover also occur on better drained, coarser-textured upland, north-facing, lower-to-upper slopes. Wetland and floodplain ecosystems exist in valley bottoms throughout the PROJECT AREA; however, they represent a small component of overall area. This region has frequent fires, therefore young, deciduous-dominated, and mixedwood stands are more common than mature conifer-dominated stands. Additionally, the region has a long history of placer gold mining; subsequently, many valley bottoms within the Project area include historic or active placer mines.

7.3 Early Baseline Studies

Baseline vegetation studies conducted in 2014-2017 are listed in Table 7-1.

Table 7-1 Vegetation Studies Conducted for the Coffee Mine Project between 2014 and 2017.

Year	Study
2014, 2015,2016	Ecosystem Mapping
2014, 2015, 2016	Rare Plant Surveys
2015, 2016	Exotic and Invasive Plant Surveys
2014-2016	Vegetation and Soils Trace Metals Sampling

7.3.1 Ecosystem Mapping and Ecological Communities

Ecosystem mapping is typically used as a method of describing vegetation across a landscape. By grouping plant species into communities, it facilitates describing possible effects such as loss of vegetation habitat. Ecosystem mapping was initiated in the spring of 2014 and completed in February 2016 to provide information and document plant communities including wetlands and other land cover types. The

ecosystem mapping and survey extent included the Mine Site area, the existing road between Coffee exploration camp and the deposit (i.e., the Mine Site access road), the current airstrip and Coffee exploration camp, the NAR to the junction with the Klondike Highway, as well as a few previous road alignment options, including the previous Casino Connector Road option and alternate alignments through the Dawson Goldfields EDI 2017b.

Ecosystems within the baseline study area were mapped at two levels: Ecological and Landscape Classification (ELC) and Broad Ecosystem Mapping (BEM). The more detailed ELC mapping was completed around the proposed Mine Site and along new sections of the proposed NAR and was divided into two zones, boreal and subalpine/alpine. BEM was completed along the proposed NAR in sections with existing roads and was not divided into zones. Approximately 23,844 ha of the study area was mapped following ELC methods and approximately 36,582 ha was mapped following BEM methods. The mapping extent identified 34 unique ELC ecosites (24 ecosites in boreal zones, 10 ecosites in the subalpine/alpine zones), 11 non-vegetative/anthropogenic units, and 13 vegetative BEM units. The ELC mapping identified seven unique wetland ecosites and the BEM identified four units (bog, fen, marsh, and swamp). A summary of the mapped communities is presented in Table 7-2.

The ecosystem mapping area (47,422 ha) contains the Boreal Bioclimate (Boreal Low and High) and Subalpine Bioclimate zones. Approximately 92% of the study area occurs in the Boreal Bioclimate zones, while the remaining 8% occurs within Subalpine Bioclimate zone (Table 7-2). The LSA does not extend into the Alpine Bioclimate zone and does not contain any alpine ecological communities.

Wetlands are found scattered across the region, but no detailed wetland mapping or classification is available regionally. The most common wetland type found within the LSA was fens (approximately 926 ha scattered across the LSA in pockets of various sizes), and swamps (approximately 230 ha of willow-dominated (*Salix spp.*) swamps were mapped within the LSA). No bogs were mapped within the LSA, and few small marshes were mapped throughout the Project area.

Less than 4% of the overall ELC survey extent was mapped as wetland ecosystems (codes F1, F2, F3, S1, S2, M, M1, M2, B, F, and S in Table 7-2). Floodplains are found throughout the ELC survey extent of the LSA and make up 6% of the area mapped. In addition, small pockets of natural wetland communities are likely to exist within the matrix of heavy placer mining activity.

7.4 Traditional and Medicinal Species

Berry-producing plants were selected to represent traditional and medicinal use plants, as berries are a diverse and important food source and were reported to be harvested in the Coffee Creek area by members of the Tr'ondëk Hwëch'in and White River First Nation (Tr'ondëk Hwëch'in 2012, Bates and DeRoy 2014) and continue to be an important source of food for local First Nations (InterGroup Consultants Ltd. 2009).

Many of the berry-producing species traditionally harvested by First Nation communities are present in one or more of the ecological communities surveyed in the Project area.

The occurrence of plants important for traditional and medicinal use was assessed using the ELC and BEM vegetation community classification mapping and quantified as sites likely to contain important berry-producing plants. Edible berry-producing species, including bog blueberry (*Vaccinium uliginosum*), lowbush cranberry (*Vaccinium vitis-idaea*), crowberry (*Empetrum nigrum*), high-bush cranberry (*Viburnum edule*), bog cranberry (*Vaccinium oxycoccos*), cloudberry (*Rubus chamaemorus*), currants and gooseberries

(*Ribes* spp.), and soopolallie (*Shepherdia canadensis*) were commonly found throughout the LSA during baseline vegetation studies. The majority of ecosystems identified within the LSA support, at minimum, one berry-producing species, and commonly support multiple species. All identified ecosystems in the LSA were rated for berry-producing potential using five categories (high, medium, low, very low, and nil potential). Table 7-3 lists the mapped berry-producing communities within the Project Proposal LSA that are considered to have high and moderate potential by Bioclimate zone.

Table 7-3 Area of High and Moderate Potential Berry-producing Sites

Traditional Use Berry Potential Class	Ecological Communities (Code)	LSA (ha)
Boreal Zone		
High Potential	• Spruce – Birch – Lowbush Cranberry – Feathermoss (31) • Black Spruce – Scrub Birch – Labrador Tea – Cloudberry (32Sb1)	1,238
Moderate Potential	• Alaska Birch – Labrador Tea – Tall Bluebells – Step Moss (01W) • Alaska – Birch – White Spruce – Labrador Tea – Lowbush Cranberry – Feathermoss (01WSw) • Spruce – Labrador Tea, Lowbush Cranberry – Feathermoss (01Sw(Sb)) • Spruce – Feathermoss (01) • Black Spruce – Labrador Tea – Reindeer Lichen (30) • Black Spruce – Labrador Tea – Cottongrass (32Sb2) • Black Spruce – Labrador tea – Cloudberry – Sedge (32) • Spruce – Willow – Labrador Tea – Sedge (F1) • Birch – Leatherleaf – Sedge (F3) • Willow – Horsetail (S1) • Willow – Reedgrass (S2).	11,198

Moderate Potential	• Upland/Closed Canopy Forest (UpF) • Low Elevation Shrubby Riparian (LSr) • Fen (F) • Swamp (S).	19,494
	Total (ha)	**38,233**

7.5 Rare Plant Species

The baseline plant surveys documented 411 plant species including seven tree, 60 shrub, 188 forb, 63 grass, 18 fern/horsetail/clubmoss, 2 aquatic, 36 mosses/liverworts, and 37 lichens (a complete list of all species can be found in Appendix G). Many of the species documented during the different surveys are considered traditional and medicinal plants including such plants as bear root (*Hedysarum alpinum*), raspberry (*Rubus ideaus*) or high-bush cranberry (*Vibernum edule*).

No Committee on the Status of Endangered Wildlife in Canada (COSEWIC) or *Species at Risk Act, S.C. 2002, c. 29* (*SARA*)-listed plant species were observed during rare plant surveys; however, populations of four Yukon Watch List plant species were found. At the time of the Vegetation Baseline Report (EDI 2017) development, Coffee Creek Scorpionweed (*Phacelia mollis*) was included on the Yukon Watch List; however, it has since been removed from the list (highlighted grey in Table 7-4). The Watch List represents taxa for which more information is needed before a conservation status can be determined but may be threatened or endangered in Yukon or throughout their range (YCDC 2019b). Watch-list plant species found during rare plant surveys are listed in Table 7-4.

Table 7-4 Locations, Abundance, and Habitat of Watch-list Plant Species Found in the LSA

Site[1]	Species Name	Abundance and Distribution	Habitat
PM-1	Coffee Creek Scorpionweed[2]	2 individuals in a patch	Open mixed forest on a moderate slope with well-developed dwarf shrub/forb understory and tufted grasses
PM-2	Coffee Creek Scorpionweed[2]	1 patch of 4 individuals	Disturbed, exposed soil along the edge of adjacent forest
PM-3	Coffee Creek Scorpionweed[2]	1 individual	Disturbed, exposed soil along the edge of adjacent forest
PM-4	Coffee Creek Scorpionweed[2]	6 individuals scattered linearly for 80 m	Open Trembling Aspen forest on moderate slope with well-developed dwarf shrub/forb understory and some leaf litter
PM-5	Coffee Creek Scorpionweed[2]	24 individuals scattered linearly for 100 m	Disturbed, exposed soil with few associated forb species
PM-6	Coffee Creek Scorpionweed[2]	17 individuals in a patch of approximately 20 m radius	Open Trembling Aspen forest on a moderate slope with dwarf shrub/forb understory and high leaf litter
CG-1	Spotted Lady's Slipper	4 scattered patches each with 11 individuals	Edge of open, Trembling Aspen forest at the crest of the bank with well-developed dwarf shrub/forb understory and tufted grasses
CG-2	Spotted Lady's Slipper	Approximately 3000 individuals in several patches within a larger patch about 1318 m²	Open Trembling Aspen forest on moderate slope with well-developed dwarf shrub/forb understory and tufted grasses
CG-6	Spotted Lady's Slipper	Approximately 3,000 individuals in two patches	Open Trembling Aspen forest on moderate slope with well-developed dwarf shrub and forb understory and tufted grass.
CA-1	Small Enchanter's Nightshade	1 patch, 1 m² of approximately 150 individuals	Transitional habitat between upland and sedge meadow, moist shaded area below deciduous shrubbery
CS-1	Dry-spike sedge	Approximately 100 individuals scattered within a somewhat linear patch about 600m in length	Open Trembling Aspen to mixed wood forest on flat to moderate slope with well-developed shrub and forb understory.

[1]Site number is unique to the species name proceeded by a number. For example, "CA" = Circaea alpina ssp. Alpina and "1" = site 1.

[2] When the Vegetation Baseline Report (EDI 2017) was developed, Coffee Creek Scorpionweed (*Phacelia mollis*) was also listed on the Yukon Watch List; however, it has since been removed from the list. These rows are highlighted grey.

7.6 Vegetation Trace Metals Sampling

Trace metals sampling for the Coffee Project characterizes baseline trace metal concentrations in soil and vegetation to anticipate future monitoring for vegetation health. Baseline data were initially collected in 2014, 2015 and 2016 focussed on the proposed mine site and within four distance categories relative to the mine footprint: adjacent (≤100 m), near (101–1,000 m), far (5.5–7.5 km) and control (≥15 km).

In 2019, supplemental sampling was implemented in response to concerns regarding five sites in the control distance category (≥15 km) at Thistle Mountain. Previously sampled sites at Thistle Mountain were removed from the dataset due to the possibility that they may have been compromised by previous disturbance, based on their proximity to an exploration road/quad track. The 2019 sampling was completed following the baseline study design and power analysis. The analyses determined that eight samples per distance category would be sufficient to detect a change in median metal concentrations before exceeding the recommended threshold for most chemicals of potential concern (CoPCs) in soil and vegetation (EDI 2017b).

As a baseline assessment of vegetation health, trace metal levels in soil and plants were sampled in July 2014, July to August 2015 and 2016. Sampling for trace metals focused on four plant species or species groups: willow, lowbush cranberry, horsetail (*Equisetum arvense, Equisetum pratense*, and *Equisetum sylvaticum*), and fruticose lichen (*Cladina* spp.). The plant species were chosen based on importance to First Nations (Bates and DeRoy 2014; Mishler and Simeone 2004), value as wildlife forage, and comparability to other studies. The vegetation health sites were considered as two areas: the Coffee Area (which includes the Mine Site, Mine Site access road, existing Coffee exploration camp and the proposed Casino Connector (no longer considered)), and the NAR. Vegetation health sample collection sites were based on variable distance from the Project footprint: adjacent (100 m), near (1,000 m), far (5.5 km to 7.5 km), and control (greater than 15 km). Adjacent sites are expected to fall within the Project footprint, while control sites represent locations unaffected by Project activities. From 2014 to 2016, a total of 89 vegetation health sites were sampled. Seventy-seven sites were located in the Mine Site and twelve sites were located along the NAR.

In the Coffee Area, trace metal concentrations in soil were low, with the exception of arsenic and chromium. Arsenic and chromium concentrations were above CCME soil quality guidelines in 24 (27%) and 4 (4%) samples, respectively. Arsenic samples above CCME guidelines were generally found within close proximity to the Mine Site, including adjacent (100 m) and near (1000 m) distances from the Project footprint. These high background levels could be due to the presence of arsenic associated with complex ores, mined primarily for their copper, lead, zinc, silver, and gold content (CCME 1997), which may be present in the Coffee Area.

Chromium samples above CCME guidelines were found at near (1,000 m) and control sites (greater than 15 km) relative to the Project footprint. Chromium rarely occurs naturally and is often introduced to the environment through anthropogenic sources (CCME 1999). All other trace metals consistently showed concentrations in soil well below the CCME guidelines. Relatively few soil samples reported mercury and selenium above the laboratory reported detection limit. The pH was below the recommended range in 71 (79%) samples at various distances from the Project footprint.

Soil samples collected along the NAR contained low concentrations of all but two of the targeted trace metals. Arsenic concentrations were higher than CCME guidelines in two out of 12 sites sampled. Zinc concentrations were well below CCME soil quality guidelines; however, two sites had higher than average concentrations and some of the highest recorded concentrations of zinc in soil across all sample sites. These sites also correspond to above average concentrations of zinc in willow. All three sites are near areas with existing anthropogenic disturbances. All other trace metals were consistently present at concentrations well below the CCME guidelines.

The vegetation and soils trace metals sampling program also informed the Human Health Risk Assessment (HHRA) completed as part of 2017 effects assessment for the Coffee Gold Project. The HHRA prioritized airborne contaminants associated with Project emissions, and a risk assessment of the impact of dust deposition on plants that are ingested by humans and animals with a specific focus on arsenic, chromium, iron and thallium. The HHRA focuses on the amount of trace metals specifically associated with waste rock disposal areas and not the whole area around any Project related activities. The Human Health Risk Assessment Technical Report and the Addendum Report are provided in Hemmera Envirochem Inc. 2017, 2018.

7.7 Invasive Plant Species

Invasive plants are ranked in degree of invasiveness (i.e., concern) from high priority (1) to least concern (7) (EDI 2017b). Yukon ranks are based on general abundance, persistence, invasiveness rank in neighbouring jurisdictions, climate projections, and expert opinion of the Yukon CDC (Environment Yukon 2012). High priority species are those that are of most concern to the economy, environment, and human health (YISC 2015). During field surveys in 2015 and 2016, 18 invasive plant species were documented including five rank 1 species (Table 7-5).

Locations within the survey extent where invasive plants were found included roadsides, pullouts, junctions and other previously disturbed areas. In general, concentrations of invasive plants were less frequent in the southern portion of the survey extent (i.e., NAR south of Stewart River, including the Mine Site) compared to the northern portion (north of Stewart River to Klondike Highway). Prior to Newmont's exploration work, human habitation at Coffee Creek (e.g., farming) led to relatively few invasive plant introductions, such as smooth brome and other lower priority species. Narrow-leaved hawksbeard and perennial sow-thistle are high priority species and were found in the vicinity of Coffee exploration camp but appear to be relatively new introductions because of the few plants found in single locations.

Table 7-5 Rank 1 Invasive Plant Species Located during Project Baseline Field Surveys

Invasiveness Rank[1]	Species Name	Common Name	Habitat	General Location		
				Northern Portion[2]	Southern Portion[2]	
				Existing Roads/ Disturbance	Existing Roads Outside of Coffee Property	Coffee Property
1	*Bromus inermis*	Smooth Brome	Roadside, Clearing	√		√
1	*Crepis tectorum*	Narrow-leaved Hawksbeard	Roadside, Clearing	√	√	√

Invasiveness Rank[1]	Species Name	Common Name	Habitat	General Location		
				Northern Portion[2]	Southern Portion[2]	
				Existing Roads/ Disturbance	Existing Roads Outside of Coffee Property	Coffee Property
1	*Melilotus albus*	White Sweetclover	Roadside, Clearing	√	√	
1	*Melilotus officinalis*	Yellow Sweetclover	Roadside	√		
1	*Sonchus arvensis* spp. *uliginosus*	Perennial Sow-thistle	Clearing			√

1 Yukon invasiveness rank (YG 2012).

2 For invasive plant surveys the study area was divided into two areas: the northern portion which included existing roads accessible by truck, north of the Stewart River, and the southern portion which included existing roads accessible by foot or UTV between the Stewart River and the current airstrip.

7.8 Post-Application Baseline Studies

Since the submission of the Project Proposal to YESAB in 2017, additional trace metals studies were completed for vegetation to supplement baseline information previously provided for the Project, address questions that were raised during the Project review, and refine proposed monitoring programs in anticipation of future Project monitoring requirements.

The 2019 Terrestrial Studies report EDI 2020 in Appendix G summarizes the environmental studies completed by EDI between October 2018 and November 2019, including the continuation of trace metals sampling. In 2019, supplemental sampling was implemented in response to concerns regarding five sites in the control distance category (≥15 km) at Thistle Mountain EDI 2020. Previously sampled sites at Thistle Mountain were removed from the dataset due to the possibility that they may have been compromised by previous disturbance, based on their proximity to an exploration road/quad track. The 2019 sampling was completed following the baseline study design and power analysis. The analyses determined that eight samples per distance category would be sufficient to detect a change in median metal concentrations before exceeding the recommended threshold for most chemicals of potential concern (CoPCs) in soil and vegetation (EDI 2017b). The 2019 trace metals program involved the collection of soil and vegetation samples at three sites in the control distance category (see Table 2-1, Map 2 of the 2019 Terrestrial Studies (Appendix G)). Vegetation sampling included three focal species or species groups: willow, fruticose lichen, and lowbush cranberry. Horsetail (*Equisetum* spp.) was not collected due to insufficient sample size determined during previous baseline sampling.

The baseline analysis was updated to include new sites collected in 2019. The 2019 baseline trace metals analysis results were generally consistent with the initial baseline assessment; mean metal concentrations of chemicals of potential concern in soil were below relevant CCME guidelines for agricultural standards in soil EDI 2020. All metal concentrations in vegetation were well below maximum tolerable levels, apart from cadmium in willow. No distinct patterns for metal concentrations in soil and vegetation were identified among distance categories, although some metals were naturally high at individual locations near the proposed mine site. Generally, metal concentrations in soil and vegetation samples were low with some high data outliers EDI 2020. No additional vegetation studies were reported in 2021.

8.0 WILDLIFE

For the purposes of this report, 'wildlife' is defined as native bird and mammal species. Wildlife assessments were completed within, or near, the Project area. This section summarizes the results of wildlife surveys conducted in the area to date, identifies species of concern, and lists ongoing and/or near-future surveys to be completed. The last update on the number and types of wildlife studies that have been conducted in the Coffee Gold Mine Project area was in a comprehensive 2021 report produced by EDI, titled Environmental, titled *Terrestrial Studies Report.*

8.1 Wildlife Study Areas

The LSA used for Site Characterization Plan was derived based on the LAA used in the Effects Assessment. The LSA includes the proposed mine site and the proposed NAR to the junction with the North Klondike Highway. Around the mine site, the LSA is delineated based on the height of land while encompassing a minimum buffer of 1 km radius around the proposed mine footprint. Along the access route, the LSA includes a 1 km radius buffer from the centreline of the proposed or existing road.

The RSA is defined as the watershed drainages overlapping the Project footprint and a 10 km buffer around the various road alignment options.

8.2 Wildlife Environmental Setting

The Project footprint is situated within the boreal forest of the Yukon, which provides suitable habitats for multiple bird and mammal species. Habitat types present in the surrounding RSA range from sparsely vegetated alpine areas to dense lowland riparian forest (EDI 2017d). Large waterbodies such as lakes are not present although smaller wetlands and streams exist.

The Project is located within the range of the Klaza and Fortymile caribou (*Rangifer tarandus*) herds (EDI 2017d). Other large ungulates present in the vicinity of the Project (EDI 2017d) include moose (*Alces alces*), mule deer (*Odocoileus hemionus*), and thinhorn sheep (*Ovis dalli*). Grey wolves (*Canis lupus*) and grizzly (*Ursus arctos*) and black bears (*U. americanus*) are the largest predators. Smaller carnivores include red fox (*Vulpes vulpes*), coyote (*Canis latrans*), wolverine (*Gulo gulo*), Canada lynx (*Lynx canadensis*), American marten (*Martes americana*), mink (*Neovison vison*), ermine (*Mustela richardsonii*) and least weasel (*M. nivalis*). Rodents, lagomorphs and insectivores are represented by beaver *(Castor canadensis*), snowshoe hare (*Lepus americanus*), red squirrel (*Tamiasciurus hudsonicus*), northern flying squirrel (*Glaucomys sabrinus*), muskrat (*Ondatra zibethicus*), and multiple species of voles, mice and shrews (EDI 2017d). Little brown myotis (*Myotis lucifugus*) has been confirmed present in the lower elevations of the LSA (EDI 2017d). The wood frog (*Lithobates sylvaticus*) is the only amphibian species expected to occur (EDI 2017d).

The Coffee Gold Project is located within the Northwest Boreal Forest Bird Conservation Region (BCR4). EDI 2017d states that 119 bird species may potentially occur in the Project Proposal RSA including: songbirds, raptors, shorebirds and upland game birds. Waterfowl and waterbirds are relatively rare due to the lack of large waterbodies in the RSA. Wildlife Key Areas defined by the Yukon government for Sharp-tailed Grouse (*Tympanuchus phasianellus*), Peregrine Falcon (*Falco peregrinus*), Golden Eagle (*Aquila chrysaetos*) and Gyrfalcon (*Falco rusticolus*) are present in the vicinity of the Coffee Gold Project.

Baseline surveys have confirmed the presence of several wildlife species federally listed as at risk by COSEWIC or Schedule 1 of SARA. Wildlife species on the Yukon Conservation Data Centre's Track List or Watch List of species of conservation concern (YCDC 2019a), or afforded special protection under the Yukon *Wildlife Act* may also be present in the vicinity of the Project. A list of wildlife species at risk known present or potentially present in the Project Proposal RSA (EDI 2017d) is presented in Table 8-1.

Table 8-1 Wildlife Species at Risk Known Present or Potential Present in the Project Proposal RSA

English Name	Scientific Name	COSEWIC Status	*SARA* Schedule 1 Status	Yukon *Wildlife Act* Status	Yukon List	Confirmed in Wildlife RSA
Woodland Caribou, Northern Mountain population	*Rangifer tarandus caribou*	Special Concern	Special Concern	none	No	Yes
Grizzly Bear	*Ursus arctos*	Special Concern	Special Concern	None	No	Yes

8.3 Focal Species

Focal species and species groups identified id 2017 by EDI Environmental Dynamics Inc. (2017d, 2017e) are listed in Table 8-2. Focal species and species groups were identified as those of conservation concern, those that are harvested by Indigenous or non-Indigenous hunters, those raised as a concern during Project consultation, those selected as focal species for previous Yukon environmental assessments, and those with the potential to interact with the proposed Project.

Table 8-2 Focal Mammal and Bird Species and Species Groups Identified in the 2017 Coffee Gold Proposal

English Name	Scientific Name
Caribou	*Rangifer tarandus*
Moose	*Alces americana*
Thinhorn Sheep	*Ovis dalli*
Mule Deer	*Odocoileus hemionus*
Grizzly Bear	*Ursus arctos*
Black Bear	*Ursus americanus*
Grey Wolf	*Canis lupus*
Wolverine	*Gulo gulo*
Furbearers	multiple
Collared Pika	*Ochotona collaris*

Olive-sided Flycatcher	*Contopus cooperi*
Bank Swallow	*Riparia riparia*
Barn Swallow	*Hirundo rustica*
Rusty Blackbird	*Euphagus carolinus*

8.4 Wildlife Baseline Studies

Baseline studies have been conducted for the Coffee Gold Project since 2011. Wildlife baseline studies are described below. Supplementary studies and monitoring programs have been conducted since 2013 to add to baseline information, address questions raised during the review, and refine wildlife monitoring programs in anticipation of future monitoring requirements.

8.4.1 Early Baseline Studies

Early baseline wildlife surveys for the Coffee Project began in 2011 and ungulate and bird studies were carried out into 2014 (Access Consulting Group 2011, 2013b, 2013a, 2014). Since 2014, EDI has conducted detailed baseline studies on the wildlife and wildlife habitats present within the Project area for Goldcorp Kaminak Ltd. (now Newmont) in anticipation of regulatory requirements associated with the Project's approval. Previous studies were generally conducted within a Regional Study Area (RSA) described as follows (EDI 2017d, 2018, 2019, 2020):

- The RSA encompassed 13,661 km² of terrain, including the proposed mine site, the NAR, and the surrounding areas (Figure 1-2). It included all game management subzones (GMS) that are near, or intersect, the proposed Project footprint.

Summaries of work completed for the 2017 Coffee Gold Project Proposal are included in the Wildlife Baseline Report (Appendix H, EDI 2017d). Studies completed for mammals included aerial surveys for ungulates, bear den surveys, sheep surveys, snow tracking surveys, remote camera studies, ground-based investigations of wildlife trails and habitat features, pellet plots, and targeted surveys for collared pika (*Ochotona collaris*), bats and small mammals. A small mammal trapping program was combined with trace metal analysis of small mammal tissue. Bird studies conducted included point count bird surveys, surveys for cliff-nesting raptors, and targeted surveys for Common Nighthawk (*Chordeiles minor*), Short-eared Owl (*Asio flammeus*), and Sharp-tailed Grouse (*Tympanuchus phasianellus*). Wildlife studies completed between 2014 and 2017 are listed in Table 8-3.

Table 8-3 Wildlife Studies Completed 2014 to 2017 for the Coffee Gold Project

Year	Target Species	Study	Report
2013, 2014, 2015	Upland birds	Bird Point Counts	EDI Environmental Dynamics Inc.(2017f)

2017	Caribou	Resource Selection Model for the Fortymile Caribou Herd	Muhly (2017)
2017	Birds		EDI Environmental Dynamics Inc. (2017f)

8.4.2 Post-Application Baseline Studies

Additional wildlife surveys were carried out between 2017 and 2019, and descriptions of those surveys are included in the following reports:

- Coffee Gold Project: 2017 Bird and Wildlife Studies Report (EDI 2018)
- Coffee Gold Project: 2018 Wildlife Studies Report (EDI 2019)
- Coffee Gold Project: 2019 Terrestrial Studies Report (EDI 2020).

8.4.2.1 2020 Baseline Studies

Further data collection occurred through winter 2019/2020 and summer 2021 (EDI 2021) to support future monitoring programs. The 2020 study areas are generally the same as those described for the Project mine site and NAR in previous years (EDI 2017d, 2018, 2019, 2020). Some of the 2020 field studies (e.g., thinhorn sheep aerial survey) were conducted within a species-specific survey extent.

Field studies completed by EDI between October 2019 and September 2020 are summarized in Table 8-4. Field monitoring programs continued to focus on target species such as caribou, moose, thinhorn sheep, and wolves. The results of the 2020 wildlife studies are generally consistent with previous baseline surveys. These results do not change the conclusions of the Wildlife and Wildlife Habitat Valued Component Report (EDI 2017c).

Table 8-4 Wildlife Studies Conducted for the Coffee Project, October 2019 to September 2020

Study	2020 Component	Target Species	Dates Conducted
Summer Sheep Aerial Survey	Baseline field survey	Thinhorn sheep	July 15, 2020
Remote Camera Studies	Baseline field survey	Thinhorn sheep, moose, caribou, wolves	October 1, 2019-September 21, 2020
Mineral Lick Monitoring	Baseline field survey	Moose	
Wildlife Camp Log	Surveillance monitoring	All species	

The 2021 report (Appendix H) provides a full description and data analysis of the field studies completed between October 2019 and September 2020. Brief summaries of the 2020 work are provided below. Studies were conducted for the area included in the Project Proposal, which includes the mine site (subject of this application) and the NAR (permitted under separate application). The descriptions of the studies focus on the mine site, however some results for the NAR are included for context, such as studies near Ballarat Creek, the northern Yukon barge staging area.

One thinhorn sheep aerial survey was conducted in July 2020. Observations included one group of three unclassified sheep on a cliff west of Ballarat Creek and a solitary unclassified sheep east of Ballarat Creek. Remote camera monitoring showed that at least two ewes and one ram use the Ballarat area.

The remote camera program continued in 2020 to monitor wildlife and wildlife habitat features throughout the Regional Study Area and traffic along the proposed Northern Access Route. There were 24 active sites, although theft and wildlife damage shortened the operating windows of several cameras. Commonly

documented species in 2020 included black bear, lynx, moose, and wolf. Focal species for the remote camera programs include thinhorn sheep, moose, caribou, and wolves. As this program focussed on the NAR, it is not discussed further.

In 2020, monitoring the Northern Access Route mineral lick between the Stewart and Yukon rivers consisted of continuing the remote camera monitoring program and collecting a water quality sample. A review of the remote camera photos showed that results were consistent between 2017 and 2020 and with other mineral lick studies. Moose were the primary users of the lick; lynx, wolves, grizzly bears, black bears, wolverine, and small mammals were observed travelling through the site. Moose used the lick between May and October annually, with the highest activity occurring between June and August. Moose use was highest in the early morning hours, and cows used the lick more frequently than bulls. The mineral lick water sample showed similar patterns in elevated nutrients compared to 2019; however, some were detected at higher concentrations than in 2019.

The 2020 camp wildlife log recorded observations for two months while the camp was open. The shorter data collection period correlates to fewer documented wildlife sightings. Fourteen species, including seven mammals, were recorded. As in previous years, black bear and moose were the most common species reported.

9.0 SOIL AND BEDROCK

This section provides the environmental setting for surface conditions (physiography and surficial materials) and permafrost. The environmental baseline report for surficial geology, permafrost, and terrain stability is provided in Appendix A.

9.1 Physiography Environmental Setting

The Project is located in the northern Dawson Range of the Yukon-Tanana terrane, forming a moderate plateau that escaped Pleistocene glaciation. The landscape evolved through erosional and periglacial processes. The dominant periglacial processes at the Coffee Gold site are cryoturbation, solifluction, slope wash and thermal erosion. The topography generally consists of rounded ridges with incised v-shaped valleys (AECOM, 2012). Elevations across the property range from 400 to 1,500 m asl with the majority of the property above the tree line and supporting short shrubby vegetation (JDS, 2016). The property has local mature pine forests with thick moss cover on the ground. Bedrock exposures on the property are rare (<5%).

9.1.1 Previous Studies

A surficial geology map of the Coffee Creek area has been compiled by the Geological Survey of Canada (Huscroft, 2002). AECOM (2012) was retained by Kaminak Gold Corporation (Kaminak), a previous owner of the Project, to compile a detailed geomorphological map to aid in the selection of appropriate sampling sites for soil geochemical characterization. Both maps identify colluvium as the most widespread surficial material within the project area. The ridgetops and upper slopes are generally dominated by in-situ residual soils and colluvium derived from weathering of bedrock. The colluvial material is variable and typically contains mixtures of gravels, sands, and silts with organic materials in the upper 0.1 to 0.2 m layer. The ridgetop soils are up to approximately 1.8 m deep and generally ice-poor. The thickness of the strongly weathered bedrock is variable but is generally less than a metre. The build up of colluvium is greatest on lower slopes, which tend to be steeper than upper slopes. Dominant colluvial processes include slope creep, debris slides and minor rock fall.

9.1.2 Bedrock Geology

A detailed account of the geologic setting and mineralization of the Coffee Gold Mine Project is provided in the 2016 Feasibility Study (JDS, 2016). The Project is underlain by a package of metamorphosed Paleozoic rocks of the Yukon-Tanana terrane that was intruded by a large granitic body in the Late Cretaceous. The Paleozoic rock package is predominantly a biotite (+ feldspar + quartz + muscovite ± carbonate) schist that overlies an augen orthogneiss. Both the Paleozoic metamorphic rocks and Cretaceous granite are cut by intermediate to felsic dykes of andesitic to dacitic composition. Grodziki *et. al.* (2015) have compiled the most recent geological map of the Coffee Gold deposit area, informed by a combination of geological traverses, bedrock mapping, borehole data, soil geochemistry, and geophysics. This map has been used as the base map for Figure 9-1, which also shows mine facilities and instrument locations for reference.

The main Coffee Gold mineralization is associated with an extensional deformation event that occurred during the Cretaceous. This event resulted in formation of steep-to-vertical brittle fractures and normal faults crosscutting all lithologies at the Project area (Berman et al., 2007). A CO_2-rich fluid flowed through the region and travelled upwards in the system into the epizonal domain of the Coffee Gold Mine Project, where

it was controlled by the structural framework of the Coffee fault system and reacted with favorable host rocks (Buitenhuis *et. al.*, 2015; Buitenhuis, 2014). The fluid travelled along brittle structures and deposited gold-rich arsenian pyrite through sulphidation, and in high-energy pulses, formed gold-rich hydrothermal breccias (Buitenhuis, 2014). The planar gold mineralized zones at the Project exhibit a number of strike orientations, dominated by east-west, north- south, and east-northeast–west-southwest strike directions.

The Supremo zone is housed in several drill-tested T-structure gold corridors which are 5 to 30 m wide. The Latte zone consists of a stacked set of moderately-to-steeply south- southwest dipping, east-southeast striking brittle-ductile structures. The Double Double zone consists of a number of discrete, high-grade strands of mineralization up to several metres wide, trends east-northeast steeply dipping to the north and consists of a number of discrete, high-grade strands of mineralization up to several metres wide. The Kona zone is hosted in equigranular granite and consists of east-northeast trending, steeply south- dipping stacked structures. The gold structures are associated with narrow, less than 5 m wide, sparsely feldspar phenocrystic to aphanitic andesite to dacite dykes.

Kaminak (2015) prepared a map of all confirmed mineralized structures identified on the property. The map identifies structures confirmed by drilling, trenching, or soil sampling and does not include regional-scale inferred faults. Structures identified in this map have been included in hydrogeologic maps provided in subsequent sections of this report due to their relevance as potential groundwater conveyance pathways.

Coffee Gold Project

TITLE:

Bedrock Geology of the Coffee Gold Project

PROJECT #: A362-4 *FIGURE:* 9-1

P:\@Drafting\Coffee Gold\Drafting Figures\MxDs\Baseline Report\Fig 2-2_Bedrock Geology_20210203.mxd

9.2 Permafrost

9.2.1 Permafrost Environmental Setting

The Project is located in an area classified by Natural Resources Canada (1995) as extensive discontinuous permafrost (i.e., 50% to 90% of the land underlain by permafrost). The most recent estimates of permafrost distribution at the site indicate that approximately 61% of the mine area is underlain by permafrost with 34% of the area estimated to be permafrost free (Tetra Tech 2019b). Of the 61% underlain by permafrost, 29.5% is underlain by predominantly ice-poor permafrost, 31% by predominantly ice-rich permafrost; and approximately 0.5% by very ice-rich permafrost. The permafrost-free area of the mine site is estimated at 39%.

9.2.2 Permafrost Studies

Frozen ground has been mapped at the Project using a variety of methods. AECOM (2012) first mapped frozen ground on the property for a geomorphological mapping study supporting strategic soil sampling for exploration purposes. EBA Tetra Tech (EBA TT) further investigated permafrost occurrence through field mapping and air photo interpretation (2016). A terrain stability/geohazard map was produced by Palmer (2016). Various investigations to characterize permafrost occurrence and extent have been completed for the Project which have resulted in the establishment of numerous thermistor installations (e.g., EBA TT in 2013, Knight Piésold in 2014, SRK in 2015, Lorax in 2014, 2015, 2016, 2017, Tetra Tech and SRK in 2016 and Tetra Tech in 2017). Additional information regarding permafrost distribution at the Mine Site are provided in Waste Rock and Overburden Management Plan (WROMP) and the General Mine Development Plan.

9.2.2.1 Ground Temperature Monitoring

As permafrost is defined based on temperature, the key method of its monitoring is a regular collection of ground temperatures. It is especially important for the zone of discontinuous permafrost (<90% of land area underlain by permafrost), such as the Project Area with 61% of it underlain by permafrost, because the collected ground temperature data allows for delineating perennially frozen and permafrost-free areas and applying different design solutions for these areas. Although various techniques and equipment are available for collecting ground temperature data, thermistors are the most widely used, reliable and accurate sensors. Multi-bead (16 beads) Ground Temperature (a.k.a. Thermistor) Cables (GTCs) and Single-Bead Thermistor Strings (SBTSs) were installed in completed boreholes throughout the Project Area. In 2022, a review of recent ground temperature data from the Coffee Mine Project Area was carried out, including updated ground temperature monitoring profiles, covering the period from 2016 to 2022 (Tetra Tech 2023).

9.2.2.2 Site Inspection

Annual helicopter-supported inspection of the permafrost conditions in the Project Area will be a part of the Permafrost Monitoring Program (PMP). The program will include Tetra Tech's permafrost specialist's site visit in early September to observe the permafrost terrain conditions and document changes that have occurred since the last inspection site visit. This will be accomplished by traversing the Project Area on foot, truck, ATV, and/or using helicopter-support. Previously identified geomorphic features indicative of permafrost degradation (such as thermokarst, thermal erosion, slope movement processes) will be re-visited, and newly identified ones will be mapped.

9.2.2.3 Drone-Supported Aerial Geospatial Data Collection

Tetra Tech will use its industrial multirotor drone (a DJI Matrice 600 Pro) along with a Light Detection and Ranging (LiDAR) sensor package developed in-house at Tetra Tech to monitor stability of permafrost terrain features in the Project Area. This sensor package is light-weight, permitting extended flight times for data collection, relative to larger, heavier sensors. The sensor acquires 100,000 shots per second across a 120° swath (i.e., 60° to either side of the drone), in 16 different sweep planes. The drone is programmed to fly in a back-and-forth pattern over the area of interest, at a constant altitude offset from the ground, typically 50 m to 60 m. Whenever possible, a series of retroreflective ground control targets should be laid down in the flight area prior to the flights, and their exact position measured with a survey system (typically an RTK GPS survey unit). The point cloud can then be corrected to these points, anchoring the LiDAR data to the "real world".

Permafrost Distribution Mapping Permafrost map polygons were delineated per the following available information:

- Geobotanical indicators: − Stunted black spruce stands on shallow permafrost; and − Deciduous (dominantly aspen and birch) stands on predominantly permafrost-free terrain
- Slope aspect: − North-facing slopes indicate predominantly permafrost terrain; whereas − South-facing slopes suggest predominantly permafrost-free terrain
- Extrapolated ground surface appearance (texture, colour, hue etc.) of those terrain units where permafrost conditions were identified and confirmed by ground temperature measurements with GTCs and SBTSs installed in selected boreholes to verify presence or absence of permafrost. The instrumentation borehole locations are shown on Figure 9.2. The latest ground temperature profiles, as of March 30, 2019, are presented in Appendix B of the Permafrost Monitoring Program Report (Tetra Tech 2022).

9.2.2.4 Permafrost Distribution Modelling

Detailed information collected on an annual basis which will include ground temperature data (Section 4.1), site inspection and aerial geospatial data (Sections 4.2 and 4.3) as well as detailed permafrost mapping update (Section 4.4) will be compiled on an annual basis to train models for permafrost distribution and refine the mapping. Mean annual air temperature, potential incoming solar radiation, soil type (organic vs. mineral; fine- vs. coarse-grained), predominant vegetation type, slope gradient, and aspect are principal factors that affect and regulate the presence and absence of permafrost. These principal factors along with annual data collection will be used to train and develop ML models for large scale permafrost distribution mapping.

9.2.2.5 Monitoring Data Analysis and Reporting

An annual Permafrost Monitoring Data Analysis Report will be prepared. The report will include:

- The ground temperature profiles updated with the latest GTC data received from Newmont and a summary of the data analysis and interpretation
- The results of annual site inspection of permafrost conditions throughout the Project Area
- Geospatial data collected annually with a drone
- Updated permafrost map of the Project Area

- Permafrost distribution model of the Project proposed expansion areas where presently no ground temperature or other geotechnical borehole data is available
- A summary of the annual climatic data review.

9.2.2.6 Permafrost Adaptive Management

Adaptive management of permafrost underlying the Project Area will be a systematic approach that links ground temperature monitoring and observations made during annual site inspections with response actions to reduce potential permafrost degradation. Possible changes in the permafrost regime, due to mine development and climate change, require triggers and planned responses to mitigate future permafrost degradation. Adaptive management will also help to evaluate the long-term success of permafrost preservation and will confirm that disturbed areas throughout the Project Area have stabilized and are performing as expected.

9.2.2.7 Permafrost Response Action Plan

The permafrost response framework includes the following:

- Triggers to identify signs of potential permafrost degradation
- Response actions to reduce or mitigate permafrost degradation.

The objective of the Permafrost Response Framework is to define best management actions, to the greatest extents possible, in response to changes documented through the PMP implemented for the Project Area. The Permafrost Response Framework will be a clearly defined and timely process that is responsive to the results of the PMP. It provides the means to respond to all reasonable monitoring outcomes, without the need to develop specific management responses to all possible (i.e., theoretical) outcomes before they occur.

10.0 SEISMICITY

10.1 Regional Seismicity

The Project is located in an area of relatively low seismic activity northeast of the seismically active St. Elias region, which includes southwestern Yukon Territory, northwestern BC, and southeastern Alaska. The Project is located between the Denali and Tintina fault systems, where the rates of seismic activity decrease dramatically (NRC 2016a). In the St. Elias region, the Pacific tectonic plate is being forced underneath the North American tectonic plate through subduction.

The seismic hazard for the Project area predominantly consists of shallow crustal earthquakes (with magnitudes of up to 7.0 on the Richter Scale) that may occur in the region south of the Project (greater than 100 km) (NRC 2016a). Seismic hazards are influenced by the potential for larger-magnitude earthquakes (with magnitudes from 7.5 to 8.0) occurring further from the Project site (greater than 100 km) on the East Denali fault zone, near the Alaska-Yukon border (NRC 2016a).

Newmont completed a review of the regional tectonics and historical seismicity in the southwest Yukon region to enable the selection of appropriate design earthquake events for key Project components, such as the HLF. The closest seismograph stations to the Project area are located in Dawson and Beaver Creek (NRC 2016b). The closest historical earthquakes have occurred near Beaver Creek, the most recent being a magnitude 4.2 earthquake in 2012, which is characterized as a light earthquake, slightly felt, but during which zero to minimal damage occurs (Belik 2013, NRC 2016c). Other stronger earthquakes have occurred recently in the southwestern part of the territory causing power outages and minor building damage in Whitehorse (Barton and Tukker 2017).

Regional seismic source zones were assigned to a map of historic earthquake events for the specific purpose of evaluating potential seismic loads for the Mine Site. Six seismic source zones were identified, which (proceeding from northeast to southwest) are as follows:

1. Tintina North Zone.
2. Inland Alaska Zone.
3. Tintina Trench Zone.
4. Denali Fault Zone.
5. Aleutian Megathrust Zone.
6. Fairweather-Queen Charlotte, Transition Fault Zone.

The purpose of identifying discrete seismic source zones is to characterize and quantify the nature of the largest earthquake that is likely to occur within the zone. In factoring in the largest earthquake that could reasonably be expected to occur within the zone, is the mean rate recurrence interval, and the location of the earthquake. Seismic source zones come in two varieties:

1. Aerial Seismic Source – where the earthquakes are uniformly distributed throughout the area and assumed to be equally likely to occur anywhere within the area.
2. Linear Seismic Source – where the earthquake occurs along a narrow linear band (fault) but are again assumed to be equally likely to occur anywhere along the fault line.

This information can be utilized in either a deterministic seismic hazard analysis (SHA) or a probabilistic seismic SHA. The results of both the deterministic and probabilistic SHAs completed for the Project are described in Appendix I.

A deterministic SHA estimates the largest earthquake event that could occur within the zone, and then relocates it to the position that most closely approaches the Project (either along the fault in a narrow linear source zone or within the area boundaries in an aerial source zone). Site-specific ground motion parameters are then estimated by attenuating ground motion between the earthquake location and the site. Although this may seem like a logical worst-case type of approach, it can lead to unrealistically severe design criteria.

The probabilistic SHA can be performed using the same seismic source zones as the deterministic SHA and replacing the maximum credible earthquake with the probability distribution of earthquake events, the site distance with the probability distribution of site distances, adding a random component to the attenuated spectral acceleration values, and using a Monte Carlo-type sampling model to compile a new distribution of spectral accelerations associated with an exceedance probability. The design ground motions from the deterministic SHA are similar but more conservative, at least for natural periods less than 0.8 seconds. The reduced probability of larger earthquakes occurring in very close proximity to the site moderates the distribution of spectral accelerations resulting in reduced short period spectral acceleration values from the probabilistic SHA. Beyond the natural period of 0.8 seconds, the design spectral acceleration (Sa) is slightly less than both the 2% and 5% exceedance earthquakes (return periods of 2,475 years and 1,000 years, respectively), implying that these rare, large earthquakes occurring at larger radial distances have a magnitude higher than the maximum credible earthquake selected for the deterministic SHA.

Table 10-1 Summary of Probabilistic Seismic Hazard Analysis Results

Annual Exceedance Probability	0.01	0.0021	0.001	0.000404
Recurrence Interval (years)	100	475	1000	2475
Probability of Exceedance in 50 Years	40%	10%	5%	2%

0.5	0.049	0.087	0.112	0.151
1	0.034	0.062	0.078	0.103
2	0.22	0.039	0.048	0.063
4*	0.011	0.0195	0.024	0.0315

Notes; * - per the 2010 NBCC the 4s Sa = (2s Sa)/2

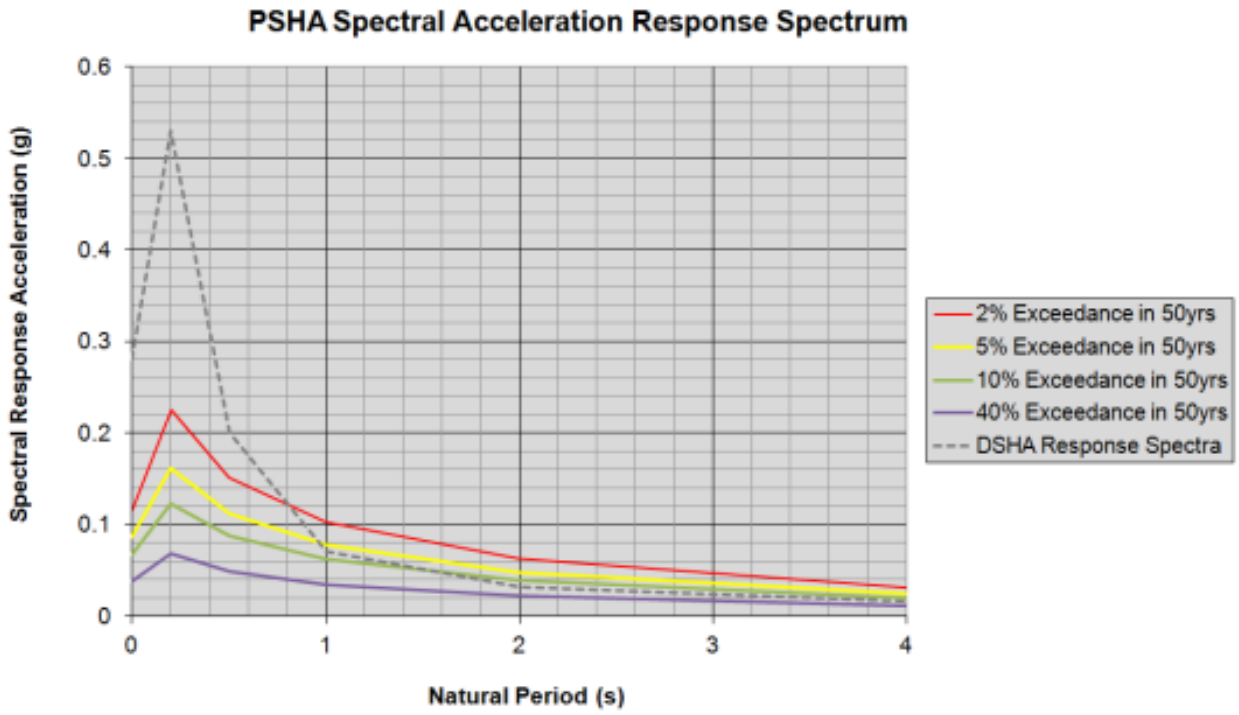

Figure 10-1 Plot of the Probabilistic Seismic Hazard Analysis Results

For the structural design of buildings and other structures at the Mine Site, the probabilistic SHA in the 2010 National Building Code of Canada (NBCC) are applied, based on the results shown in Table 10-1 and Figure 10-1, for the earthquake event having a 2% probability of exceedance in 50 years.

11.0 GEOCHEMISTRY AND GEOTECHNICAL INFORMATION

11.1 Geotechnical Hazards

The Mine Site is located in an area with gentle to moderate slopes that are typical of lower valley sides and in uplands. Geohazards identified within the Mine Site area include rockfall, debris slides, rock creep, gullying, solifluction, thermokarst, and slopewash. The majority of the Mine Site area (~85%) is considered to be relatively stable (terrain stability classes 0 to II) (Table 11-1;Figure 11-2). When combined with areas that are considered to be generally stable with minor potential for instability (class III), this increases to approximately 97%. Areas that are considered relatively unstable (terrain stability classes IV and V) within the Mine Site area are minor (Figure 11-2).

Along the NAR (including areas requiring new construction), ~80% is considered to be relatively stable (stability classes 0 to II) (Table 11-1). When terrain stability class III is included, the proportion increases to 93%. Approximately 7% has been classified as relatively unstable (classes IV and V), owing primarily to steep, gullied slopes and areas underlain by permafrost displaying thermokarst activity. Approximately 14% of the NAR area has no terrain stability rating assigned (class 0) and is associated with anthropogenic disturbances, largely from placer mining activity along the valleys of larger tributaries.

Table 11-1 Distribution of Terrain Stability Classes within the Mine Site Area and Northern Access Route

Existing Terrain Stability Class	Terrain Stability Class Description	Mine Site Area		Northern Access Route	
		(ha)	(%)	(ha)	(%)
0	N/A, Anthropogenic	-	-	2,823	14
I	Stable	-	-	509	3
II	Generally Stable	1,561	85	12,422	63
III	Generally Stable with Minor Potential for Instability	214	12	2,621	13
IV	Potentially Unstable	18	1	199	1
V	Unstable	44	2	1,199	6
	Total	**1,837**	**100**	**19,773**	**100**

The primary hazards requiring consideration during construction of the mine facilities and access road include rockfall, debris slides, icing, slope failure, active layer detachments and thermokarst activity. Infrastructure has been sited to maximize stability and minimize exposure to geotechnical hazards. Further, careful site preparation, and mitigation during construction will minimize exposure to these hazards, where unavoidable. Erosion protection, such as riprap, will be required along sections of the NAR near migrating meanders and river crossings. Special consideration will be given to the design and maintenance of drainage crossings prone to icing.

11.2 Geochemical Source Term

Geochemical source terms have been developed for the major mine components, taking into account mine-related activities throughout the Construction, Operations, Reclamation and Closure and Post-closure phases. The source terms are based on site-specific static and kinetic geochemical test results, as well as data from analogue sites. The approach and assumptions used to develop the geochemical source terms are discussed in detail in Geochemical Source Term Report (Appendix J).

Coffee Mine Project Geochemical Source Term Report describes geochemical source terms used in the Coffee Mine project water quality model (WQM). Geochemical source terms are water quality predictions for water in contact with geologic material disturbed by mining activities. Individual source terms are developed on an annual basis for each year of mine life at for post-closure. The report describes source terms for:

- WRSFs
- Pit Wall Rock
- Haul Roads
- ROM Stockpiles
- Active and Passive Treated Heap Leach Solutions.

All source term inputs used in the current version of the WQM, including those related to the HLF, are presented in Appendix J. For each mine component, an upper case and a base case source term has been calculated. The base case source term is meant to reflect a best estimate, while the upper case is meant to reflect a reasonably conservative upper estimate. These predictions become inputs to the site wide water quality model used to assess potential effects of the Project on the receiving environment. The source terms developed in this report are compared to the previous iteration of source terms (Lorax, 2018) in Appendix J. Source terms presented herein reflect updated mine configuration and changes to the proposed mine waste management practices.

11.2.1 Waste Rock Storage Facilities

Approximately 300-330 Mt of waste rock will be excavated from the Supremo Pit, Double Double Pit, Latte Pit and Kona Pit over the life of the Project. Waste rock will be stored in one out of pit waste rock facilities (Alpha WRSF) and four in-pit WRSFs (In-Pit Supremo, In-Pit Latte, In-Pit Double Double and In-Pit Kona). An annualized progression of WRSF footprints and volumes has been provided by JDS for the 300 MT CMUS (Shape file reference). The lithologic composition of each waste rock facility is estimated by assuming; no re-handling of waste rock take place, and waste rock is deposited in the WRSF nearest the origin of excavation; and the proportion of different weathering states is the same as what was anticipated in the Project Proposal. This assumption results in waste rock from the Latte Pit and Kona Pit being stored in the Alpha WRSF, while waste rock from the Supremo Pit and Double Double pits are placed in the Alpha WRSF and all four In-pit dumps. This results in the Alpha WRSF being the only facility which contains a mixture of different lithologies. The other waste rock dumps will be composed of exclusively gneiss waste rock. The tonnage and geologic composition of the five WRSFs can be found in Appendix J. The annualized footprint of WRSF's is provided in Table 11-2. Additional information regarding design criteria and WRSF construction and material management at the Mine Site are provided in WROMP.

At the end of mine life, the mine pits will begin to flood. The ultimate pit lake volume will be controlled by the spillway elevation of each backfilled pit. The percentage of each backfill dump below the spillway elevation, and the percentage of the dump footprint occupied by saturated waste rock, is provided in Table 11-3.

Table 11-2 Surface Area of Mine Facilities in each Year of Mine Life

	Alpha WRSF	In-Pit Kona	In-Pit Latte	In-Pit Supremo	In-Pit Double Double
Year	ha	ha	m2	ha	ha
Y1	57.4	-	-	-	-
Y2	96.8	-	-	-	-
Y3	109.7	-	10.1	-	-
Y4	145.4	-	10.1	10.1	-
Y5	161.4	-	10.1	19.7	-

Y7	179.0	-	25.6	19.7	-
Y8	179.8	3.2	25.6	19.7	8.4
Y9	187.9	3.2	25.6	19.7	11.9

Table 11-3 Percentage of Footprint and Mass Submerged Once Pits Flood to Spillway Elevation

	Alpha WRSF	In-Pit Kona	Latte In-Pit	Supremo In-Pit	DD Backfill In-Pit
Footprint	0%	77%	37%	43%	45%
Mass	0%	39%	13%	17%	14%

11.2.2 Pit Wall Rock

Pit wall rock refers to rock exposures within the mining pit itself. This includes the pit floor, benches, and blast damaged fractured rock. Fracturing and slope ravelling of the pit walls exposes a greater proportion of the wall rock to weathering. The WQM includes two types of geochemical loading released from pit wall rock: meteoric runoff from unsaturated pit wall rock exposures; and submergence of pit wall exposures. Pit wall runoff source term represents weathering from sub-aerially exposed pit wall. The second type of pit wall loading is from submergence of pit wall by pit lake formation. This source terms represents the flushing of oxidation products which may accumulate on mineral surfaces while the wall rock is unsaturated.

The pit wall source term assumes that 75% of rock surfaces in the blast damaged zone and 50% of the blast fractured zone are flushed by meteoric water when subaerially exposed. When the pit wall becomes inundated by a pit lake, the blast-fractured and blast-influenced zone will be entirely flushed, and the accumulated load will be released at that time. That is, 25% of the rock surface in the blast damaged zone and 50% of the surface in the blast fractured zone accumulates oxidation products, which are released once the pit wall is submerged.

The same assumptions regarding wall rock geochemical loading rates and solubility controls developed for the end-of-mine (EOM) model described in Appendix J are applied to the Project Operations source terms.

11.2.3 ROM Pad and Stockpile

Approximately 60 Mt of ore mined from the open pits will either be taken directly to the HLF or temporarily stockpiled on the ROM pad. The maximum capacity of the ROM stockpile is 3 Mt, with the actual value fluctuating seasonally. The mass of ore on the ROM pad will fluctuate widely, with a mass ranging from 3.0 Mt to 0.33 Mt during Project Operations (Figure 11-2). Peak volumes occur during the winter months when ore is still being produced from the pits, but no new material is stacked on the HLF, and minimum volumes occur during summer or fall months when ROM material is being removed to the HLF.

No granite ore from the Kona Pit will be placed in the ROM stockpile due to the elevated ML potential and mildly acidic pH associated with this ore type. The granite ore will be immediately directed to the HLF, where it will be mixed with lime and stored with other non-potentially acid generating ore types.

Stockpiled ore will be placed upon a pad constructed with waste rock. The pad will be constructed exclusively of schist waste rock in order to utilize the metal attenuating attributes of this rock type. The ability of schist waste rock to attenuate As and U is related to the relatively high Fe content of this rock type and has been demonstrated in column experiments.

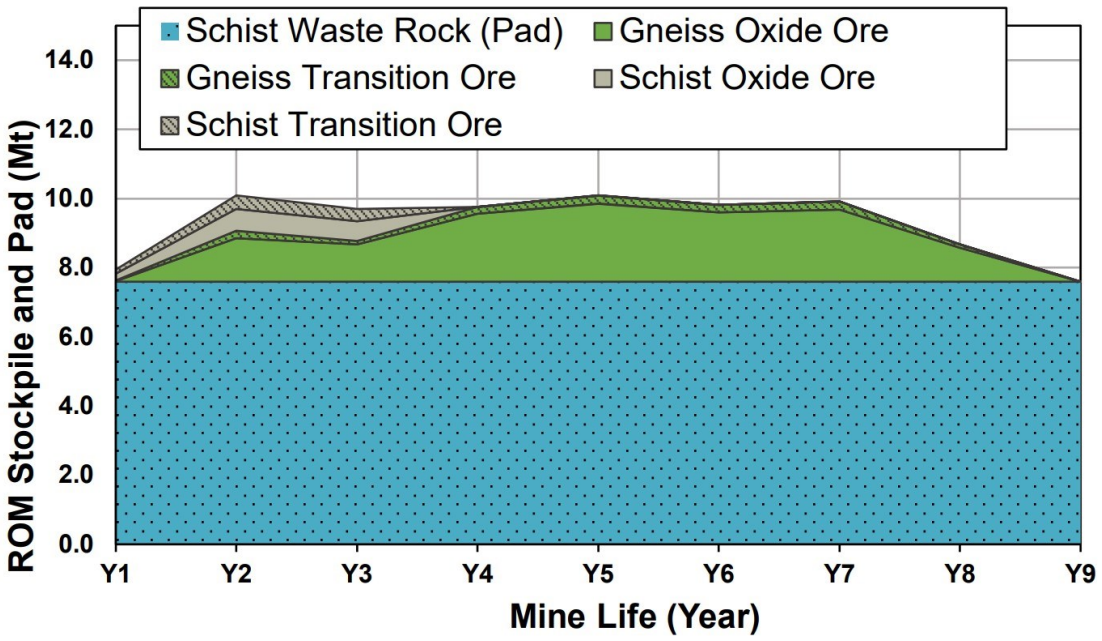

Figure 11-2 Mass and Composition of ROM Ore Stockpile and Waste Rock used in Pad Construction

The ROM pad source terms are calculated by upscaling geochemical loading rates from ore unsaturated columns and waste rock field bins to estimate the loading generated from these two components of the facility. The loading rate from ore on the stockpile is calculated using the median and 75th percentile loading rates measured in unsaturated column work.

The annual surplus water of the ROM stockpile is used to convert loading rates to concentrations.

The ROM stockpile source terms are calculated by upscaling kinetic test loading rates. A number of parameters are affected by thermodynamic solubility controls and scaleindependent release mechanisms. Concentrations of As and 226Ra are calculated using the same approach that was applied in Lorax (2018).

Ore stockpiled on the ROM pad will be placed on a pad of schist waste rock. Infiltration of ore contact water through schist waste rock will attenuate a portion of the As and U load associated with the ore material. To quantify this effect, the solubility of As and U parameters is calculated assuming that ROM pad pore water is in contact with schist waste rock prior to discharge. An example of calculated infiltration for the ore stockpile, waste rock pad, and Rom Pad which combines the two source terms is shown for two conservative parameters (SO4 and Zn) and two non-conservative parameters (As and U) in Table 11-4.

Table 11-4 Example of Infiltration Chemistry Calculated for the Ore Stockpile, Waste Rock Pad and Combined Source Term for Y2 Base Case Scenario.

	SO_4	As	U	Zn
	mg/L	mg/L	mg/L	mg/L
Ore Stockpile Component	159	0.151	0.055	0.014
Waste Rock Component	146	0.002	0.021	0.015
Combined Source Term	305	0.018	0.024	0.029

11.2.4 Haul Roads

Haul roads will be constructed from ROM waste rock and represent a potential source of geochemical loading. The significance of the geochemical loading associated with haul roads will in large part depend on the ML/ARD screening criteria used to select construction material. For the purpose of source term calculation, it is assumed that no screening protocols are in place, and that the haul roads are constructed with gneiss waste rock, which represents the dominant waste rock type produced by the mine. The length of out-of-pit haul roads connecting mine facilities is available for the end of mine life.

The length of haul roads in the Halfway Creek, Latte Creek and YT24 catchments are shown in Table 11-5. It is assumed that the length and distribution of haul roads shown in Table 11-5 are present throughout the Project Operations. Haul roads are assumed to have an average fill thickness of 1.5 m and average width of 12 m.

Table 11-5 Length of Haul Roads at End of Operations by Catchment

Scaling Factors	Haul Road Length (km)
Latte Catchment	0.89
Halfway Catchment	13.6
YT-24 Catchment	0.69

Haul roads will be constructed primarily with waste rock. The lithology of waste rock that will be used in haul road construction is not yet defined. For the purpose of source term calculation, it is assumed that haul roads are constructed entirely of gneiss waste rock. This is the dominant rock type (~80%) of waste rock that will be produced over mine life. In the base case scenario, the loading rate assigned to haul road construction material is weighted based on the relative proportion of gneiss oxide, gneiss transition, and gneiss fresh waste rock that will be produced over mine life (13% oxide, 56% transition and 31% fresh).

Roads will be constructed using gravel and sand particle size fraction of waste rock. Only the relatively fine grain size fraction will be used for road construction, with boulders and cobbles being excluded.

11.2.5 Active and Passive Treated Heap Leach Solution Source Terms

A cyanide heap leaching facility is planned for extraction and recovery of Au from oxide and transition ore. Ore will be leached with lime buffered sodium cyanide (NaCN) solution applied with drip emitters. The leach solution will drain into collection pipes that will direct the gold-bearing solution to the process plant where precious metals will be recovered. The resulting barren solution will be amended with additional lime and NaCN as required and then recirculated to the heap to continue the leaching cycle.

The HLF will be constructed in stages and gold recovery from certain areas of the pad will be completed while other areas are undergoing leaching. For those areas where leaching is completed, progressive reclamation will be able to commence.

During operations and early closure, discharge of any excess HLF solution will undergo active treatment prior to release to the Alpha Pond and ultimately, Halfway Creek. Active treatment will consist of a two-step process, where cyanides (CN) is first destroyed by hydrogen peroxide (H_2O_2) and then residual nitrate, sulphate, metalloids, and metals are treated with a biological system termed the Electrochemical Biological Reactor (EBR) system.

Once active treatment is terminated and closure of the HLF is completed and stabilized, it may be necessary to direct residual HLF seepage waters through the events ponds converted to passive systems prior to discharge to Halfway Creek. Conceptually, the passive treatment system (PTS) would target, primarily, the reduction of nitrate, arsenic, and uranium concentrations in HLF drainage using a matrix of zero valent iron, coarse organic composted wood chips and suitable geologic material; other potential contaminants of concern could also be treated with this system.

11.2.6 Leach Tailings

Leach tailings will be generated when ore placed in the HLF is mixed with lime (CaO) and irrigated with NaCN solution which will change the character of metal leaching by raising pore water pH and by the formation of CN-metal complexes. At the end of mine life, the HLF will be rinsed to remove residual CN from HLF pore water. Lime that remains in the HLF will eventually be rinsed or re-precipitate as calcite, resulting in a decline in pH from the alkaline values required to support CN stability to more neutral values. The goal of this geochemical characterization test work is to describe HLF drainage at the end of mine life and in the long term after rinsing and detoxification is complete.

Leach tailings have a lower ARD potential compared to ore due to the increased NP from lime that is added to maintain CN stability. Geochemical test work completed for tailings samples are consistent with results for ore (and waste rock), whereby tailings samples derived from granite ore have a lower NP content and, therefore, a greater potential to be PAG. Elements of potential concern from the HLF process water include Sb, As, Cr, Cu, Hg and possibly Cd and Zn from each of the ore units, sulphate and Se from the schist unit, and U from the granite and gneiss units. Metal solubility in process solution is supported by the high pH (>9.8) and presence of CN.

Kinetic testing on leach tailings sampled produced from metallurgical testing showed an immediate decline in pH from rinsing of residual lime, with pH values stabilizing at slightly alkaline values.

The mineralogy of leach tailings is expected to be generally similar to that of ore. During the CN leaching process, some water-soluble minerals, such as sulphates (i.e., gypsum) or other secondary oxidation

products (i.e., oxides) may be rinsed from particle surfaces. The addition of lime may also result in the precipitation of secondary oxides and carbonates.

11.3 Source Term Calculations

Geochemical source terms are calculated by upscaling kinetic test geochemical loading rates to reflect site conditions. The scaled loading rates are then applied to incorporate the mass, footprint, hydrology and rock types present in a given mine facility. Solubility controls are then derived for certain parameters that are not expected to behave conservatively in the geochemical conditions of a given mine waste environment. These solubility controls are based on a combination of first principles, thermodynamic equilibrium, and experimental data or field monitoring data. Overall, the approach to source term calculation is consistent with what has been done in past iterations of source term developments for the Coffee Gold Mine Project.

A variety of updates have been made to source term model inputs in the current source term iteration. These updates include kinetic test results; solubility controls; and assumptions regarding release of a geochemical load from saturated waste rock and pit wall. Updated kinetic test results are used to update loading rates and estimate metal release from sub-aqueously stored mine rock. The updated kinetic test results are shown in Appendix J. Solubility calculations have been updated to incorporate the geochemical modelling program PHREEQC to calculate solubility constraints for surface sorption of U to Fe-oxide mineral surfaces, and mineral solubility controls for certain major ions (Ca, Mg and P). More details on the Source Term Calculation results can be found in Appendix J.

Major ion loading rates are predicted based on geochemical test results for metallurgical columns and leach tailings kinetic tests. Metallurgical column and leach tailings kinetic testing samples used in source term development are shown in Table 11-6. Data for solubility constraints are generated from empirical observations of analogue mines described above or using the geochemical modelling program PHREEQC coupled to the llnl.dat database.

Table 11-6 Metallurgical Columns and Kinetic Test

Lithology	Weathering	Met Columns	Kinetic Tests
		Head ID (*Column IDs*)	**Column ID (*Composition*)**
Schist	Oxide	72133 (*73001*), 72136 (*72153, 72156*)	Column 15 (*100% Schist*)
Schist	Transition	72137 (*72759, 72162*), 72138 (*72165, 72168*)	
Granite	Oxide	72139 (*72717, 72174*)	Column 17 (*90% Gneiss, 10% Granite*)
Granite	Transition	72177 (*72177, 72180*)	
Gneiss	Oxide	72134 (*73004*), 72142 (*73010, 73013, 73007*), 72143 (*73019, 73022, 73016*), 72144 (*73025, 73028*), 72145 (*73031, 73034*)	
Gneiss	Transition	72146 (*73037, 73040*)	

The major ions SO4, Na and Cl are modeled to behave conservatively and accumulate in the process solution during operations. Two types of loading are used to predict these concentrations; a water-soluble load that will be released shortly after ore is stacked on the heap and irrigated with process solution; and a kinetic weathering rate representing gradual release of major ions from primary minerals in the spent leach tailings.

EXECUTIVE SUMMARY

Tetra Tech EBA Inc. (Tetra Tech EBA) was retained by Kaminak Gold Corporation (Kaminak) to provide surficial geology, permafrost, terrain, and soils baseline information for the Coffee Gold Project, in preparation for submission of an Environmental Assessment to the Yukon Environmental and Socio-Economic Assessment Board (YESAB).

This report presents summary background information, methods, and results for baseline conditions for the purposes of an environmental assessment. The baseline conditions covered include surficial geology, physiography, permafrost, and terrain stability studies conducted for the Coffee Gold Project from 2011 to 2016. These baseline studies provide important input for the Effects Assessment portion of the Environmental Assessment. The soils portion of the report will be submitted under separate cover.

The study area for this baseline report encompasses the conceptual Coffee mine development area (the mine site study area), as it was proposed at the time of writing. The mine site study area is situated on the divide between the headwaters of Latte Creek and Halfway Creek, in the northern Dawson Range.

First, a literature review was completed to summarize the known conditions at site to date. It shows that the area has not been glaciated, resulting in a landscape consisting of rounded ridges separated by deep, V-shaped valleys. Climate is characterized by warm, short summers and long, cold winters. Weathered bedrock, colluvium derived from weathered bedrock and loess, and fluvial deposits are found in the mine site study area, but colluvial deposits are by far the most common. These deposits are affected by gullying, cryoturbation, solifluction, permafrost processes, periglacial processes, landslides, and snow avalanches. The mine site study area is located within the zone of extensive discontinuous permafrost. Permafrost is most common on north-facing slopes with thick organic cover and in colluvial apron/muck deposits located on lower slopes and at valley bottoms. South-facing slopes are typically permafrost-free. Permafrost-related processes include cryoturbation, solifluction, active layer detachments, slope creep, frost heave, and thermal erosion. Open-system pingos are present locally.

Since 2011, ten field investigation programs have been completed for the baseline studies. These include soils, hydrogeology, permafrost, and geotechnical studies. Drilling, instrument installation in boreholes, testpitting, ground investigations on foot, and helicopter flyovers were all included in these studies.

Evaluations of surficial geology, permafrost, and terrain stability were undertaken for this report. The first two used PurVIEW software for the analysis, while the latter used PurVIEW and DAT/EM Summit Lite software. The desktop mapping draws heavily on the data supplied by the many field investigations; these were used as ground-truthing points for the mapping.

Various permafrost maps, a map of the surficial geology of the mine site, terrain maps, and terrain stability/hazard maps were generated from these studies; these are included at the end of this report. Geohazards and organic soil surface layers were also described.

Results from this study conclude that colluvium is indeed pervasive, and that ridge tops may have exposed weathered bedrock, some of which form tors. Colluvium is dominated by silt and sand, but also contains angular pebbles, cobbles, and boulders. Organic material interbedded with the colluvium at a few sites shows that downslope creep or possibly sliding of some colluvial deposits may be fairly recent (Holocene in age). Thin fluvial deposits consisting of gravelly silt are found in the narrow valley bottoms and a few fluvial fans are present at the mouths of small tributary valleys. Organic deposits are rare; they are found in the Latte Creek valley and overlying colluvial apron/muck deposits at the base of some slopes.

The only rare landforms in the mine site study area are tors and one collapsed open-system pingo.

Permafrost distribution determined from the mapping shows that approximately 62% of the mine site study area is underlain by permafrost. Permafrost thicknesses range from approximately 30 m to 165 m. The active layer is highly variable: it is usually thin (approximately 0.3 m to 0.6 m), but it can be several metres thick in bedrock areas or where coarse surficial sediments are present. Ground temperatures range from close to 0ºC to approximately -2ºC, indicating warm permafrost conditions. Ground containing permafrost is therefore sensitive to disturbance. Ground ice has been classified as non-visible, visible, or forming significant accumulations, such as massive ice bodies, although the latter is rare. The spatial distribution of these across the mine site was determined to be 34% for ice-poor permafrost with non-visible ice; 27% for permafrost with visible excess ice; and 1% for very ice-rich permafrost, which is mainly found at the bottom of the Latte Creek valley.

Five terrain stability classes (stable; generally stable; generally stable with minor instability; potentially unstable; and unstable) were mapped by Palmer Environmental Consulting Group (PECG) within the mine site. These classes were differentiated for both the existing and disturbed condition because of the complexity of the permafrost terrain in the mine site study area. The “existing terrain stability” class represents current conditions, in the absence of any project-related activity; whereas the “disturbed terrain stability” class represents conditions following disturbance to ground conditions from exploration activities and road/mine facility construction without mitigation. This format of mapping, in PECG’s opinion (Appendix B), distinguishes natural hazards, which may be triggered by occurrences such as wildfire, from those potentially exacerbated or initiated by project-related disturbance.

Calculations of the areas occupied by each of the five terrain stability classes using ArcGIS technology show that prior to the proposed construction activities (existing undisturbed terrain) the majority (approximately 78%) of the mine site study area has an existing terrain stability class of “generally stable” (Class II). Approximately 15% is considered “generally stable with isolated minor instability” (Class III). Approximately 1% of the mine site study area is considered “potentially unstable” (Class IV) and approximately 6% - “unstable” (Class V).

According to the disturbed terrain stability class, the proportion of terrain stability polygons in the mine site study area with a “generally stable” (Class II) rating drops from 78% to 27% (disturbed). The majority (approximately 42%) becomes “generally stable with isolated minor instability” (Class III). Approximately 24% of the mine site study area becomes “potentially unstable” (Class IV) and approximately 7% - “unstable” (Class V).

Various hazards were identified and described by magnitude, frequency, and considerations for mitigation of each. These include rockfall, debris slides, rock creep, gullying, solifluction, thermokarst, and slopewash. The various geohazards within each proposed infrastructure footprint were also described.

Finally, the organic surface soil was described. It is generally 0.2 m thick, but is slightly thinner on ridge tops, and is thicker in areas of non-visible ground ice or areas of very ice-rich permafrost. Organic silt is most common on north-facing slopes and is found only in areas of visible or non-visible ground ice. The presence of silt within the organics may be caused by a combination of more active slope creep in permafrost areas, cryoturbation or loess capture by permafrost-bearing units, which are wetter in summer.

GLOSSARY OF TERMS

Term	Definition
Active Layer	The top layer of ground above the permafrost table that is subject to annual thawing and freezing.
Active Layer Detachment	Shallow slope failure in which the thawed or thawing active layer and vegetation mat detach from the underlying frozen material. Common on colluvial slopes in areas of fine-grained, ice-rich deposits.
Apron	Coalesced fans which occur at foot of bluffs, escarpments, or steep slopes. They are formed by materials transported from the steeper slope and form wedge-shaped deposits with concave to planar surfaces. Deposition of materials typically occurs during extreme storm or runoff events.
Blanket	A mantle of surficial materials thicker than about 1 metre, which reflects the topography of the bedrock or older surficial materials upon which it rests, although minor details of the topography may be masked.
Colluvial Deposits/Colluvium	Materials deposited as a result of downslope movements due to gravity, such as rockfall, soil creep, and debris flows, including talus slopes and mantles of weathered bedrock. Colluvial deposits are composed of rock fragments of all sizes derived from the local bedrock and reworked loess, as well as finer textured material derived from in place weathering of the rock fragments. These deposits are generally poorly sorted and poorly consolidated.
Creep	The imperceptibly slow downward movement of soil or rock on slopes or slow deformation of frozen ground; caused by gravity or long-term application of a stress too small to produce failure in the frozen material.
Cryoplanation	Alteration by intense frost action that effectively reduces slope steepness and lowers mountain and hill peaks, modifying landscapes into cryoplanation terraces, i.e. step-like benches cut in bedrock.
Cryoturbation	Heaving, churning, and sorting of soil and surficial materials due to repeated freezing and thawing; results in the development of convoluted and flame-like structures in the soil and patterned ground.
Debris Flow	A sudden and destructive landslide where loose material on a slope, with more than 50% of particles larger than sand size, is mobilized by saturation and flows down a channel or canyon. The flow contains a combination of or all of the following: soil, surficial materials, bedrock, and plant material. Whether saturated or dry, a debris flow behaves much like a viscous fluid when moving.
Debris Slide	A shallow slide consisting of a mass of soil, vegetation, and surficial material; initial displacement is along one or several surfaces of rupture. Composed of comparatively dry and largely unconsolidated surficial material and results in an irregular, hummocky deposit.
Dendritic	Surface drainage pattern where streams branch out in an irregular tree-like fashion.
Depth of Zero Annual Amplitude	The distance from the ground surface downward to the level beneath which there is practically no annual fluctuation in ground temperature.

Eolian	Well sorted materials, predominantly silt and fine to medium sand, which have been eroded, transported, and deposited by wind.
Excess Ice	The volume of ice in the ground, which exceeds the total pore volume that the ground would have under natural unfrozen conditions.
Felsenmeer	An accumulation of angular boulders on a level or gently sloping surface, comprising local rocks broken up by frost action, generally located in high altitude or high latitude regions.
Fluvial Deposits	Sediments transported and deposited by streams and rivers, including floodplain deposits, river terraces, and fluvial fans. “Alluvial” is an older term meaning the same.
Fluvial Fan	A fan-shaped deposit built by streams, usually located at the mouth of a tributary valley. The sediment flows start at the apex of the fan, and over time move to occupy many positions on the fan surface. Sediments generally consist of sand and gravel, and are formed by a combination of stream flood and debris flow activity. Fluvial fans typically have gradients of less than 10%.
Friable Permafrost	Permafrost in which the soil particles are not held together by ice; the material is easily broken up under light to moderate finger pressure.
Frost Action	The process of alternate freezing and thawing of moisture in soil, rock, and other materials, and the resulting effects on materials, and on structures placed on, or in, the ground.
Frost Heave	The upward or outward movement of the ground surface (or objects on, or in, the ground) caused by the formation of ice in the soil.
Glaciofluvial Deposits	Sediments formed by meltwater issuing from, or within, a glacier. The deposits are stratified and may form outwash plains, or terraces.
Ground Ice	Ice in pores, cracks, and other openings in surface sediments or rock, which forms in permafrost terrain. A general term referring to all types of ice formed in freezing or frozen ground.
Ice Wedge	A massive, generally wedge-shaped body of ground ice with its apex pointing downward, composed of foliated or vertically banded, commonly white, ice; forms in permafrost environments.
Loess	A homogeneous massive deposit formed by wind consisting mainly of silt. Loess sediment sources include glaciofluvial and glaciolacustrine deposits or fine-grained colluvium.
Muskeg	A North American term frequently used for peatlands. The word is of Algonquin Indian origin and is applied in ordinary speech to natural and undisturbed areas covered more or less with *Sphagnum* mosses, tussocky sedges, and an open growth of scrubby trees. (The terms peatland and muskeg are commonly used interchangeably).
Peat	Unconsolidated compressible material consisting largely of undecomposed, or slightly decomposed, organic matter accumulated under water-saturated conditions. Peat is commonly formed by the slow decay of successive layers of aquatic and semi-aquatic plants in swampy or water-logged areas, where oxygen is absent.

Periglacial	Pertaining to cold climates, in proximity to the margin of a continental ice sheet, such as in arctic and alpine areas, where frost action is an important feature.
Permafrost	Ground (soil or rock) that remains at or below 0ºC for at least two years.
Pingo	A large perennial frost mound consisting of a core of massive ice, formed primarily by injection of water, and covered with soil and vegetation. Pingos occur in the zones of continuous and discontinuous permafrost. There are two varieties of pingos: closed-system and open-system.
Pingo, Closed-System	A pingo formed by doming of frozen ground due to freezing of injected water supplied by expulsion of pore water during permafrost growth. Found mainly in the zone of continuous permafrost, in flat, poorly-drained terrain.
Pingo, Collapsed	A pingo remnant represented by a low or arcuate ridge of material resulting from the slumping of the sides of the pingo during thawing. The former centre is marked by a depression which may be filled with water.
Pingo, Open-System	A pingo formed by doming of frozen ground due to freezing of injected water supplied by groundwater moving downslope through taliks to the site of the pingo, where it moves towards the surface. Found mainly in the zone of discontinuous permafrost, in areas of marked relief.
Rockfall	The process, associated sediments or resultant landform characterized by very rapid downslope movement of newly detached pieces of bedrock that fall freely from a cliff or cascade down a steep slope.
Rotational Slide	The process, associated sediments or resultant landforms characterized by an extremely slow to moderately rapid landslide, in which movement occurs along a well-defined, spoon-shaped shear surface; produces a backward rotation of the displaced block or blocks; sometimes referred to as a slump.
Segregated Ice	Ice in discrete layers or ice lenses, formed by ice segregation; commonly occurs in alternating layers of ice and soil. Segregated ice layers can range from hairline to more than 10 m in thickness.
Solifluction	Slow downslope movement of saturated unfrozen (in non-permafrost regions) or thawed (associated with frozen ground) earth materials across a frozen (in permafrost regions) or otherwise impermeable substrate.
Talik	A layer or body of unfrozen ground in a permafrost area.
Thermal Erosion	The general process whereby frozen soils thaw and then are removed by moving water or remain in place in waterlogged conditions.
Tor	A high, isolated pinnacle, or rocky peak; or a pile of rocks, heavily jointed and usually granitic, exposed to intense weathering, and often assuming peculiar shapes.
Veneer	A cover of surficial material with a thickness less than 1 metre.
Well-Bonded	A condition in which soil particles are strongly held together by ice, so that the frozen soil possesses relatively high resistance to chipping or breaking.

CONFIDENTIALITY STATEMENT

LIMITATIONS OF REPORT

This report and its contents are intended for the sole use of Kaminak Gold Corporation and their agents. Tetra Tech EBA Inc. (Tetra Tech EBA) does not accept any responsibility for the accuracy of any of the data, the analysis, or the recommendations contained or referenced in the report when the report is used or relied upon by any Party other than Kaminak Gold Corporation, or for any Project other than the proposed development at the subject site. Any such unauthorized use of this report is at the sole risk of the user. Use of this report is subject to the terms and conditions stated in Tetra Tech EBA's Services Agreement. Tetra Tech EBA's General Conditions are provided in Appendix A of this report.

1.0 INTRODUCTION

Tetra Tech EBA Inc. (Tetra Tech EBA) was retained by Kaminak Gold Corporation (Kaminak) to provide surficial geology, permafrost, terrain, and soils baseline information for the Coffee Gold Project, in preparation for submission of an Environmental Assessment to the Yukon Environmental and Socio-Economic Assessment Board (YESAB).

This report presents summary background information, methods, and results for the baseline physiography, surficial geology, permafrost, and terrain stability studies conducted for the Coffee Gold Project from 2011 to 2016. The soils portion of the report will be submitted under separate cover.

The baseline study provides important input for the Effects Assessment portion of the Environmental Assessment. The study area for this baseline report encompasses the proposed Coffee mine development area (the mine site study area), and is shown in Figure 1. The mine site study area is situated on the divide between the headwaters of the Latte Creek and the Halfway Creek, in the northern Dawson Range, and has a slightly different extent than the study area used for the terrain stability study by Palmer Environmental Consulting Group Inc. (PECG Appendix B).

Work completed for the baseline report for the proposed access road is outside the scope of this study.

2.0 METHODS

2.1 Literature Review

A literature review was undertaken to summarize existing information on surficial geology, permafrost, physiography, and terrain stability for the mine site study area. Surficial geology maps, unpublished reports, and published journal articles were reviewed to determine general information for the area, as it was known at the time of this study. Maps and other documents are referenced accordingly within the Literature Review section.

2.2 Previous Field Programs

Ten field investigation programs have been completed for the baseline study since 2011. These are described below.

Ground Truthing Program (AECOM, August 2011)

Results of the soils field investigations conducted within the mine site study area in August 2011 (AECOM 2012) were used to confirm surficial geology and permafrost mapping, where possible.

Hydrogeological Field Program (Tetra Tech EBA, Fall 2013)

This first hydrogeological field program (Tetra Tech EBA 2014) consisted of installing four single-point vibrating wire piezometers (VWPs) in NQ2-sized boreholes to collect hydraulic testing and ground temperature data. This information was referred to while compiling the permafrost map of the mine site study area.

Hydrogeological Drilling Program (Lorax, August-September 2014)

The 2014 hydrogeological drilling program was implemented within upland areas in and around proposed pits and the formerly proposed valley-fill Heap Leach Facility (HLF) footprint. This data was mainly used to confirm surficial geology mapping, permafrost mapping, and soil texture.

Geotechnical Field Program (Knight Piesold, August-September 2014)

This geotechnical field investigation (Knight Piesold 2015) was conducted in the formerly proposed valley-fill HLF footprint area. The investigation comprised a combination of test pits and borings to assess shallow and deeper subsurface conditions. This information aided with the compilation of the permafrost map of the mine site study area.

Hydrogeological Drilling Program (Lorax, March 2015)

This hydrogeological field investigation consisted of drilling vertical boreholes and installing thermistor and VWP strings downgradient of the proposed North and South Waste Rock Storage Facilities (WRSF). This information aided with the compilation of the permafrost map.

Geotechnical Field Investigation Sonic Drilling Program (SRK, April 2015)

The April 2015 geotechnical investigation included field and laboratory tests to characterize the proposed waste rock dump, HLF pad, and plant site footprints. This data was mainly used to confirm surficial geology, permafrost mapping, and soil texture.

Hydrogeological Drilling Program (Lorax, April-June 2015)

The hydrogeological investigation consisted of drilling vertical and angled boreholes and installing thermistor and VWP strings. This information aided with the compilation of the permafrost map.

Geotechnical Field Investigation Supplementary Test Pitting Program (SRK, June-July 2015)

The June 2015 supplementary test pitting program confirmed findings of the sonic drilling program and provided additional bulk samples for laboratory testing and analyses. This data was mainly used to confirm surficial geology, permafrost mapping, and soil texture.

Terrain Stability Field Investigation (PECG, August 2015)

The August 2015 field investigation focused on the terrain stability of the mine site study area, albeit with slightly different study area boundaries. The investigation included documenting terrain characteristics, permafrost, and drainage conditions. Observations regarding permafrost conditions and terrain hazards were also recorded.

Geotechnical Site Reconnaissance Program (Tetra Tech EBA, September 2015)

The Tetra Tech EBA field program is described in detail in Section 2.4.

2.3 Data Analysis

2.3.1 Surficial Geology Mapping

Mapping of surficial geology was completed using PurVIEW software, which is an add-on to ArcGIS. PurVIEW is a 3D mapping tool that allows stereo pair air photos to be viewed on a computer screen with 3D glasses. High-resolution digital images provided by Kaminak were loaded into PurVIEW and analyzed. Polygons, lines, and point symbols were mapped in ArcGIS/PurVIEW and map figures were created in ArcGIS.

Surficial geology was mapped (Figures 2a to 2f) according to the Yukon Digital Surficial Geology Compilation and Terrain Classification System (YG 2016). However, only the surficial units and expressions (e.g. colluvial veneer)

were mapped for simplicity, as requested by Kaminak. Textures of the materials were recorded only for mapped polygons in which ground data describing soil texture was available.

A number of additional data sources were used to confirm mapping for this study and to determine sediment texture for applicable portions of the mapped area. These include:

- Borehole data (KP 2015), (Lorax 2016), and (SRK 2016a);
- Terrain field data supplied by PECG;
- Soils field data supplied by AECOM (2012); and
- Terrain field data collected by Tetra Tech EBA during field reconnaissance for permafrost studies.

The above field site and borehole locations were loaded into ArcGIS and were referred to while mapping.

2.4 Permafrost Mapping

Reconnaissance of permafrost conditions in the mine site study area was completed between September 5 and September 8, 2015, by Vladislav E. Roujanski, Ph.D., P. Geol., of Tetra Tech EBA and Chalsie Warren of Kaminak. Fieldwork involved measurement of active layer thickness with a permafrost probe, hand-dug testpit excavation, and acquisition of georeferenced field photographs of terrain features indicative of various permafrost conditions. Some areas were accessed by pickup truck, while others were accessed by helicopter or on foot. Several helicopter overview flights were also completed.

Permafrost and related geohazard mapping within the mine site study area was carried out by Vladislav E. Roujanski and Shirley McCuaig, Ph.D., P. Geol. in November-December 2015, and was subsequently updated in February 2016 as new data became available. Digital colour air photos covering the mine site study area were acquired by Kaminak in August 2011 at a nominal scale of 1:20,000. These were provided to Tetra Tech EBA in November 2015 and were used to generate 3D digital models of the landscape in PurVIEW. Permafrost mapping was initially carried out at 1:20,000 scale, based on stereoscopic interpretation (using a Sokkia MS27 stereoscope) of the colour air photo printouts. The permafrost distribution linework was then refined using the PurVIEW system. This software allowed the mappers to zoom in and out of the 3D air photos, which increased mapping accuracy. The PurVIEW-based mapping was done at 1:5,000 to 1:20,000 scale, but is presented in this report at a scale of 1:20,000.

Permafrost terrain units (map polygons) were delineated according to geobotanical indicators, e.g. stunted black spruce stands on shallow permafrost vs. deciduous (dominantly aspen) stands on unfrozen soils, slope aspect (north-facing vs. south-facing slopes), and extrapolated surface appearance (texture, colour, hue etc.). Where possible, mapped permafrost conditions were confirmed by ground temperature measurements acquired from thermistor-instrumented boreholes. In addition, intrusive exploration data and detailed ground/soil/terrain/ permafrost observation site logs were used to inform the mapping, as described in Section 2.3.1. Limited ground temperature data, frozen soil condition information, and other relevant data contained therein were useful data points for the permafrost mapping effort.

Hazardous permafrost-related geomorphic processes and landforms that may pose a challenge to mine site construction and operations were mapped as point and line symbols.

Two versions of the permafrost map were compiled (Figures 3a to 3d): one with permafrost polygons colour-coded according to ground ice occurrence in perennially frozen ground (Figure 3a) and one with transparent labelled polygons overlaid on the orthophotographs (Figure 3b). Figure 3c shows the mine facility layout plan overlaid on

Figure 3b. Figure 3d shows the as-drilled borehole locations along with the mine facility footprints and permafrost distribution.

2.5 Terrain, Terrain Stability and Hazard Mapping

The terrain, terrain stability, and hazard mapping was completed by PECG and the results are summarized in a report dated March 19, 2016. This work is included as Appendix B of this report; the map figures have been edited to include only those that pertain to the mine site study area.

The work completed by PECG included the following tasks:

- Background review and consultation;
- Field investigation;
- Terrain and terrain stability mapping;
- Hazard identification; and
- Assessment of soil erosion potential[1].

Terrain, terrain stability, and geohazard methods described by PECG are summarized below.

2.5.1 Background review and consultation

PECG reviewed aerial photography, LiDAR-derived elevation data, satellite imagery, surficial and geomorphological mapping, previous investigations, and peer-reviewed literature. They also consulted with senior members of the Yukon Geological Survey (YGS) regarding their field experience with the paleo-landslides in the area and members of Yukon Highways to discuss mass movement and icing hazards in the mine site study area.

2.5.2 Field Investigation

A field investigation was completed in August 2015. There were at least 15 sites investigated within the PECG mine site study area, including both helicopter reconnaissance and detailed ground investigations. Site characteristics, terrain characteristics and hazards, drainage conditions, permafrost conditions, and vegetation were recorded at each site. Hand-dug soil pits were used to examine subsurface materials and the active layer thickness was determined by making a minimum of five frost-probing measurements at each ground investigation site.

2.5.3 Terrain and Terrain Stability Mapping

The terrain and terrain stability mapping was completed in accordance with YESAB's mapping requirements (Guthrie and Cuervo 2015). However, the terrain stability classes were modified to include disturbances that may result from thermokarst processes and have been tailored to consider the presence or absence of warm permafrost with variable ground ice content (not to be confused with "existing" and "disturbed" terrain stability classes).

Terrain mapping was completed by dividing the terrain into polygons according to surficial materials, landform characteristics, and geomorphological processes. Each polygon was assessed to be stable, potentially unstable, or unstable. The terrain maps of the mine site study area are provided in Appendix B (Map 1).

[1] Soil erosion potential will be discussed in the Soils portion of this Environmental Assessment.

The delineation of the polygons was completed using either PurVIEW or DAT/EM Summit Lite software with digital air photos having a scale of 1:10,000. Photos having a scale of 1:2,500 were used when additional details were required. The polygons were delineated based on eight attributes: surficial material, surface expression, texture, geomorphological process, and drainage class, depth to permafrost, ice content, and slope class.

Additional point or linear features, such as thermokarst ponds or slope failures that are too small to be mapped as polygons are identified with point and line symbols.

The terrain stability maps were compiled with the aid of AECOM's (2012) geomorphological maps.

PECG assessed terrain stability both before and after disturbance ("existing" and "disturbed" classes) to provide design engineers with all potential hazard information in the area of development, particularly as the mine site study area is characterized by extensive discontinuous permafrost.

2.5.4 Hazard Identification

Terrain polygons were categorized by the dominant hazard type to depict the nature of the hazard governing the terrain stability class of each polygon. Three categories were used to classify the stability class of each polygon:

i. Slope failure potential is dominant;

ii. Thermokarst potential is dominant; or

iii. Slope failure and thermokarst potential are co-dominant.

2.6 Organic Soils Analysis

The organic surface layer analysis was completed by reviewing borehole logs recorded in Lorax (2016) and SRK (2016a). The thickness and composition of organic cover at each borehole was summarized and uploaded to an ArcGIS database. A topographic map was created in ArcGIS and the organic thicknesses labelled for each borehole, but it was not necessary to present this map as a figure in this report.

The organic thickness map was reviewed to determine if elevation or aspect had any effect on the amount or type of organic material present on the ground surface within the mine site study area. The surficial geology/permafrost map was also reviewed in the context of the organic soil thicknesses to check for relationships to sediment type and ground ice content.

3.0 RESULTS

The following sections begin with the literature review, and then present results for surficial geology and permafrost mapping completed by Tetra Tech EBA, followed by a summary of the terrain and terrain stability mapping completed by PECG (full report is provided in Appendix B).

3.1 Literature Review

3.1.1 Physiography and Climate

The mine site study area is located within the Klondike Plateau physiographic region. The Klondike Plateau is a Tertiary-age upland that has undergone variable uplift and stream dissection, resulting in rounded summits and ridges, and deep V-shaped valleys hosting **dendritic** streams (Mathews 1986; Huscroft 2002). Most valley sides exhibit convex profiles (Photo 1), with concave profiles restricted to localized bench or gully features and valley bottoms filled with material derived from upslope erosion (PECG Appendix B). The mine site study area, which is

situated within the Coffee Creek and Yukon River watershed, was not glaciated during the last Wisconsin glaciation (Duk-Rodkin 1999) and has since been modified by frost action and permafrost-related processes.

Photo 1: Latte Creek valley exhibiting convex valley slopes, looking east. Sparse stunted black spruce on the north-facing slope (on right side of photo) is indicative of shallow ice-rich permafrost; whereas the south-facing slope (left side), covered with moderately dense aspen and aspen/white spruce mixed forest, is predominantly permafrost-free.

There is little traditional knowledge related to terrain in the region: most traditional uses pertain only to topography. Trails used by First Nation groups tend to be located on gently sloping or flat “easy passage” areas, such as ridge tops and valley bottoms. Some high elevation areas are used as lookouts.

The climate of the Klondike Plateau is continental: it is characterized by warm, short summers and long, cold winters. Mean annual air temperature is near -5ºC, mean January temperatures range from -23ºC to -32ºC and mean July temperatures from 10ºC to 15ºC (Yukon Ecoregions Working Group 2004). Strong thermal inversions are common from December to February, in association with prolonged atmospheric stability (Williams 1995). During this period, air temperatures on valley bottoms can be tens of degrees lower than surrounding higher-elevation areas (PECG Appendix B). Mean annual precipitation ranges from about 300 mm to 500 mm, giving the region a semi-arid classification (Yukon Ecoregions Working Group 2004). The wettest period occurs in summer, when most precipitation falls as rain during convective rain showers and thunderstorms (PECG Appendix B).

3.1.2 Surficial Geology

Although the mine site and most of its access road fall within the unglaciated portion of the Yukon, glaciers occupied the Stewart River valley to the north and a few small glaciers were present east and west of the mine site study area in Pliocene to early Pleistocene time (3 million to 1.8 million years ago) (Duk-Rodkin 1999). Glacial Lake Yukon was dammed by this ice sheet (Duk-Rodkin 1996).

The lack of glaciation in the mine site study area means that the area has experienced a significant period of weathering. Surficial deposits comprise weathered bedrock, **colluvium** derived from weathered bedrock and **loess**, and **fluvial** deposits (Huscroft 2002; AECOM 2012). Colluvium is expected to be coarser grained on steeper slopes, while colluvial aprons on lower slopes commonly include ice-rich resedimented loess and **peat** (informally called "muck" when taken together) (Huscroft 2002; McKenna and Lipovsky 2014). Colluvial deposits dominate high elevation areas and valley slopes, while fluvial deposits are found in valley bottoms. These deposits may be affected by gullying, **cryoturbation**, **solifluction**, permafrost processes, **periglacial** processes, landslides, and snow avalanches (AECOM 2012; McKenna and Lipovsky 2014; KP 2015).

Weathered bedrock is exposed on several ridge tops in the mine site study area; it locally exhibits **cryoplanation** terraces or granitic **tors** (Huscroft 2002; AECOM 2012). Weathered bedrock consists of fractured and jointed bedrock exposures covered with less than 1 m of **felsenmeer** or residual soil, which commonly forms a yellowish sand consisting of quartz, feldspar, plagioclase, biotite, and hornblende derived from the disintegration of the Coffee Creek granite (AECOM 2012; KP 2015). Bedrock terraces are present in some valley bottoms and bedrock is exposed in a few valleys where it has been cut by stream erosion (AECOM 2012).

Most of the area is covered with colluvium. **Creep, debris slides, rockfall**, and one **rotational slide** have been identified within the mine site study area (AECOM 2012). Colluvial deposits comprise loose, poorly sorted angular gravel, and boulders with a sandy silt to silty sand matrix (KP 2015; SRK 2016a, b). Colluvial apron/muck deposits consist of **eolian** fine sand and silt reworked with organic silt, organic deposits, colluvium, and locally, fluvial fan gravel and sand. The colluvial apron/muck deposits are most common on north-facing lower valley slopes and commonly contain **segregated ice** bodies and buried **ice wedges** (Huscroft 2002). Colluvium thickness is estimated at less than 1 m on ridge tops, less than 1 m to 2 m on valley slopes and up to 10 m on valley bottoms and lower slopes (Huscroft 2002; AECOM 2012; KP 2015; SRK 2016b). Organic soils 0.2 m to 0.3 m thick typically cover the colluvial deposits (SRK 2016b).

Fluvial deposits consist of beds of sand, silt, and organic layers in slow-moving reaches, or gravel and cobbles in faster-moving reaches or underlying the finer-grained units (AECOM 2012; KP 2015). Fluvial deposits may also contain reworked eolian silt and sand (McKenna and Lipovsky 2014).

Eolian deposits formed when parts of the surrounding region were vegetation-free, shortly after the Pliocene-Pleistocene deglaciation and other younger, less extensive glaciations. Fine sand and silt (loess), derived from **glaciofluvial** deposits in the Donjek and White River valleys, has coated the surficial deposits within the mine site area, but has since been eroded, redeposited and reworked (Huscroft 2002; AECOM 2012).

Organic deposits are typically poorly drained due to the presence of permafrost and consist mainly of moss (AECOM 2012).

Numerous boreholes and testpits have been completed within the mine site study area (Lorax 2016; SRK 2016a). These were referenced while mapping and rather than summarizing them here, individual areas of interest are highlighted in the surficial geology descriptions.

3.1.3 Permafrost

The mine site study area is located within the zone of extensive discontinuous permafrost, where 50% to 90% of the area is expected to be perennially frozen (Heginbottom et al. 1995). Locally, permafrost distribution is related to slope aspect, angle and shape, soil texture and moisture, and the presence, thickness, and type of organic cover (Williams 1995; Williams and Burn 1996; PECG Appendix B). Permafrost is most common on north-facing slopes with thick organic cover and within the colluvial apron/muck deposits (Bond and Lipovsky 2011). Steep, well drained, south-facing slopes are invariably permafrost-free (PECG Appendix B).

Although initially permafrost was thought to be thickest on lower slope aprons with northerly aspects and to thin toward ridge tops (AECOM 2012), recent data suggests that permafrost extends to its greatest depths in ridge areas and appears to thin towards areas of lower elevation (Lorax 2016) (with the notable exception of colluvial apron/muck units). Permafrost was found to be 135 m to 165 m thick on Supremo Ridge, with temperatures of approximately -1.1°C at those depths (SRK 2016b). Permafrost depths were 75 m to 83 m below the West WRSF and the toe of the North WRSF (SRK 2016b). Permafrost was absent at two boreholes within the South WRSF (SRK 2016b).

Active layer thickness primarily depends on elevation, aspect, soil texture, drainage, snow pack, vegetation cover, and wildfire history (Williams and Burn 1996; McKillop et al. 2013). The active layer is generally 1 m to 2 m thick within the region encompassing the mine site study area (Yukon Ecoregions Working Group 2004; Bond and Lipovsky 2011), except in areas where vegetation has been stripped, i.e. in road cuts (Lorax 2016). Well drained, coarse-grained soils tend to have a thicker active layer than poorly drained, fine-grained ones (PECG Appendix B). The active layer is suggested to be about 1 m thick in the HLF area (KP 2015). Permafrost temperatures within the mine site study area are measured with thermistor strings installed by Lorax (2016) and SRK (2016a). While most thermistor installations indicate sub-zero temperatures in bedrock, observations of ice in bedrock are limited (Lorax 2016).

The ice content of permafrost across the mine site study area is highly variable. Areas of perennially frozen intact or weathered bedrock and well drained, coarse-grained colluvial mantles generally contain little to no visible ice. Such ice-poor permafrost is common in upland settings, on summits, along ridges and spurs, and on moderate to moderately steep valley sides with convex or straight slopes (PECG Appendix B). Permafrost more commonly contains excess ice in the form of thin seams and lenses in silt-rich colluvial blankets, on solifluction slopes and in inactive portions of fluvial plains. Ice-rich permafrost containing massive ice bodies is most commonly encountered in organic terrain and silt-rich colluvial complexes in fluvial valley bottoms (PECG Appendix B). Lorax (2016) reports on three large bodies of ground ice intercepted between 8 m and 13 m below ground surface in Borehole MW15-01T (Figure 3d, this report). The drill pad was located on a slope classified as poorly drained colluvial veneer modified by solifluction (AECOM 2012). In general, perennially frozen deposits contain visible and non-visible ice, largely in the form of ice crystals, inclusions and/or coatings on soil particles (KP 2015).

Permafrost-related processes and landforms within the mine site study area include cryoturbation, solifluction, **active layer detachments**, slope creep, **frost heave**, and **thermal erosion** (AECOM 2012; McKillop et al. 2013; KP 2015). Open-system **pingos** are present locally, commonly in slope-toe settings of small drainages where groundwater discharges to surface through discontinuities in the permafrost table (Hughes 1969; Bond and Lipovsky 2011; Huscroft 2002; AECOM 2012; McKillop et al. 2013). Saturation of fine-grained colluvial soils in summer is caused by the underlying permafrost; these soils are referred to as “thaw unstable” (SRK 2016b).

3.2 Surficial Geology

The mapping done for this report is given in Figures 2a to 2f. The maps show that the mine site study area is dominated by the colluvium described in Section 3.1.2. Colluvial blanket and veneer (thick and thin deposits) are dominant. The colluvial apron/muck deposits cannot be identified definitively from air photo interpretation alone. As a result, at slope breaks near valley bottoms, units mapped as Ca (colluvial apron), may in fact contain some amount of eolian material. Colluvial aprons are generally poorly to very poorly-drained due to the presence of permafrost. It is also possible that silt-dominated colluvial deposits also contain some component of wind-blown silt.

Although colluvium dominates the mine site area, a few other units are present as well. Weathered bedrock is exposed in places, mainly on the ridge tops, while limited areas of fluvial and organic deposits are found in valley bottoms. In some tributary valleys, thin fluvial deposits are present, but are too small to map.

3.2.1 Weathered Bedrock

In the borehole and testpit logs, bedrock exposed at surface is described as coarse-grained granite or felsic gneiss with clay alteration and fracture-controlled hematite and limonite (Lorax 2016). Weathered bedrock consists of coarse angular gravel with silt and sand or heavily fractured bedrock. The angular gravel fragments are weak and can be broken apart by hand (SRK 2016a). Areas mapped as weathered bedrock may contain local patches of fresher-looking rock. They are mainly found on ridge tops and include the tors, which are mapped with point symbols (Figures 2a to 2f). Bedrock exposed on slopes in valley bottoms appears to be less weathered on the air photos.

3.2.2 Colluvial Deposits

Colluvium is pervasive across the mine site area. It is described in the borehole/testpit data as comprising nonplastic, non-cohesive deposits of angular pebbles, cobbles and boulders (rubble), silt and/or sand. Silt and sand are generally the main components, but some areas are dominated by cobbles (Lorax 2016; SRK 2016a). Rubble lithologies in the areas covered by the boreholes are local: felsic or mafic gneiss, granite and schist (Lorax 2016). Beds of silt, sand, or both may be interspersed with otherwise non-bedded material. Less commonly, organic soil layers may be interbedded with colluvium near the surface (SRK 2016a). Tetra Tech EBA interprets this surface layering as recording previous downslope movement of the upper portions of the colluvium.

Boreholes SRK-15S-07 and -09 and testpit SRK-15TP-38 all contain organic material within the colluvium that can be dated to determine the timing of slope activity in these locations. The material at Boreholes SRK-15S-07 and SRK-15TP-38 consists of organic gravelly silt with large woody pieces at 1.4 m depth and organic woody material at 0.2 m depth, respectively. Borehole SRK-15S-07 records a piece of wood at about 0.2 m depth, as well as organic layers at 1.22 m and 3.96 m. This site could potentially give an approximate return frequency for slope movement at this location. These organic pieces are suspected to be Holocene in age.

3.2.3 Fluvial Deposits

Fluvial deposits are generally thin and are found in narrow valley bottoms. The Latte Creek valley is an exception – here fluvial sediments are thicker and are overlain by organic deposits.

At the confluence of two small streams in the northern part of the mine site area, Borehole SRK-15S-02 describes the fluvial deposit as silty sand with subangular pebbles and cobbles, while nearby Testpit SRK-15TP-36A describes the unit as gravelly silt with cobbles, overlying cobbles. This testpit may be located within thin fluvial sediments overlying colluvium. Further south at the bottom of another tributary valley, Boreholes SRK-15S-12 and SRK-15S-35 identified thin deposits of sandy silt with gravel, containing angular to subangular clasts.

A few fluvial fans are present in the Latte creek valley. One fan has a borehole within it (MW15-02T), which describes the deposit as colluvium ranging from silty sand to boulders. Rounding is not described so it is possible the deposit represents the debris flow portion of the fan; however, the tributary valley is short, so fluvial deposits are unlikely to be well sorted or well-rounded and thus would likely resemble colluvium.

3.2.4 Organic Deposits

Organic deposits are the primary unit in only four locations within the mine site study area; three of these are in the Latte Creek valley and one is in an unnamed valley in the northeast. Organics make up the second or third component of mapped surficial geology units in the bottom of Latte Creek valley, where the primary units are either valley floor fluvial deposits or colluvial aprons.

Unfortunately, there is no field data for organic deposits. Tetra Tech EBA assumes that they consist of peat and/or organic silt as described in Huscroft (2002).

3.2.5 Landforms

The geomorphic processes and landforms within the mine site study area include mass-wasting features (landslide failure scars and headscarps; retrogressive thaw flow scars and headscarps; active layer detachment scars and headscarps; solifluction); thermal erosion, gullying, a collapsed open-system pingo, cryoplanation terraces, and tors (Figures 2a to 2f; 3a and 3b). Two of these landform types are considered rare landforms: the pingo and the tors.

The collapsed pingo is located in the central portion of the mine site study area, in a small creek valley that is a tributary of Latte Creek (Photo 2). It indicates the former presence of massive ground ice and ice-rich permafrost underlying the lower slope of northwesterly aspect at that location.

Photo 2: Collapsed open-system pingo in in a small tributary valley of Latte Creek, looking south.

The tors, erosional remnants of a higher plateau level, are found on ridge tops in the western, southwestern, and central parts of the mine site study area (Figures 2a to 2f; Photos 3 and 4), towering over otherwise smooth rounded ridges underlain by granitic bedrock. Tors are surrounded by either a thick colluvial halo or weathered bedrock. Some of the tors are located within the HLF footprint and there are quad trails visible on the air and field photos in this area on the ridge top (Photo 4).

Photo 3: Ground view of a tor located within the HLF footprint in the western part of the mine site study area.

Photo 4: Aerial photograph of the same tor. Note quad tracks to left of the tor.

Although pingos and tors are not specifically mentioned in the Traditional Knowledge (TK) data collected to date for the Coffee Project, the importance of these features is inferred through views that expressed traditional ways of life being tied to “healthy and intact ecosystems” (Bates et al 2014). The importance of terrain features, possibly including tors and pingos, has been identified with respect to the use of elevated landforms as lookouts (Dobrowolsky 2014; Tr'ondëk Hwëch'in 2012).

There are no trails leading to the collapsed pingo; it is therefore not suspected to be used by First Nations peoples. The quad tracks on the ridge tops may or may not be of First Nations origin.

3.3 Permafrost

3.3.1 Permafrost Distribution

Our calculations of spatial distribution of permafrost within the mine site study area using ArcGIS technology show that approximately 62% of the mapped area is underlain by permafrost (Tetra Tech EBA 2016; Figures 3a and 3b), which is in agreement with Heginbottom et al. (1995). Approximately 38% of the mine site study area is therefore estimated to be permafrost-free. However, permafrost-free areas may contain patches of permafrost in locations where conditions are favourable for its formation.

Relationships between permafrost distribution, slope aspect, and vegetation in the mine site study area are illustrated in Photo 5. In the South WRSF area located within the small creek valley, shallow permafrost underlies the northeast-facing slope, which is vegetated with sparse, stunted black spruce and thick moss; whereas the southwest-facing slope is permafrost-free and covered by almost pure stands of trembling aspen. Aspen requires warmer air temperatures and deeper root penetration; it is therefore unable to grow in shallow permafrost conditions.

Photo 5: South WRSF, Perennially frozen northeast-facing slope (right) and permafrost-free southwest-facing slope (left), looking south towards the Latte Creek valley.

3.3.2 Permafrost Thickness

Permafrost thicknesses within the mine site study area are highly variable, ranging from approximately 30 m (MW15-04T and MW14-02B) to approximately 165 m near the north end of the proposed Supremo open pit (MW14-04T, Figures 3c and 3d). Permafrost thickness measurements are shown in Figures 3a and 3b (borehole locations shown in Figure 3d).

3.3.3 Active Layer

Active layer thickness in the mine site study area varies spatially and temporally. In areas with thicker insulating organic cover, it is usually thin (approximately 0.3 m to 0.6 m), whereas it can be several metres thick within partially exposed bedrock or within coarse surficial material with a high clast content.

3.3.4 Ground Temperatures

Ground temperatures within the mine site study area have been monitored since 2013 by the companies listed in Section 2.2. Permafrost temperatures measured at the **depth of zero annual amplitude** range from temperatures near the freezing point to approximately -2ºC. These temperatures are indicative of warm permafrost conditions; the ground is therefore sensitive to disturbance. The spatial distribution of permafrost temperatures and the measurement locations are shown in Figures 3a and 3b.

The depth of zero annual amplitude within the permafrost interval was estimated from the ground temperature profiles plotted by Lorax (2016). It varies across the mine site study area, but generally lies between approximately 10 m (MW15-07T) and 15 m (MW14-04T) below the ground surface.

3.3.5 Ground Ice

Ground ice content in the perennially frozen surficial materials is highly variable and was mapped accordingly based on the limited information on volumetric ice content (percent by volume) currently available. The mine site study area was found to be underlain by perennially frozen ground with ground ice that is predominantly:

- Non-visible (Nf, Nbn, Nbe) labeled as "**Fn**";
- Visible (Vx, Vc, Vr, Vs) labeled as "**Fv**"; or
- Forms significant accumulations, such as massive ice bodies, labeled as "**Fi**".

The following describes each of the three permafrost types mapped in Figures 3a to 3d (**Fn**, **Fv**, and **Fi**) in detail:

- Areas labelled as **"Fn"** are generally ice-poor (Frozen, Non-Visible Ice). These consist of perennially frozen ground that is **well-bonded** to **friable** and typically does not contain visible excess ice. However, these areas may include patches of permafrost with visible ground ice (Fv), having ice contents ranging from 1% to 5% by volume, as well as patches of unfrozen ground.
- Areas labelled as **"Fv"** contain visible excess ground ice (Frozen, Visible Ice). This ice-rich permafrost is well-bonded but rarely includes large ground ice bodies. The ice-rich areas may include patches of ice-poor permafrost with ground ice that is not visible to the unaided eye (**Fn**) and patches of permafrost-free ground. Ice content is estimated to range from 1% to 30% by volume (SRK, 2016a). The visible excess ice content (percent by volume) within areas designated as "**Fv**" may exceed 30% (e.g. Borehole SRK-15S-08, West WRSF (SRK, 2016a)).
- Areas labelled as **"Fi"** (Frozen, Ice-Rich) are generally very ice-rich and may include large accumulations of ground ice, such as ice wedges and other massive ice bodies.

In the mine site study area, distribution of these three permafrost types characterized by ground ice content can be broken down as follows:

- 34% is underlain by predominantly ice-poor permafrost with predominantly non-visible ice (**Fn**);
- 27% is underlain by permafrost with visible excess ice (**Fv**); and
- Approximately 1% is underlain by very ice-rich permafrost (**Fi**), which is located at the bottom of some of the creek valleys, e.g. the Latte Creek and the May Lady Creek.

3.4 Terrain Stability

The terrain stability mapping of a mine site study area with slightly different boundaries conducted by PECG is given in Appendix B and is summarized in this section.

PECG's mapping was based on delineating five standard terrain stability classes which are as follows:

- I – stable;
- II – generally stable;
- III – generally stable with isolated minor instability;
- IV – potentially unstable; and
- V – Unstable.

However, because of the complexity of the landscape, which is within the zone of widespread discontinuous permafrost with variable ground ice content and warm permafrost temperatures, PECG differentiated the terrain stability classes in both the existing and disturbed condition. The “existing terrain stability” class represents current conditions, in the absence of any project-related activity; whereas, the “disturbed terrain stability” class represents conditions following disturbance to ground conditions during exploration and from road/mine facility construction without mitigation. This format of mapping, in PECG’s opinion, distinguishes natural hazards, which may be triggered by occurrences such as wildfire, from those potentially exacerbated or initiated by project-related disturbance.

Calculations of the areas occupied by each of the five terrain stability classes using ArcGIS technology show that prior to the proposed construction activities (the existing undisturbed terrain), the majority (approximately 78%) of the mine site study area has an existing terrain stability class of “generally stable” (Class II). Approximately 15% of the mine site study area is considered “generally stable with isolated minor instability” (Class III). Approximately 1% of the mine site study area is considered “potentially unstable” (Class IV) and approximately 6% - “unstable” (Class V).

According to the disturbed terrain stability class, the proportion of terrain stability polygons in the mine site study area with a “generally stable” (Class II) rating drops from 78% to 27% (disturbed). The majority (approximately 42%) of the mine site study area becomes “generally stable with isolated minor instability” (Class III). Approximately 24% of the mine site study area becomes “potentially unstable” (Class IV) and approximately 7% - “unstable” (Class V).

PECG’s mapping of terrain and terrain stability and hazards, together, identify various geohazards through the assignment of geomorphic process codes (polygon-scale) and discrete geomorphologic processes (point or linear features) in addition to the terrain stability classes (Appendix B, Maps 1 and 2). Table 3-1 outlines the likelihood and potential magnitude of hazard occurrence over the mine life, generalized according to each of the identified hazards with the potential to affect proposed mine infrastructure footprints. The hazards identified and shown in Table 3-1 vary in likelihood and magnitude, and carry with them different project concerns for avoidance and/or mitigation.

Table 3-1. Hazards with the Potential to Affect the Proposed Mine Site Study Area (Summarized from Tables 5-1 and 5-2, PECG Appendix B)

Hazard	Likelihood (over mine life)	Magnitude	Project Considerations
Rockfall	High – typically recurrent and frequent, where present, freshness of talus at base of bluff indicate recent activity	Moderate – generally small in volume, but rapid and dense	Plan for rockfall below bluffs, especially in areas of fresh deposits (avoid or mitigate) and on steep slopes with small bedrock outcrops
Debris slide	Moderate – most likely to occur on steep slopes with a history of debris sliding, especially within areas adjacent to scars	High – generally small to moderate in volume, but rapid and moderately dense	Avoid debris slide slopes and runout zones
Rock creep	High – periodic movement expected; freshness of patches of rock debris indicate recent activity	Low – small volume, short distance, slow movements of angular rock debris	Expect increased maintenance and allow for minor settlement and shifting of rock debris
Gullying	High – periodic and localized gully erosion processes (e.g. fluvial incision, side wall mass-wasting)	Low – generally incremental and localized incision, minor surface sloughing	Minimize crossings of gullied slopes, especially where underlain by permafrost, and expect increased maintenance

Table 3-1. Hazards with the Potential to Affect the Proposed Mine Site Study Area (Summarized from Tables 5-1 and 5-2, PECG Appendix B)

Hazard	Likelihood (over mine life)	Magnitude	Project Considerations
Solifluction	High – near-continuous, incremental movement	Low – small volume, short distance, slow movements of silt-rich debris	Expect increased maintenance and allow for minor settlement and shifting of surficial material
Thermokarst	Moderate – gradual or periodic settlement, especially in areas of ice-rich permafrost	Low – isolated, slow deepening of ground surface depressions, formation and expansion of tension cracks, possible slow, inward slumping	Minimize disturbance to surface organics and drainage in areas of ice-moderate to ice-rich permafrost through use of appropriate gravel embankments/pads and water management. Expect increased maintenance that could involve localized road reconstruction; consider monitoring settlement
Slopewash	High – seasonal slopewash and transport of fine sediments within runnels; near continuous seepage	Low – localized, slow transport of fine sediments; seepage and icing, especially in runnels	Accommodate seepage-induced icing accumulation especially within intercepted runnels, expect increased maintenance due to fine sediment delivery adjacent to road, manage downslope drainage

3.4.1 Geohazards by Footprint

The hazards identified by PECG include those that have the potential to affect the various infrastructure footprints of the mine site. These are detailed in this section.

3.4.1.1 Open Pits

Deep, ice-poor permafrost is present in the vicinity of most of the proposed open pit areas. There are a few slopes with active rock creep, some ice-moderate permafrost on the west side of the Latte pit, and gullied terrain on the south side of the Supremo pit.

Surface runoff should be managed around the rim of the pits to prevent retrogressive gullying and settlement of the overburden cap.

3.4.1.2 West WRSF

The West WRSF footprint is on a laterally-convex hillside that is covered with thin colluvium. Here, continuous, ice-poor permafrost is shallow to deep. There is an area of potentially ice-rich permafrost and a fringing colluvial blanket in the southwest portion of the WRSF.

In September 2015, Tetra Tech EBA observed human-induced **thermal erosion** developing along the recent access trail within the area of potentially ice-rich permafrost mentioned above (Figures 3a and 3b; Photos 6 and 7).

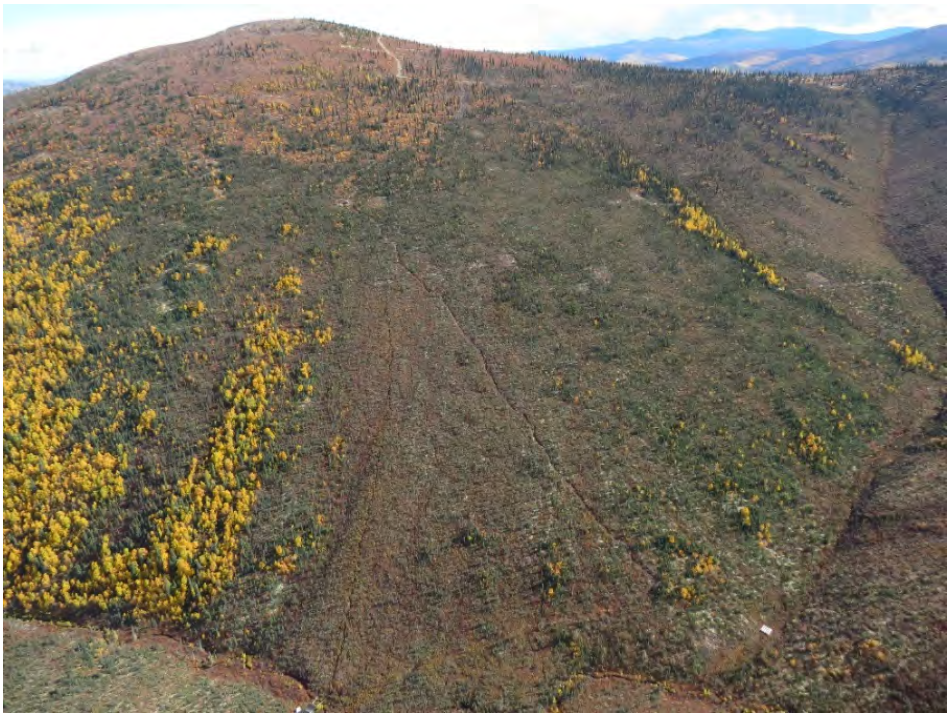

Photo 6: West WRSF, Recent access trail along west-northwest-facing perennially frozen slope, looking southeast. Drillers' access trail crosses photo from the hill top in the upper left to the base of the slope on the lower right.

Photo 7: West WRSF, west-northwest-facing slope. Thermal erosion along recent access trail, looking west.

3.4.1.3 South WRSF

This WRSF is located in a small, first order tributary valley. The west side of the valley contains shallow, ice-moderate permafrost. Slopewash was the only geomorphological process mapped. There are a few subdued gullies on the east side of the valley and permafrost is suspected at lower elevations.

3.4.1.4 North WRSF

The North WRSF partially fills a headwater basin mostly covered with colluvial veneer, but areas of thicker colluvium are also present. All of the colluvium contains permafrost; it is ice-moderate[2] in places. There is potential for thermokarst, rock creep, and slopewash.

3.4.1.5 Unnamed WRSF

This WRSF is located in an area of weathered bedrock and colluvial veneer with shallow to deep, ice-poor permafrost. There is an area of infilled colluvial and fluvial material at the valley bottom that may contain ground ice at depth.

3.4.1.6 HLF Area

A gentle ridge of weathered bedrock with colluvial veneer hosts the proposed HLF. Shallow to deep, ice-poor permafrost is present throughout the footprint. An area of colluvial blanket in the northwest corner may contain ice-moderate permafrost. There is a small active layer detachment on the slope in this area, which indicates permafrost thaw. Solifluction and related rock creep are also evident within the footprint.

3.4.1.7 Plant Site Area

The plant site footprint is located on a broad, near level section of a ridge. It is covered with a veneer of weathered bedrock and colluvium and ice-poor permafrost is shallow to deep. There are no stability concerns in this area.

3.5 Organic Soils

No organic cover was observed at boreholes SRK-15S-05 (disturbed), 15S-26 to 15S-28, 15TP-68, 15TP-69, 15TP-75A, and 15TP-82A (SRK 2016a). Organic deposits were not described in the Lorax boreholes (Lorax 2016), with the exception of MW15-04WB, MW15-01AZ, and MW15-01T. At the latter site, 2 m of muddy brown organics and colluvium were observed, but the thickness of the organics is not given.

The organic surface soil layer typically ranges from 0.1 m to 0.3 m thick, but is most commonly 0.2 m in thickness. Thicknesses of 0.1 m are more common on, but are not limited to, the ridge tops, and thicknesses of 0.3 m or greater tend to be found in areas of non-visible ground ice (Fn). The greatest organic layer thickness recorded (0.6 m) is located in an area of very ice-rich permafrost (Fi).

The organic soils were generally described as moist, dark brown organics containing moss and fibrous lichens (SRK 2016a) or simply as moss with root inclusions (KP 2015). However, a few were described as organic silt or organic silt with sand, gravel, and/or cobbles (Lorax 2016; SRK 2016a), one was described as topsoil/**muskeg** (Lorax 2016), and two were described as green moss (SRK 2016a).

[2] See Appendix B for definition

Organic silt is most common on north-facing slopes and is found only in areas of visible or non-visible ground ice. The presence of silt within the organics may be caused by a combination of more active slope creep in permafrost areas, cryoturbation, or loess capture by permafrost-bearing units, which are wetter in summer.

Very few holes were drilled in valley bottoms, so the wet fluvial units are under-represented in the borehole and testpit data. The topsoil/muskeg site is found adjacent to one of the fluvial units (MW15-05T, Lorax 2016) in an area of very ice-rich permafrost.

4.0 SUMMARY AND CONCLUSIONS

This report elucidates the Coffee Gold Project mine site study area's surficial geology, physiography, permafrost, and terrain stability baseline conditions for the purposes of an environmental assessment.

First, a literature review was completed to summarize the conditions at site to date. It shows that the area has not been glaciated, resulting in a landscape consisting of rounded ridges separated by deep, V-shaped valleys. Climate is characterized by warm, short summers and long, cold winters. Weathered bedrock, colluvium derived from weathered bedrock and loess, and fluvial deposits are found within the mine site study area, but colluvial deposits are by far the most common. These deposits are affected by gullying, cryoturbation, solifluction, permafrost processes, periglacial processes, landslides, and snow avalanches. The mine site study area is located within the zone of extensive discontinuous permafrost. Permafrost is most common on north-facing slopes with thick organic cover and in colluvial apron/muck deposits on lower slopes and on creek bottoms. South-facing slopes are permafrost-free. Permafrost-related processes include cryoturbation, solifluction, active layer detachments, slope creep, frost heave, and thermal erosion. Open-system pingos are present locally.

Since 2011, ten field investigation programs have been completed, each of which provides useful information for this baseline study. These field programs include soils, hydrogeology, permafrost, and geotechnical studies. Drilling, instrument installation in boreholes, testpitting, ground investigations on foot, and helicopter flyovers were all included in these studies.

Surficial geology, permafrost, and terrain stability mapping were undertaken for this report. The first two were completed by Tetra Tech EBA and the third by PECG. The desktop mapping draws heavily on data supplied by the many field investigations; these were used as ground truthing points for three types of mapping.

Various permafrost maps, a map of the general surficial geology of the mine site, and terrain stability/hazard maps were generated for this baseline study; these are included at the end of this report. Geohazards and organic surface soils were also described.

Results from this baseline study conclude that colluvium is indeed pervasive, and that ridge tops may have exposed weathered bedrock, some of which forms tors. Colluvium is dominated by silt and sand, but also contains angular pebbles, cobbles, and boulders. Organic material interbedded with the colluvium at a few sites shows that downslope creep or possibly sliding of some colluvial deposits may be fairly recent. Thin fluvial deposits consisting of gravelly silt are found in the narrow valley bottoms and a few fluvial fans are present at the mouths of small tributary valleys. Thick organic deposits are rare; they are found in the Latte Creek valley and overlying colluvial apron/muck deposits at the base of some slopes.

The only rare landforms in the mine site study area are the tors and one collapsed open-system pingo.

Permafrost distribution determined from the mapping shows that approximately 62% of the mine site study area is underlain by permafrost. Permafrost thicknesses range from approximately 30 m to 165 m. The active layer is highly variable: it is usually thin (approximately 0.3 m to 0.6 m), but it can be several metres thick in bedrock areas or where coarse surficial sediments are present. Ground temperatures range from close to 0ºC to approximately -2ºC,

indicating warm permafrost conditions. Ground containing permafrost is therefore sensitive to disturbance. Ground ice has been classified as non-visible, visible, or forming significant accumulations, such as massive ice bodies, although the latter is rare. The spatial distribution of these across the mine site was determined to be 34% for ice-poor permafrost with non-visible ice; 27% for permafrost with visible excess ice; and 1% for very ice-rich permafrost, which is mainly located at the bottom of the Latte Creek valley.

Five terrain stability classes (stable; generally stable; generally stable with minor instability; potentially unstable; and unstable) were mapped within the mine site. These classes were differentiated in both the existing and disturbed condition because of the complexity of the mine site study area permafrost terrain. The “existing terrain stability” class represents current conditions, in the absence of any project-related activity; whereas, the “disturbed terrain stability” class represents conditions following disturbance to ground conditions from road/mine facility construction without mitigation.

Calculations of the areas occupied by each of the five terrain stability classes using ArcGIS technology show that prior to the proposed construction activities (the existing undisturbed terrain) the majority (approximately 78%) of the mine site study area has an existing terrain stability class of “generally stable” (Class II). Approximately 15% of is considered “generally stable with isolated minor instability” (Class III). Approximately 1% of the mine site study area is considered “potentially unstable” (Class IV) and approximately 6% - “unstable” (Class V).

According to the disturbed terrain stability class, the proportion of terrain stability polygons in the mine site study area with a “generally stable” (Class II) rating drops from 78% to 27%. The majority (approximately 42%) of the mine site study area becomes “generally stable with isolated minor instability” (Class III). Approximately 24% becomes “potentially unstable” (Class IV) and approximately 7% - “unstable” (Class V).

Various hazards were identified and described by magnitude, frequency, and considerations for mitigation of each. These include rockfall, debris slides, rock creep, gullying, solifluction, thermokarst, and slopewash. The various geohazards within each proposed infrastructure footprint were also described.

Finally, the organic surface soil was described. It is generally 0.2 m thick, but is slightly thinner on ridge tops, and is thicker in areas of non-visible ground ice or where very ice-rich permafrost is found. Organic silt is most common on north-facing slopes and is found only in areas of visible or non-visible ground ice. The presence of silt within the organics may be caused by a combination of more active slope creep in permafrost areas, cryoturbation, or loess capture by permafrost-bearing units, which are wetter in summer.

5.0 CLOSURE

We trust this report meets your present requirements. If you have any questions or comments, please contact the undersigned.

Respectfully submitted,

APPENDIX A
TETRA TECH'S GENERAL CONDITIONS

GENERAL CONDITIONS

GEOTECHNICAL REPORT

This report incorporates and is subject to these “General Conditions”.

1.0 USE OF REPORT AND OWNERSHIP

This geotechnical report pertains to a specific site, a specific development and a specific scope of work. It is not applicable to any other sites nor should it be relied upon for types of development other than that to which it refers. Any variation from the site or development would necessitate a supplementary geotechnical assessment.

This report and the recommendations contained in it are intended for the sole use of Tetra Tech EBA’s Client. Tetra Tech EBA does not accept any responsibility for the accuracy of any of the data, the analyses or the recommendations contained or referenced in the report when the report is used or relied upon by any party other than Tetra Tech EBA’s Client unless otherwise authorized in writing by Tetra Tech EBA. Any unauthorized use of the report is at the sole risk of the user.

This report is subject to copyright and shall not be reproduced either wholly or in part without the prior, written permission of Tetra Tech EBA. Additional copies of the report, if required, may be obtained upon request.

2.0 ALTERNATE REPORT FORMAT

Where Tetra Tech EBA submits both electronic file and hard copy versions of reports, drawings and other project-related documents and deliverables (collectively termed Tetra Tech EBA’s instruments of professional service), only the signed and/or sealed versions shall be considered final and legally binding. The original signed and/or sealed version archived by Tetra Tech EBA shall be deemed to be the original for the Project.

Both electronic file and hard copy versions of Tetra Tech EBA’s instruments of professional service shall not, under any circumstances, no matter who owns or uses them, be altered by any party except Tetra Tech EBA. Tetra Tech EBA’s instruments of professional service will be used only and exactly as submitted by Tetra Tech EBA.

Electronic files submitted by Tetra Tech EBA have been prepared and submitted using specific software and hardware systems. Tetra Tech EBA makes no representation about the compatibility of these files with the Client’s current or future software and hardware systems.

3.0 ENVIRONMENTAL AND REGULATORY ISSUES

Unless stipulated in the report, Tetra Tech EBA has not been retained to investigate, address or consider and has not investigated, addressed or considered any environmental or regulatory issues associated with development on the subject site.

4.0 NATURE AND EXACTNESS OF SOIL AND ROCK DESCRIPTIONS

Classification and identification of soils and rocks are based upon commonly accepted systems and methods employed in professional geotechnical practice. This report contains descriptions of the systems and methods used. Where deviations from the system or method prevail, they are specifically mentioned.

Classification and identification of geological units are judgmental in nature as to both type and condition. Tetra Tech EBA does not warrant conditions represented herein as exact, but infers accuracy only to the extent that is common in practice.

Where subsurface conditions encountered during development are different from those described in this report, qualified geotechnical personnel should revisit the site and review recommendations in light of the actual conditions encountered.

5.0 LOGS OF TESTHOLES

The testhole logs are a compilation of conditions and classification of soils and rocks as obtained from field observations and laboratory testing of selected samples. Soil and rock zones have been interpreted. Change from one geological zone to the other, indicated on the logs as a distinct line, can be, in fact, transitional. The extent of transition is interpretive. Any circumstance which requires precise definition of soil or rock zone transition elevations may require further investigation and review.

6.0 STRATIGRAPHIC AND GEOLOGICAL INFORMATION

The stratigraphic and geological information indicated on drawings contained in this report are inferred from logs of testholes and/or soil/rock exposures. Stratigraphy is known only at the locations of the testhole or exposure. Actual geology and stratigraphy between testholes and/or exposures may vary from that shown on these drawings. Natural variations in geological conditions are inherent and are a function of the historic environment. Tetra Tech EBA does not represent the conditions illustrated as exact but recognizes that variations will exist. Where knowledge of more precise locations of geological units is necessary, additional investigation and review may be necessary.

7.0 PROTECTION OF EXPOSED GROUND

Excavation and construction operations expose geological materials to climatic elements (freeze/thaw, wet/dry) and/or mechanical disturbance which can cause severe deterioration. Unless otherwise specifically indicated in this report, the walls and floors of excavations must be protected from the elements, particularly moisture, desiccation, frost action and construction traffic.

8.0 SUPPORT OF ADJACENT GROUND AND STRUCTURES

Unless otherwise specifically advised, support of ground and structures adjacent to the anticipated construction and preservation of adjacent ground and structures from the adverse impact of construction activity is required.

9.0 INFLUENCE OF CONSTRUCTION ACTIVITY

There is a direct correlation between construction activity and structural performance of adjacent buildings and other installations. The influence of all anticipated construction activities should be considered by the contractor, owner, architect and prime engineer in consultation with a geotechnical engineer when the final design and construction techniques are known.

10.0 OBSERVATIONS DURING CONSTRUCTION

Because of the nature of geological deposits, the judgmental nature of geotechnical engineering, as well as the potential of adverse circumstances arising from construction activity, observations during site preparation, excavation and construction should be carried out by a geotechnical engineer. These observations may then serve as the basis for confirmation and/or alteration of geotechnical recommendations or design guidelines presented herein.

11.0 DRAINAGE SYSTEMS

Where temporary or permanent drainage systems are installed within or around a structure, the systems which will be installed must protect the structure from loss of ground due to internal erosion and must be designed so as to assure continued performance of the drains. Specific design detail of such systems should be developed or reviewed by the geotechnical engineer. Unless otherwise specified, it is a condition of this report that effective temporary and permanent drainage systems are required and that they must be considered in relation to project purpose and function.

12.0 BEARING CAPACITY

Design bearing capacities, loads and allowable stresses quoted in this report relate to a specific soil or rock type and condition. Construction activity and environmental circumstances can materially change the condition of soil or rock. The elevation at which a soil or rock type occurs is variable. It is a requirement of this report that structural elements be founded in and/or upon geological materials of the type and in the condition assumed. Sufficient observations should be made by qualified geotechnical personnel during construction to assure that the soil and/or rock conditions assumed in this report in fact exist at the site.

13.0 SAMPLES

Tetra Tech EBA will retain all soil and rock samples for 30 days after this report is issued. Further storage or transfer of samples can be made at the Client's expense upon written request, otherwise samples will be discarded.

14.0 INFORMATION PROVIDED TO TETRA TECH EBA BY OTHERS

During the performance of the work and the preparation of the report, Tetra Tech EBA may rely on information provided by persons other than the Client. While Tetra Tech EBA endeavours to verify the accuracy of such information when instructed to do so by the Client, Tetra Tech EBA accepts no responsibility for the accuracy or the reliability of such information which may affect the report.

Tim Smith, P.Geo.
Vice President Exploration
Kaminak Gold Corporation
1020 – 800 West Pender Street
Vancouver, BC V6C 2V6

Dear Mr. Smith,

Re: Terrain Stability and Hazard Mapping for the Coffee Gold Project

Palmer Environmental Consulting Group Inc. is pleased to provide Kaminak Gold Corporation with the results of the terrain stability and hazard mapping we completed for the Coffee Gold Project in west-central Yukon.

This report, in combination with the appended mapping of terrain (Map 1), terrain stability and hazards (Map 2) and soil erosion potential (Map 3), provides the information necessary to inform engineering and environmental studies being completed in support of project proposal submission to the Yukon Environmental and Socio-economic Assessment Board. It characterizes the types and distribution of terrain hazards in the vicinity of proposed project infrastructure, as a basis for evaluating risks and prioritizing opportunities for avoidance and mitigation.

Should you or technical reviewers have any questions or require additional information, please feel free to contact Robin McKillop at 604-629-9075 (ext. 106) or via email at robin@pecg.ca.

Yours truly,

Palmer Environmental Consulting Group Inc.

Executive Summary

Kaminak Gold Corporation is proposing to develop its Coffee Gold Project, located approximately 130 km south of Dawson, in Yukon's White Gold District. A service road, approximately 215 km in length and comprising existing and new sections, is proposed to provide access from Dawson. Kaminak retained PECG to complete terrain stability and hazard mapping within a 526 km^2 study area that encompasses the proposed mine facilities and access road corridor. The objective of the mapping is to inform engineering and environmental studies advancing in support of project proposal submission to the Yukon Environmental and Socio-economic Assessment Board.

The study area is within the zone of discontinuous permafrost in an unglaciated region of rolling mountains in Yukon's Klondike Plateau. The proposed mine area straddles a broad subalpine ridge south of Yukon River. The proposed access road from Dawson traverses several large valleys, gently undulating ridge systems, rounded mountain passes, and crosses the Stewart and Yukon rivers. Ten main terrain units occur within the study area, the majority of which are colluvial mantles of varying thicknesses on slopes with (45%) and without (24%) permafrost. Comparatively small portions of the study area are dominated by intact or weathered bedrock (3%), mixed weathered bedrock and colluvium (14%), fluvial (6%) or glaciofluvial (<1%) deposits, or organic terrain (1%). Anthropogenic disturbance from placer mining is common (6%) within most of the valleys along which the road is proposed. Mass movement and slope erosion processes that contribute to the geomorphology of the landscape include rockfall, debris slides, rock slumps, rock creep, gullying, solifluction, active layer detachments, thermokarst subsidence, thermal erosion, slopewash and pingos. The fluvial processes with the greatest potential to affect the project are meander migration and icing.

The study area was divided into areas (polygons) based on their terrain stability class prior to (existing state) and following (disturbed state) conventional facility/road construction without mitigation. In its existing state, approximately 85% of the study area is considered stable (Class I), generally stable (Class II) or generally stable with minor potential for instability (Class III), with approximately 8% considered potentially unstable (Class IV) or unstable (Class V). The remaining approximately 7% is unclassified anthropogenic disturbances or open water. In a disturbed state, the proportion of Class I to III polygons would decrease to 64% and correspondingly increase the proportion of Class IV and V polygons to 29%. This elevation in terrain stability class mainly reflects increased potential for permafrost-related slope failures or thermokarst activity if facility/road construction proceeded without regard for the sensitivity of ground underlain by permafrost. The distinction between existing and disturbed terrain stability classes facilitates accurate recognition of upslope or downslope hazards unaffected by project activities.

The primary hazards requiring consideration in the final siting and design of the mine facilities and access road include rockfall, debris slides, active layer detachments and thermokarst activity. Careful site preparation, construction and mitigation will minimize exposure to these hazards, where unavoidable. Erosion protection, such as riprap, will be required along sections of the access road near migrating meanders and river crossings. Special consideration will need to be given to the design and maintenance of drainage crossings prone to icing.

1 Introduction

Palmer Environmental Consulting Group Inc. (PECG) is pleased to provide Kaminak Gold Corporation (Kaminak) with the results of our terrain stability and hazard mapping for the Coffee Gold Project (the Project). Our work aligns with the hazard mapping expectations of Yukon Environmental and Socio-economic Assessment Board (YESAB). The landscape encompassing the proposed mine area and access route was mapped to support engineering planning, including risk assessment, and environmental studies such as terrestrial ecosystem mapping, aquatic risk assessment and acid rock drainage potential evaluations. This report and its appended maps inform the routing and design of the access road, and the footprint and site preparation for mine facilities. We provide a comprehensive description of the distribution, characteristics and implications of different terrain units and geomorphological processes, as a basis for minimizing construction and maintenance costs, and avoiding and mitigating risks to infrastructure and the natural environment.

Following provision of important background information (Section 1), the physical setting of the region encompassing the study area is described (Section 2). The methods used for field work, mapping and hazard identification are outlined in Section 3. Dominant terrain units and geomorphological processes encountered within the study area are characterized in Section 4. Section 5 presents the results of the terrain stability and hazard mapping, and summarizes the distribution, characteristics and implications of potential hazards to project infrastructure footprints. Considerations for hazard avoidance and mitigation and highlighted in Section 6. Key conclusions are stated in Section 7, followed by acknowledgment of study limitations in Section 8. References cited throughout the report are provided in Section 9.

Mapping of terrain (Map 1), terrain stability and hazards (Map 2), and soil erosion potential (Map 3) is provided in **Appendices A**, **B** and **C**, respectively. **Appendix D**, submitted digitally, includes data collected by PECG at detailed field sites throughout the study area. A technical memorandum prepared by Tetra Tech EBA (TT-EBA) on geotechnical considerations for road design in areas underlain by permafrost is included in **Appendix E**.

1.1 Background

Kaminak is proposing to develop a gold mine, comprising four open pits known as Latte, Double Double, Supremo and Kona, using conventional shovel and truck methods at an average rate of 5 million tonnes per year of heap leach feed (JDS Energy & Mining Inc., 2016). The ore will be crushed and placed in a heap leach facility for nine months of the year. During the coldest winter months, run-of-mine ore will be stockpiled. Gold will be extracted from pregnant leach solution by a 5 tonnes per day Adsorption-Desorption Recovery carbon plant with mercury retorting to produce a final gold doré product. A total of 1.9 million ounces of gold is planned to be recovered over a ten-year mine life. The mine is proposed to be accessed from Dawson along a 215 km-long, upgraded and extended existing road. Stewart and Yukon Rivers are proposed to be crossed by barge in summer and ice road in winter.

In order to inform mine facility and access road planning, Kaminak retained PECG, working in association with Kryotek Arctic Innovation Inc. (Kryotek), to complete terrain stability mapping and hazard mapping for the Project area. PECG's recognized experts in terrain and terrain stability mapping led all aspects of the mapping assignment, applying knowledge of permafrost conditions and associated hazards specific to the valleys south of Dawson gained through extensive drilling and geophysical surveys by Kryotek. PECG's mapping also benefited from collaboration with TT-EBA, which concurrently mapped permafrost distribution and related geohazards along a 200 m-wide corridor along the proposed access road centreline (TT-EBA, 2016b) and within the mine site area (TT-EBA, 2016c).

PECG recognized that accurate terrain stability mapping in the unglaciated region south of Dawson requires an understanding of the distribution and implications of permafrost, in addition to mass movement processes. Permafrost is extensive, occurring on all aspects and underlying approximately two-thirds of the ground (Hegginbottom et al., 1995; Bonnaventure et al., 2012; McKillop et al., 2013). Permafrost terrain exhibits unique challenges for road construction and maintenance, particularly where it contains significant ground ice, due to its sensitivity to changes in ground thermal regime. The potential for permafrost-related mass movements, whether on slopes or in valley bottoms rich in ice, must be considered. Other hazards that warrant attention in the valleys south of Dawson relate to icing, mostly at stream crossings, and meander migration, alongside sections of road traversing valley bottoms.

1.2 Study Area

The Project is located in the White Gold District of west-central Yukon, approximately 130 km south of Dawson. Detailed terrain stability and hazard mapping were completed to encompass all proposed mine site facilities and the access route from Dawson (**Figure 1-1**). The 526 km^2 study area consists of two main sections:

1. **Access Road Corridor** – The proposed access road corridor extends from KP 700 of the North Klondike Highway, 16 km east of Dawson, southward to the proposed mine site. It has a minimum width of 2 km, roughly centred along the proposed road alignment, with local widenings up to 5 km to encompass heights of land where processes upslope could potentially affect infrastructure (**Figure 1-1)**. From north to south, the route initially follows existing government-maintained roads ascending Hunker Creek, over the divide near King Solomon Dome and descending Sulphur Creek. Along and south of the Indian River valley, the route generally follows existing roads used by placer miners, with some upgrades, realignments and extensions required to meet design criteria and make the road suitable for year-round access. After crossing Indian River, the route ascends Eureka Creek, follows a ridge system at the headwaters of Henderson Creek, and then descends Maisy May Creek to Stewart River, which is proposed to be crossed by barge in summer and ice road in winter. Crossing will not be possible during spring break-up and fall freeze-up each year. South of Stewart River, the route ascends Barker Creek, climbs over a divide and descends lower Ballarat Creek to its confluence with Yukon River, which is also only proposed to be crossed by barge in summer and ice road in winter. The route follows the south side of Yukon River until it crosses Coffee Creek to Coffee Camp, after which it ascends a ridge above "Latte Creek" to the proposed mine site.

2. **Mine Site Area** – The proposed mine site is situated on the divide between the headwaters of "Latte Creek" and Halfway Creek, in the northern Dawson Range. The mine site study area encompasses the footprints of all proposed mine infrastructure, with a surrounding buffer of at least about 1 km. Key infrastructure within the overall mine footprint includes four open pits, waste rock storage facilities, a heap leach facility, ore stockpiles and processing facilities.

Mapping and assessment of the buffer around the overall Project footprint was completed such that any upslope instabilities or hazards were identified, minor adjustments in site or route selection were accommodated, and environmental studies had a foundation on which their potential effects assessments could be based. A geographic division of the study area into 14 contiguous sections is depicted on **Figure 1-1** as a basis for reference throughout the report.

The Black Hills Creek and upper Ballarat Creek valleys were investigated as possible route options (as described further in Section 3.2). Both route options, however, were excluded from further mapping and consideration due to the extent and distribution of less favourable conditions for road construction and maintenance.

1.3 Objective

PECG completed project-specific terrain stability and hazard mapping to inform the siting and design of mine site facilities and the access road, in general accordance with YESAB's hazard mapping expectations for Project proposal submission. Three supporting objectives facilitated this ultimate goal: (1) delineate and characterize distinct terrain units and geomorphological processes within the study area; (2) identify potential hazards posed by the environment on the Project, and by the Project on the environment; and (3) provide a basis for project engineers to evaluate and mitigate risks to project infrastructure.

2 Physical Setting

Understanding the regional setting is critical to accurate representation of terrain stability and hazards within the Project area. The following sections describe the physical setting, largely drawing on summaries from McKillop et al. (2013) that were prepared for the same Klondike Plateau study region.

2.1 Physiography

The Project is entirely within the Klondike Plateau physiographic region (Mathews, 1986) and ecoregion (Smith et al., 2004). The Klondike Plateau is a Tertiary-age upland that has undergone variable uplift and stream dissection, resulting in rounded summits and ridges, and deep, V-shaped valleys (Mathews, 1986). Accordant hill crests represent an approximation of the former plateau surface. Most valley sides exhibit convex profiles, with concave terrain restricted to localized bench or gully features and valley bottoms filled with material derived from upslope erosion. Elevations within the study area range from just under 370 m above sea level at the Stewart River to about 1,250 m along "Henderson Ridge" (**Figure 1-1**). Local relief is typically between 300 and 450 m.

The proposed access road crosses the Indian, Stewart and Yukon rivers, which have incised deeply into the plateau surface. The Indian and Stewart rivers are both major tributaries to Yukon River; all three rivers meander westward across the access road corridor. Valley reaches of the rivers and major tributaries become more deeply incised with increased proximity to the Yukon River (Bond and Lipovsky, 2011). Reaches in close proximity to the Yukon River commonly contain stream-cut bedrock terraces, along one or both sides of the valley, which are typically capped by fluvial sand and gravel. Bedrock terraces are thought to be formed by accelerated down-cutting initiated by the reversal of the Yukon River from a south to north-flowing drainage during the late Pliocene to early Pleistocene (Tempelman-Kluit, 1980; Jackson et al., 2008). Some headwater tributaries also exhibit anomalously steep toe slopes that may correspond to this base level change.

The climate of the Klondike Plateau is continental; summers are warm and short, and winters are long and cold. Mean annual temperature is near -5°C, with mean January temperatures of -23 to -32°C and mean July temperatures of 10 to 15°C (Yukon Ecoregions Working Group, 2004). Strong thermal inversions are common from December to February, in association with prolonged atmospheric stability (Williams, 1995). During this period, valley bottom temperatures can be tens of degrees Celsius lower than surrounding higher-elevation areas. Mean annual precipitation ranges from about 300 to 500 mm, giving the region a semi-arid classification (Yukon Ecoregions Working Group, 2004). The wettest period is in the summer, when most precipitation falls as rain during convective rainshowers and thunderstorms.

Thunderstorms trigger wildfires throughout the region, which exhibits the highest frequency of lightning strikes in Yukon (Yukon Ecoregions Working Group, 2004). Yoshikawa et al. (2003) estimate natural wildfire recurrence of 50 to 300 years in the similar boreal forest of interior Alaska. **Figure 2-1** depicts the fire history within the region encompassing the study area. As described below in Section 2.4, fire has important implications for ground stability in areas of permafrost, such as observed in a recently burned area along Barker Creek that post-dates the fire inventory depicted on this figure.

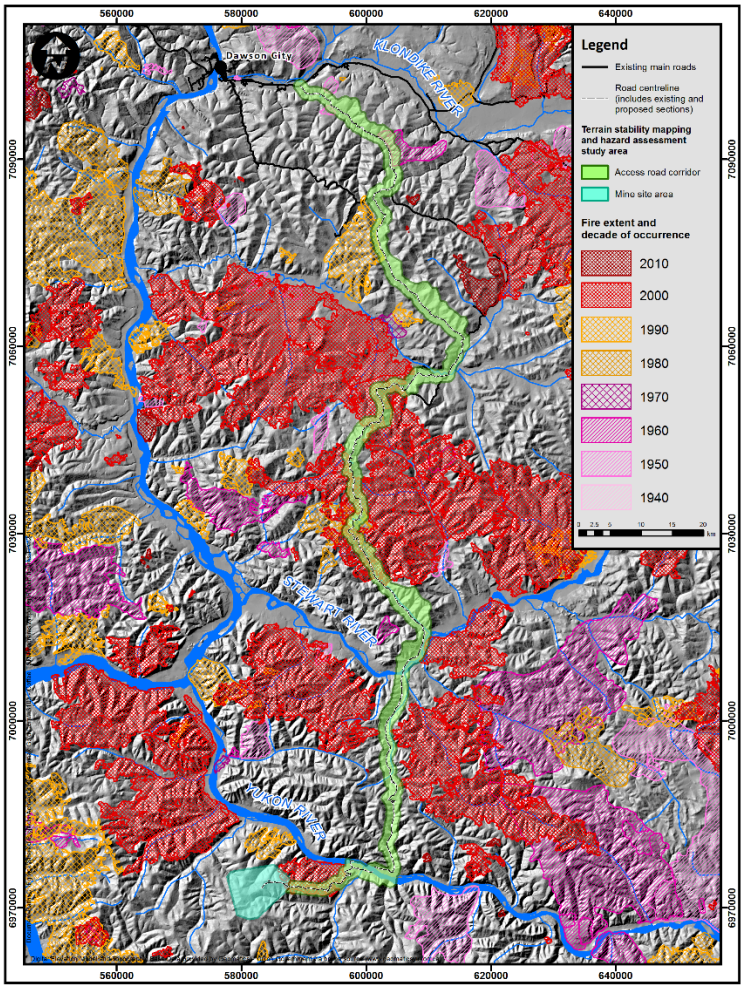

Figure 2-1. Fire history in the region encompassing the study area

2.2 Bedrock Geology

The Project area occurs mainly within the Yukon-Tanana Terrane, an accretionary sequence including former volcanic island arcs and continental shelf depositional environments (Mortensen, 1992) (**Figure 2-2**). This terrane comprises metamorphosed Paleozoic-aged schists and gneisses, intruded by Mesozoic-aged granitic rocks, and locally overlapped by volcanic rocks (Colpron et al., 2006). Devonian to Mississippian-aged quartzite and muscovite quartz-rich schist of the Nasina assemblage are the most extensive (Gordey and Makepeace, 2003). The Late Devonian- to Mississippian-aged Pelly Gneiss Suite of granitic gneisses with localized amphibolite, quartz-mica schist and phyllite occurs throughout the region. The Klondike Schist, a Carboniferous to Permian-aged assemblage of metamorphosed pelitic and volcanic rocks, with bands of marble and inclusions of phyllite, is widespread in the vicinity of Dawson. The Dawson Range Batholith intruded the schist-dominated metamorphic rocks in the mid-Cretaceous. Its Whitehorse Suite consists of granitic rocks of felsic to mafic composition; granodiorites, granites and quartz monzonites are common. During the Late Cretaceous, the andesitic Carmacks formation was emplaced across portions of the region.

Outcrops of intact bedrock are rare across the region. The most prominent bedrock outcrops form tors, which are erosional, castellated towers from former plateau surfaces. Tors typically form in granitic lithologies and punctuate several high summits and ridges in the mine area. Ridges and spurs composed of metamorphic rocks are typically overlain by mantles of weathered fragments of bedrock, resulting in few intact outcrops. Bedrock is also exposed in lower-slope settings, where fluvial incision has over-steepened valley walls and outpaced compensatory hillslope adjustments. This is most common within the major river valleys and in tributaries near Yukon River.

The study area is situated within an area of low seismic activity between the Denali and Tintina faults, with only several mapped earthquake epicentres occurring north of the Stewart River (Hyndman et al., 2005) (**Figure 2-3**). As such, most mass movements in the study area are triggered by processes other than earthquakes (as described further in Section 2.5).

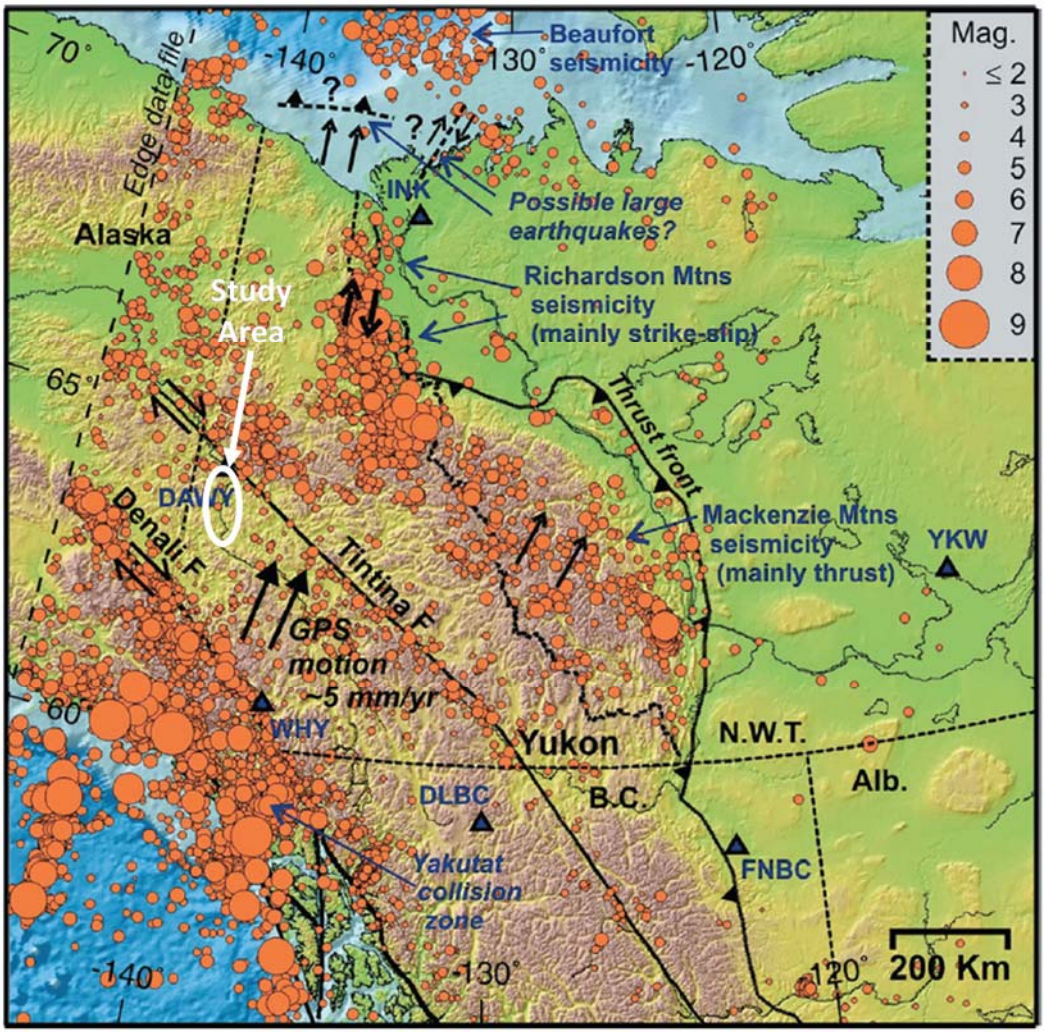

Figure 2-3. Historical instrumental seismicity in northwestern Canada (seismographs shown as triangles; modified from Hydman et al., 2005).

2.3 Surficial Geology

Nearly all of the study area remained unglaciated throughout the Pleistocene, with the exception of a few cirque glaciers that once occupied the high, north-facing, alpine headwaters of Coffee Creek, and portions of the Stewart River valley and its adjacent tributaries that were ice-covered during the pre-Reid glaciation (>200 ka) (Duk-Rodkin, 1999). Periglacial weathering and colluvial, fluvial and eolian processes have largely modified and redistributed any remnant glacial sediments. Thus, areas within the pre-Reid glacial limit, which may once have been mantled by glacial deposits (e.g., till), are mapped primarily as colluvium.

Discontinuous glaciofluvial terraces occur along the Yukon River valley, which was a major meltwater channel during pre-Reid glaciations. These terraces may be observed at several elevations, up to 250 m above the current level of the Yukon River (Huscroft, 2002; Huscroft et al., 2006). Recognition of glaciofluvial terraces is difficult in areas where fine-grained colluvium blankets the terrace surfaces.

Loess, windblown silt and fine sand, is widespread throughout the Klondike Plateau. Most loess in the region was mobilized from unvegetated outwash plains along the Donjek, White and Yukon River valleys. It was dominantly active during glacial and deglacial periods of the Pleistocene, transported by prevailing southerly winds, and katabatic winds draining off the former ice sheets (Bond and Lipovsky, 2011). Significant loess deposits accumulated in valley bottoms directly down-wind of the major outwash plains (Bond and Lipovsky, 2011), on the lee (north) side of hills (Birkeland, 1984), and in other areas where topography, vegetation and soil moisture provide suitable environments for trapping loess (Tsoar and Pye, 1987). Loess is best preserved on northerly aspects where it is effectively anchored in place by shallow permafrost, and on relatively level ground in hollows amongst boulder-sized blocks. *In situ* loess was observed in at least one road cut along the proposed access route. Much of the loess in the region has been redistributed and concentrated through periglacial, colluvial and fluvial processes. Resedimented loess mixes with organic material to form aprons on lower slopes and in valley bottoms that rival in thickness the >20 m *in situ* loess deposits preserved near the mouths of tributaries of the Donjek River (Bond and Lipovsky, 2011).

In the absence of glacial erosion, a mantle of *in situ* weathered bedrock known as felsenmeer has accumulated on level to gently sloping ground. The character of the felsenmeer depends primarily on the bedrock lithology and the intensity and depth of periglacial weathering. Large, angular clasts that detach from the underlying fractured bedrock gradually weather to cobble, gravel and eventually sand or silt-sized particles. A metre-thick, fining-upward gradation is commonly visible in pits or trenches dug within felsenmeer. Deep horizons have a jigsaw puzzle-like fit to the clasts, commonly preserving original bedrock structures. Shallow horizons have undergone sufficient disaggregation and cryoturbation to destroy any structure, and they contain a higher matrix content.

Colluvium is the most widespread surficial material within the study area and broader Klondike Plateau. Typically, it is composed of weathered bedrock and loess reworked by gravitational processes. It covers almost all slopes with thicknesses ranging from less than a metre, near ridge crests and on steep slopes, to more than ten metres in slope concavities and valley bottoms. The texture of colluvium reflects the local bedrock lithology and the amount of loess and organics intermixed with it. Colluvium derived from the weathering and entrainment of granitic rocks tends to be blocky to pebbly, with a silty-sand matrix, whereas

colluvium derived from schists and gneisses is generally finer-grained, comprising cobble-sized angular fragments and a more silt-rich matrix (Schaetzl and Anderson, 2005). Slopes underlain by permafrost tend to have a higher silt content than those without permafrost, and aprons in toe-slope positions are dominated by silt and organics. These aprons are locally referred to as 'muck' (Tyrrell, 1917; Fraser and Burn, 1997). Colluviation occurs mainly through soil creep, solifluction, slopewash and landsliding, the relative importance of each depending on slope steepness and permafrost distribution.

Fluvial deposits occupy valley bottoms throughout the region. Headwater streams are typically confined to narrow, V-shaped valleys and have beds of cobbly gravel veneered by sand. Channel bed and bank material along meandering lower reaches are typically composed of sandy gravels overlain by silty flood deposits. Floodplains are typically absent in headwater reaches, but are hundreds of metres wide along the lower reaches of major tributaries. Inactive floodplains may be overlain by loess, and interbedded with, or overlain by, organic material.

Organic deposits are common throughout the Klondike Plateau. On well drained forested slopes free of permafrost, organic deposits are relatively thin (<15 cm) and composed predominantly of fibrous woody forest litter. On slopes with shallow permafrost and in depressions with poor drainage, poorly to moderately decomposed peaty organic material is commonly 30-40 cm thick and may exceed 100 cm. The type and thickness of organic material is closely associated with permafrost distribution and drainage conditions.

2.4 Permafrost

2.4.1 Distribution

Permafrost is ground that remains below 0°C for more than one year. The study area is within the zone of extensive discontinuous permafrost, in which 50 to 90% of the ground is underlain by permafrost (Heginbottom, 1995). Recent permafrost modelling completed by Bonnaventure et al. (2012) for southern Yukon indicates that the distribution of permafrost within the region exhibits characteristics of both subarctic and mountain permafrost, being prevalent in valley bottoms and on northern aspects. Locally, permafrost distribution is related to slope aspect, angle and shape, soil texture and moisture, and the thickness and type of organic cover (Williams, 1995; Williams and Burn, 1996). Permafrost is most common on north-facing slopes with thick organic cover and in fine-grained colluvial aprons extending into valley bottoms (Bond and Lipovsky, 2011). Steep, well drained, south-facing slopes are invariably permafrost-free.

A variety of landforms indicates the presence of permafrost within the study area, including pingos (**Figure 2-4**). Open-system pingos are scattered across the region, commonly in slope-toe settings of small drainages where groundwater discharges to surface through discontinuities in the permafrost table (Hughes, 1969; Bond and Lipovsky, 2011). Most are collapsed and distinguished based on the ramparts encircling a small pond. Other indicators of permafrost in valley settings include thermokarst ponds and gullies, ice-wedge polygons, active layer detachments, cryoplanation terraces, solifluction lobes, stone stripes and slopewash runnels (**Figure 2-4**).

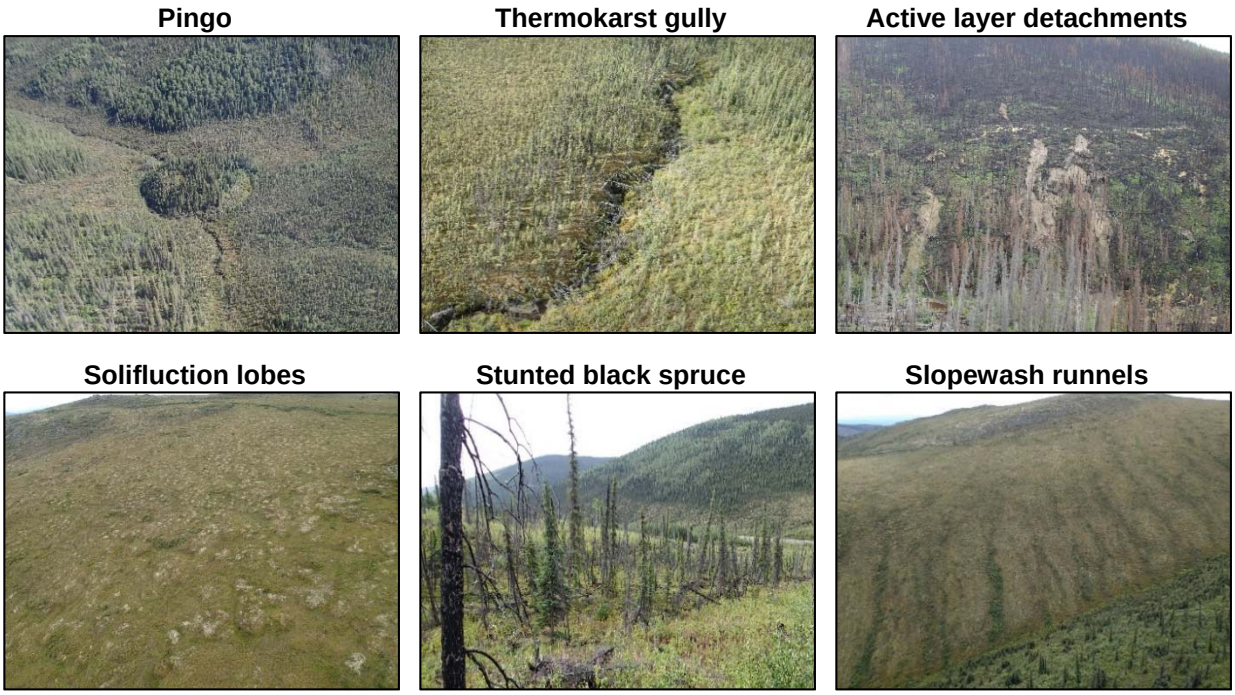

Figure 2-4. Example of features indicative of permafrost in the study area

Vegetation distribution and health can be reasonable predictors of permafrost presence or absence, although local disequilibrium of permafrost and present climate can mislead inferences. In general, deciduous trees root more deeply than coniferous trees, and are unable to grow in thin active layers where soils are permanently wet or saturated. Stands of trembling aspen are invariably restricted to permafrost-free ground (Zoltai and Pettapiece, 1973; Williams, 1995). Conversely, black spruce is tolerant of cool, saturated soils and commonly grows in areas underlain by permafrost. A sparse, stunted canopy of black spruce with thick moss cover or sedge tussocks is a reliable indicator of shallow permafrost. Mixed coniferous and deciduous forests, including Alaska birch, may or may not be underlain by permafrost. In riparian zones, vegetation patterns reflect the frequency of flooding and presence of permafrost. The most frequently flooded areas are permafrost-free and dominated by willow, alder and balsam poplar. Irregular species composition and stand structure within the valleys south of Dawson commonly reflects a combination of regrowth from forest fire and other disturbances since the Yukon gold rush (Naldrett, 1981), which complicates interpretations of permafrost distribution.

Maximum thicknesses of permafrost within the study area and broader Klondike Plateau are highly variable. Thicknesses of 60 to 85 m have been reported from the Dawson area and valley bottoms in the nearby Klondike goldfields (McConnell, 1905; Brown, 1967; Milner, 1976; EBA, 1977, 1978). Drilling in the vicinity of the Project mine area in association with hydrogeological investigations penetrated permafrost with a wide range in thickness, up to about 165 m (Lorax Environmental Services Ltd., 2016).

2.4.2 Active Layer and Depth of Permafrost

The active layer is the upper layer of ground that freezes and thaws seasonally above the permafrost table. It may be restricted to soils and unconsolidated surficial materials, or it may extend into underlying, weathered or intact bedrock. At a local scale, its thickness primarily depends on elevation, aspect, soil texture, drainage, snow pack, vegetation cover and wildfire history (Williams and Burn, 1996; McKillop et al., 2013). The active layer is generally 1 to 2 m thick within the region encompassing the study area (Yukon Ecoregions Working Group, 2004; Bond and Lipovsky, 2011). Well drained, coarse-grained soils tend to have thicker active layers than poorly drained and fine-grained areas. In areas of thick, mossy organic cover, permafrost may be encountered at depths as shallow as just a few tens of centimetres. Areas with thick organic cover and variable moisture contents exhibit the greatest spatial variability in active layer thickness (Smith et al., 2009).

Active layer thickness varies seasonally and in response to natural and anthropogenic disturbances. Each year active layer thickness increases following spring snowmelt and typically peaks in late summer, before refreezing in the autumn. Active layers thicken by up to several times their original thickness following wildfire, which burns most or all of the insulating surface organic mat, reduces interception of snow by trees (where present), lowers the surface albedo, increases exposure to solar radiation, and decreases evapotranspiration (e.g., Burn, 1998; Smith et al., 2015).

2.4.3 Ground Ice

Permafrost may or may not contain ice. The ice content of permafrost is highly variable at both the regional and local scale. Areas of intact or weathered bedrock and well drained, coarse-grained colluvial mantles with permafrost generally contain little to no visible ice. Such ice-poor permafrost is common in upland settings, on summits and along ridges and spurs, and on moderate to moderately steep valley sides with convex or straight slopes. Permafrost more commonly contains excess ice[1] in the form of thin seams and lenses in silt-rich colluvial blankets, on solifluction slopes and in inactive portions of fluvial plains. Ice-rich permafrost with massive bodies of ice is most commonly encountered in organic terrain and silt-rich colluvial complexes in valleys. Enlarging thaw lakes in silt-rich valley bottom deposits provide evidence of locally high ice contents, perhaps as high as 50% by volume (Bond and Lipovsky, 2011).

Ground ice is sensitive to melting in response to permafrost degradation (thaw). Permafrost degradation occurs naturally over different time scales in response to localized surface disturbances such as wildfire or windthrow, which alter the ground thermal regime by removing the insulating surface organics, and climate change, which can result in anomalously high late-summer rainfalls or anomalously deep winter snowpacks. Anthropogenic disturbances also alter the ground thermal regime and are a common trigger for permafrost degradation. Permafrost degradation has little to no effect on ground surface topography or stability in areas of ice-poor permafrost where the permafrost table is commonly deep within coarse-grained colluvium or weathered bedrock. Areas of ice-rich permafrost within fine-grained materials, in contrast, are susceptible to irregular subsidence and thermokarst pond formation in response to permafrost degradation.

[1] The term excess ice is used throughout the report to represent the condition in which the volume of ice in the ground exceeds the total pore volume the ground would have under natural, unfrozen conditions.

2.5 Mass Movement Processes

Most mass movements within the study area are influenced, either directly or indirectly, by permafrost or related periglacial processes. Climatic warming is contributing to the degradation of permafrost, especially on southerly aspects and in broad valley bottoms exposed to prolonged sunlight during the summer. Permafrost degradation results in an increase in the volume (mass) of surficial material available for downslope transport and degree of soil saturation provided by the release of water from thawing ground ice. Shallow landsliding (e.g., active layer detachment) occurs once the shear stress exceeds the shear strength of the material. Thermokarst subsidence and gullying may occur in gentler terrain with excess ground ice. Deep-seated failures within thick overburden or weathered bedrock occur in response to failures of weak layers or thawing of ice bodies at depth. Deep-seated permafrost failures may result from movement of groundwater within unfrozen zones (taliks) in or beneath permafrost.

In the YGS' compilation of regional-scale surficial geology mapping (Lipovsky and Bond (compilers), 2014), a number of features interpreted as paleo-landslides are identified. All were assessed in the field and/or using the high-resolution spatial data acquired specifically for this project (as described below in Section 3.1). Some of the features may have evolved over millennia of differential erosion and mass wastage, as opposed to coherent mass movements. Most exhibit subdued topography with no evidence of recent movement in ground or vegetation disturbance patterns. Only those with possible evidence of continued instability have been included in the project-specific mapping of terrain stability and hazards (Map 2, **Appendix B**).

The most common triggers for both shallow and deep-seated failures are intense or prolonged rainfall, or heat events and wildfires (**Figure 2-1**). Seasons of increased mass movements include the period from late July to early September, when active layers are thickest, permafrost is warmest and rainfall is greatest, as well as late May or early June, when erosion during snowmelt freshet freshly exposes permafrost to fluvio-thermal erosion and slumping. Slopes underlain by permafrost that have not experienced recent wildfires are more prone to active layer detachment failures immediately following a fire (Coates, 2008).

2.6 Anthropogenic Disturbance

Anthropogenic disturbances related to placer mining dating back to the Yukon gold rush of the late 19th century are widespread within most of the valleys in the study area. Valley bottoms and adjacent terraces have been most severely altered, commonly having all their surficial material mined for placer gold before being deposited in hummocky piles of placer tailings (**Photo 2-1**). Valley sides and uplands have been locally disturbed by construction of access roads and exploration teams searching for gravel terraces and the bedrock source of the placer gold. A more detailed characterization of the disturbances and their implications for project infrastructure is provided below in reference to the specific terrain unit, Anthropogenic Disturbances (Section 4.1.10).

Photo 2-1. Hummocky tailings piles from placer mining in the Indian River valley

3 Methods

PECG employed a systematic approach for completing terrain stability and hazard mapping for the Project, leveraging local knowledge of permafrost conditions and extensive experience mapping mass movement and fluvial hazards in this unglaciated region. Each main phase of work is described below.

3.1 Background Review and Consultation

PECG strengthened our pre-existing understanding of terrain characteristics and related hazards within the study area by reviewing several important data sources: aerial photography; LiDAR-derived elevation data; satellite imagery; existing bedrock, surficial and geomorphological mapping; previously collected field data; and peer-reviewed literature (**Table 3-1**).

PECG also took advantage of our existing collaborative working relationships with senior staff at Yukon Geological Survey (YGS) and Yukon Highways & Public Works (Yukon Highways) to acquire local knowledge from their field experience in the study area. We consulted Jeff Bond (Manager, Surficial Geology, YGS) about his knowledge of the stability of paleo-landslides within the study area. Our team met with staff at Yukon Highways, in Dawson, to discuss their experience with mass movement and icing hazards along the government-maintained section of the proposed access road south of Dawson. Stream crossings prone to icing, according to Yukon Highways' staff, have been included in the map inventory of potential icing hazard sites (Map 2, **Appendix B**).

3.2 Field Investigations

Field work was completed prior to completion of the terrain stability mapping due to concurrent acquisition and processing of the high-resolution aerial photography and LiDAR-derived elevation data on which the mapping of the access road corridor is now based. A thorough review of available data sources identified above in Section 3.1 in advance of field work ensured field investigations provided satisfactory representation of the diversity of terrain and hazards within the study area. Areas with the greatest potential for instability were prioritized for investigation.

Field investigations were conducted throughout the study area by a two- to three-person crew over a two-week period in mid-August 2015 (**Figure 3-1**). Jim Coates (Kryotek) additionally participated in the early phases of the field program, including an initial helicopter reconnaissance of the entire study area, in order to share his local knowledge. Conditions were mostly favourable for field work: the ground was free of frost and snow, active layer thicknesses were likely near their maxima, and weather conditions had little to no effect on progress or site access. A helicopter was used strategically for reconnaissance and site access purposes during the program, with priority for landing sites given to areas inaccessible from existing roads or trails. A 4WD pick-up truck was used for site access along existing sections of government-maintained road, as well as other sections of placer mining roads in reasonable condition. A helicopter-dropped UTV facilitated access along rougher sections of road or trail in the southern portion of the study area. Foot traverses from vehicle drop-off locations enabled access to sites inaccessible to vehicles and better afforded understandings of transitional conditions.

In total, 96 sites were investigated on the ground in detail, including along candidate sections of access road corridor no longer under consideration ('detailed field sites' in **Figure 3-1**). At each site, a hand-dug soil pit or existing exposure (e.g., road cut) was used to examine the sub-surface. Standardized field sheets were used to record data on site characteristics (e.g., coordinates; elevation and aspect; slope position, shape and steepness), terrain characteristics (e.g., surficial material, texture, surface expression and geomorphological process), drainage conditions (e.g., drainage class; seepage depth) and vegetation (e.g., dominant tree species and ground cover), based on pertinent sections and standards of the *Field Manual for Describing Terrestrial Ecosystems* (BC Ministry of Forests and Range and BC Ministry of Environment, 2010), with an additional allowance for observations related to permafrost conditions (e.g., active layer thickness; ground ice observations) and terrain hazards. Active layer thickness was determined through a minimum of five frost probing measurements at each site. At sites most representative of common terrain units, soil horizons were examined, documented and classified to at least the Great Group level according to *The Canadian System of Soil Classification* (Soil Classification Work Group, 1998) in order to support terrestrial ecosystem mapping being completed by other project team members. A basic sketch of the soil profile, along with photographs of both the soil profile and the surrounding area, accompanied all observations. Photographs were taken of all field sites, as well as of any features of interest. Field data from all detailed sites are included in **Appendix D**.

Pertinent observations from several hundred additional sites were recorded based on visual reconnaissance during short stops along a foot traverse, vehicle drive-by or helicopter fly-over (**Figure 3-1**). Most observations related to surficial material thickness, vegetation associations, drainage and evidence of instability or permafrost characteristics. Accompanying photographic documentation was collected at the majority of observation sites. Basic field notes from visual reconnaissance sites were referenced during mapping, but are not appended due to inconsistency in their contents and formats.

3.3 Terrain and Terrain Stability Mapping

PECG completed terrain and terrain stability mapping within the 526 km^2 study area to support project engineering and environmental studies[2], in accordance with YESAB's recent publication, *Geohazards and Risk: A Proponent's Guide to Linear Infrastructure* (Guthrie and Cuervo, 2015). Terrain mapping is the process of dividing the landscape into areas (polygons) according to surficial materials, landform characteristics and geomorphological processes. Terrain stability mapping involves further consideration of drainage, slope and, in this case, permafrost characteristics, resulting in the classification of each polygon as stable, potentially unstable or unstable.

3.3.1 Mapping Protocols and Attributes

PECG completed all mapping based on field-calibrated interpretations of high-resolution digital aerial photography and LiDAR-derived elevation data (acquired at a flight scale of approximately 1:30,000), using

[2] In addition to supporting the siting and design of the proposed mine facilities and access road, mapping was completed in general accordance with bioterrain mapping protocols (e.g., includes drainage and aspect considerations) in order to support terrestrial ecosystem mapping being completed by other project team members.

softcopy photo-interpretation workstations with either PurVIEW or DAT/EM Summit Lite software packages. Polygon delineation was typically completed at a scale of 1:10,000, although larger scales (e.g., 1:2,500) were used as necessary to delineate important details. Previous geomorphological (terrain) mapping completed by AECOM (2012) within Kaminak's property south of Yukon River was adapted and refined for terrain stability mapping purposes, and to ensure consistency with mapping protocols used north of Yukon River.

Terrain (stability) polygons were delineated primarily based on the YGS' adaptation of the *Terrain Classification System for British Columbia* (Howes and Kenk, 1997) and the *Mapping and Assessing Terrain Stability Guidebook* (BC Ministry of Forests, 1999). We also consulted *A User's Guide to Terrain Stability Mapping in British Columbia* (J.M. Ryder and Associates, Terrain Analysis Inc., 2002) and *A Guide for Management of Landslide-Prone Terrain in the Pacific Northwest* (BC Ministry of Forests, 1994). Certain refinements were made based on unique conditions encountered in the study area and to better meet project-specific objectives.

Terrain stability polygons were delineated with consideration for eight main attributes, each of which is defined below, in addition to the terrain stability classes described below in Section 3.3.2. Complete explanations and descriptions of attribute values are available on the terrain mapping (Map 1) and its cover page of code definitions (**Appendix A**).

- **Surficial Material** – e.g., colluvium (C), weathered bedrock (D), alluvium (F)

  This attribute defines the surficial material present and its depositional (genetic) origin. The surficial material represents the core element of a particular terrain unit and label.

- **Surface Expression** – e.g., veneer (v), blanket (b), terrace (t)

  This attribute refers to the form, or pattern of forms, expressed by the surficial material. Up to two surface expressions describe a particular surficial material.

- **Texture** – e.g., silty (z) sand (s), mixed angular fragments (x), gravel (g)

  This attribute refers to the size, sorting and shape of the particles comprising the surficial material. Textures were assigned to all polygons, including those not investigated in the field, based on typical conditions observed at field sites and documented in previous investigations in the region (e.g., Bond and Lipovsky, 2011; McKillop et al., 2013). Such an approach is consistent with textural characterization in YGS' surficial geology mapping (Lipovsky and Bond (compilers), 2014) and aids standardization of terrain units. Up to three textures describe a particular surficial material, in order of increasing proportion[3].

- **Geomorphological Process** – e.g., gully erosion (-V), active layer detachment (-Xf)

  This attribute refers to geomorphological processes that are either occurring, or have occurred, within a polygon. Up to three geomorphological processes and respective subclasses can be identified.

[3] This convention is used in place of YGS' opposite convention – in order of decreasing proportion – due to its consistency with verbal description (e.g., sgF is a sandy gravel fluvial deposit dominated by gravel).

- **Drainage Class** – e.g., well drained (w), imperfectly drained (i), poorly drained (p)

  This attribute refers to the speed and extent to which water is removed from the soil in relation to additions. It considers both the rate at which water is able to be removed from an area as a result of landscape characteristics (e.g., slope), and the permeability of the surficial materials themselves. In this study area, drainage class is strongly influenced by the depth to permafrost, where present. Drainage class is represented by a single value, or a range between two values.

- **Depth to Permafrost** – e.g., near-surface (n, <0.4 m), shallow (s, 0.4-1 m), deep (d, >1 m)

  This attribute refers to the estimated maximum (end of summer) depth to permafrost, inferred from vegetation and drainage indicators, and landform associations characterized based on field measurements. Depth to permafrost is locally variable, so this is considered an average for the polygon.

- **Permafrost Ice Content** – e.g., ice-poor (p), ice-moderate (m), ice-rich (r)

  This attribute refers to the relative volumetric ice content of permafrost, interpreted based on field observations of ground ice in different hydrogeomorphic settings; Kryotek's previous permafrost-related drilling and geophysical survey experience in the region; and recent research in this unglaciated region (e.g., Bond and Lipovsky, 2011; McKillop et al., 2013). Project-specific permafrost mapping and characterization undertaken concurrently by TT-EBA along the access road centreline (2016b) and within the mine area (2016c), which references geotechnical/hydrogeological drilling results from the mine area (Lorax Environmental Services Ltd., 2016), also informed ice content interpretation. This classification is not intended to apply any particular volumetric ice content (%); rather, its purpose is to distinguish areas relatively and according to distinct forms of ground ice. With approximate correlations with TT-EBA's (2016b,c) ice content classification identified in parentheses, ice-poor permafrost typically contains no visible ice (~Fn: ice not visible); ice-moderate permafrost typically contains segregated ice in the form of seams and lenses, but rarely any large ground ice bodies (~Fv: visible excess ice); and ice-rich permafrost typically contains large accumulations of segregated ice in the form of ice wedges and other massive bodies, in addition to seams and lenses (~Fi: very ice-rich)[4]. Localized differences between TT-EBA's (2016b,c) and PECG's (this study) interpretations of permafrost distribution and ice content have been reviewed, are generally minor, and are expected in light of limited ground data.

- **Slope Class** – e.g., 2 (gentle, 6-26%), 4 (moderately steep, 50-70%)

  This attribute refers to the dominant, typically average, range in slope steepness. Slope class was visually assigned based on a five-level raster model of slope class generated from the LiDAR-derived elevation data.

[4] The terms ice-poor, ice-moderate and ice-rich, as defined here, are used throughout the report.

Additional point and linear features too small to be mapped as polygons were identified using on-site symbols. Examples include thermokarst ponds (point) and slope failures (line). Whether or not a polygon encompassing an on-site symbol that represents a geomorphological process (e.g., gully erosion) was attributed as such (e.g., -V) depended on the proportional area of the polygon that is affected by the process. For example, a single gully did not necessarily require inclusion of the gullying process in the polygon label. Point or linear features occurring entirely within anthropogenic disturbance polygons were not mapped.

3.3.2 Terrain Stability Classification

Terrain stability mapping in British Columbia typically involves the assignment of a single terrain stability class to each polygon, in order to provide a relative ranking of the likelihood of a landslide occurring after timber harvesting or road construction (BC Ministry of Forests, 1999). This protocol yields a map depicting terrain stability classes after a disturbance – for example, following road construction – but does not readily distinguish the stability of polygons in the absence of disturbance. The hazards posed by a slope above and unaffected by road construction (i.e., potential effects of the environment on the Project), for example, could be inaccurately represented on a conventional terrain stability map. Particularly in this landscape of discontinuous permafrost, some of which is ice-rich and prone to thermokarst activity, it is important to differentiate terrain stability classes in both the existing and disturbed condition. As such, both existing and disturbed terrain stability classes were assigned to each polygon to enable mine facility and road design engineers to accurately evaluate risks posed locally and by hazards upslope or downslope of the proposed infrastructure.

The ‘existing terrain stability’ class represents current conditions, in the absence of any project-related activity; the ‘disturbed terrain stability’ class represents conditions following disturbance to ground conditions from road/facility construction without mitigation (**Table 3-2**). As a conservative base case, the disturbed stability class assumes typical cut-and-fill road construction without any measures to mitigate potential instability on steep slopes or from disturbance to permafrost with excess ice. Stripping or compaction of organics, and only regular surface water management, would be typical disturbances. Full details for both the existing and disturbed terrain stability classes are provided on the mapping of terrain stability and hazards (Map 2) and its cover page of code definitions (**Appendix B**).

Further modification of conventional terrain stability classes used in British Columbia was necessary to accommodate the potential for instability related to thermokarst processes. If overlooked in the siting and design of project infrastructure, thermokarst could significantly increase infrastructure (e.g., road) maintenance costs and potentially affect worker safety through its potential influence on ground stability (e.g., road surface grade) (McGregor et al., 2010). Therefore, the assignment of terrain stability classes additionally considers the presence or absence of permafrost (as shown on the cover page of the mapping of terrain stability and hazards (Map 2) in **Appendix B**).

Table 3-2. Terrain stability classification system developed for the Coffee Gold Project

Symbol	Class	Condition	Interpretation		Common terrain characteristics	
			Existing	Disturbed	Existing	Disturbed
I	stable	permafrost	No significant stability problems.		Planar to gently sloping bedrock and weathered bedrock; active fluvial units.	Planar to gently sloping bedrock, weathered bedrock and active fluvial units with deep, ice-poor permafrost.
		no permafrost			Planar to low sloping bedrock and weathered bedrock; active fluvial units.	
II	generally stable	permafrost	Very low likelihood of slope instability.	Very low likelihood of slope instability; no thermokarst subsidence or erosion expected.	Colluvial mantles on gentle slopes; gently sloping colluvial complexes; gently sloping fluvial units; organic deposits; moderately steep bedrock and weathered bedrock.	Colluvial mantles on gentle slopes with deep, ice-poor permafrost; gently to moderately sloping fluvial units with deep, ice-poor permafrost.
		no permafrost	Very low likelihood of slope instability.		Gently to moderately sloping colluvial mantles and fluvial units; moderately steep bedrock and weathered bedrock.	
III	generally stable with minor potential for instability	permafrost	Low to moderate likelihood of slope instability.	Low to moderate likelihood of slope instability and/or minor thermokarst subsidence or erosion possible.	Poorly drained colluvial mantles on moderate slopes; moderately sloping colluvial complexes; imperfectly drained colluvial mantles on moderately steep slopes; ice-poor to ice-moderate permafrost.	Poorly drained colluvial mantles on gentle slopes; imperfectly drained colluvial mantles on moderate slopes; ice-poor to ice-moderate permafrost.
		no permafrost	Low to moderate likelihood of slope instability.		Colluvial mantles on moderately steep slopes.	
IV	potentially unstable	permafrost	Expected to contain areas with a high likelihood of slope instability.	Expected to contain areas with a high likelihood of slope instability and/or moderate thermokarst subsidence or erosion.	Poorly drained colluvial mantles on moderately steep slopes; moderately steep colluvial complexes.	Any surficial unit thicker than a veneer with ice-moderate permafrost; poorly drained colluvial mantles on moderate slopes; imperfectly drained colluvial mantles on moderately steep slopes.
		no permafrost	Expected to contain areas with a high likelihood of slope instability.		Colluvial units on moderately steep to steep slopes.	
V	unstable	permafrost	Expected to contain areas with a very high likelihood of slope instability and/or thermokarst; may or may not exhibit evidence of previous slope failure and/or thermokarst.	Expected to contain areas with a very high likelihood of slope instability and/or major thermokarst subsidence or thermal erosion; typically exhibits evidence of previous slope failure and/or thermokarst.	Any unit with evidence of slope failure and/or thermokarst subsidence or thermal erosion.	Any unit with evidence of slope failure or ice-rich permafrost; poorly drained colluvial mantles on moderately steep slopes.
		no permafrost	Expected to contain areas with a very high likelihood of slope instability; typically exhibits evidence of previous slope failure.		Any unit with evidence of slope failure; typically occur on moderately steep to steep slopes.	

3.4 Hazard Identification

Hazards posed by mass movements and fluvial processes were identified and characterized in this study.

3.4.1 Slope Failure and Thermokarst

The type and distribution of mass movement (slope failure) and thermokarst hazards within the study area were identified by assessing geomorphological process codes (polygon label), on-site symbols (point or linear features) and terrain characteristics (Map 2, **Appendix X**; see Section 4.2 for hazard process descriptions). Mass movements involve the downslope transport of material, such as soil and/or rock, under the influence of gravity. Mass movements may or may not be associated with water, snow or ice[5]. Within the study area, mass movements occur through a variety of processes in addition to landsliding. Landslide terminology used in this report follows the standards defined by Hungr et al. (2014), a recent update to the classic classifications established by Varnes (1978) and Cruden and Varnes (1996), which describe the process as well as the type of material involved in the mass movement. Where two modes of failure contribute to movement, terminology was assigned based on the apparent dominant mode. The landslide terms applied in this report are illustrated schematically in **Figure 3-2**.

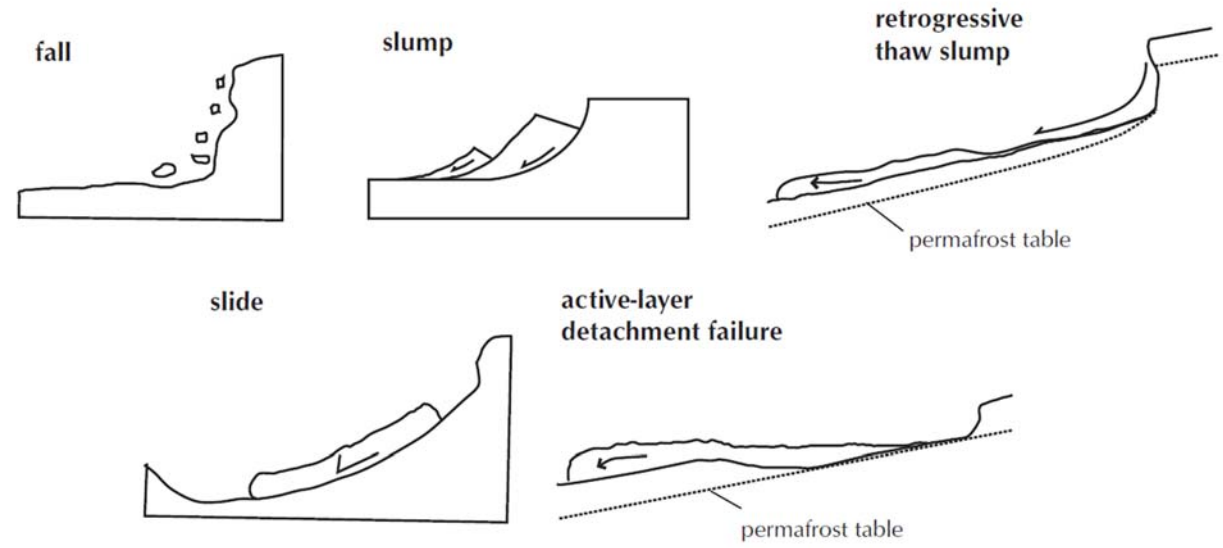

Figure 3-2. Schematic of landslide types in the study area (adapted from Huscroft et al., 2004)

[5] Snow avalanches were not included in this description of mass movement processes because there is no mappable evidence (e.g., vegetation patterns) of their occurrence within the study area; small loose snow or slab avalanches may occur on moderate to steep slopes in wind-loaded alpine areas.

Where more accurate representation of the role of permafrost was required, refinements to standardized landslide terminology were made based on the *Multi-language glossary of permafrost and related ground-ice terms* (van Everdingen, 2005), which is consistent with the approach applied in the regional characterization of landslides along Yukon's Alaska Highway corridor (Huscroft et al., 2004). For example, permafrost environments also uniquely include "active layer detachments" and "retrogressive thaw slumps" (also known as retrogressive thaw flows) (**Figure 3-2**), each of which is described below. Also mapped and described below as part of this assessment are rock creep (*cf*. Blais-Stevens, 2010), gullying, thermokarst subsidence, thermokarst gullying, slopewash, solifluction and pingos.

Each polygon was broadly categorized according to its dominant hazard potential in order to clearly depict the nature of hazard governing the terrain stability class of each polygon. One of three categories was used: (i) slope failure potential is dominant, (ii) thermokarst potential is dominant, or (iii) slope failure and thermokarst potential are co-dominant. A hatch pattern was overlaid to indicate the 'applicable hazard category' in mapping of terrain stability and hazards (Map 2, **Appendix B**). This designation does not indicate whether or not the polygon exhibits any evidence of such hazards; the geomorphological process codes or on-site symbols serve that purpose. The 'slope failure potential is dominant' category is the default, thus all units that do not pose a thermokarst hazard (e.g., gentle, ice-poor colluvium and even flat, permafrost-free fluvial plains) are represented by this category. A terrain unit generally must exhibit ice-moderate or ice-rich permafrost to be considered for the 'thermokarst potential is dominant' category. Polygons with ice-moderate or ice-rich permafrost and slope classes of 3 or higher are candidates for the 'slope failure and thermokarst potential are co-dominant' category.

A generalized characterization was made of the nature of hazard posed by different geomorphological processes – in terms of likelihood, magnitude and project considerations – based on review of historical aerial photography in conjunction with field observations, in addition to professional experience in the region.

3.4.2 Meander Migration

Creek and river meanders that migrate through progressive bank erosion may pose a hazard to adjacent sections of the proposed access road (see Section 5.4 for hazard details). A systematic review was completed using the 2015, high-resolution aerial photography and LiDAR-derived elevation data to identify areas subject to erosion. Road segments proposed in close proximity to the outer bank of a meander, especially if separated by alluvial or fine-textured colluvial soils, or where meandering watercourses are crossed, were identified as sites of meander migration hazard.

A more detailed, time-transgressive assessment of meander migration hazard was completed for the proposed crossings of Indian, Stewart and Yukon rivers. These locations will have important project infrastructure, and minor shifts in the river thalwegs can trigger considerable erosion of unconsolidated banks. Historical river bank locations were digitized from georeferenced, historical aerial photographs and 2015 orthophotography, and then compared to estimate bank erosion trajectories and rates.

3.4.3 Icing

Icing, which refers to wintertime accumulation of aufeis, may pose a hazard and increase road maintenance requirements at certain stream crossings and draws (see Section 5.5 for hazard details). Sites along the proposed access road interpreted to be prone to icing in winter were identified based on consultation with Yukon Highways' staff and Jim Coates (Kryotek) for the government-maintained section of road. These identified sites were used to calibrate interpretations and identify potential icing hazards along the remainder of the proposed road alignment. In general, draws that contain fluvial veneers underlain by permafrost, are densely covered with willows, and are shaded by adjacent valley sides are commonly subject to icing. No attempt was made to estimate the width or thickness of icing at particular road crossings.

3.5 Soil Erosion Potential

Soil erosion potential represents the combined likelihood and magnitude of soil erosion as a result of surface runoff over exposed soils. Knowledge of soil erosion potential in advance of construction facilitates design of erosion and sediment control measures that are commensurate with site-specific risks to project infrastructure and adjacent ecological features (e.g., fish habitat). A five-level classification was developed to rank polygons according to their soil erosion potential (**Table 3-3**), based on the general approach and criteria outlined by BC Ministry of Forests (1999) and the erosion and sedimentation risk mapping completed by PECG (2013) for Casino Mining Corporation's proposed extension to the nearby Freegold Road. In general, soil erosion potential is directly proportional to silt and/or organic content, slope gradient, ground ice content and the severity of pre-existing gullying (mapping of soil erosion potential (Map 3, **Appendix C**).

Table 3-3. Soil erosion potential classification developed for the Coffee Gold Project

Symbol	Class	General criteria	Common terrain characteristics	Management implications
VL	very low	Increasing silt and/or organic content Increasing slope gradient Increasing ground ice content Increasing severity of pre-existing gullying ↓	Bedrock; planar weathered bedrock; planar fluvial deposits without permafrost.	No or only very minor surface erosion within small areas of exposed soil on locally steeply sloping ground (e.g., creek banks); conventional surface runoff management appropriate.
L	low		Gently to moderately sloping weathered bedrock; gently to moderately sloping, permafrost free colluvial mantles; gently to moderately sloping, permafrost-free fluvial deposits.	Expect minor erosion of fine sediments along ditch lines, cut slopes and across disturbed soils; avoid channelling water toward more sensitive downslope units.
M	moderate		Planar to gently sloping organic material; gently to moderately sloping colluvial veneers with shallow or near-surface permafrost; gently sloping colluvial blankets with shallow or near-surface permafrost; moderately steep to steeply sloping, permafrost-free veneers and thin veneers; fluvial deposits with shallow or near-surface permafrost.	Expect moderate erosion when water is channelled down road surfaces or ditches (minor thermal erosion possible in areas of permafrost); plan for preventative and remedial actions in disturbed areas, including measures to minimize concentrated surface runoff in areas of permafrost and to trap sediments.
H	high		Moderately steeply sloping colluvial veneers; moderately to moderately steeply sloping colluvial blankets with shallow to near-surface permafrost; gently sloping colluvial complexes; ridgetop saddles with silt-rich colluvial veneer.	Significant erosion problems are expected when water is channelled onto or over exposed soil on these sites (moderate thermal erosion possible in areas of permafrost), particularly on cut slopes; plan for preventative and remedial actions in disturbed areas, including measures to minimize concentrated surface runoff in areas of permafrost and to trap sediments.
VH	very high		Steeply sloping colluvial mantles with shallow or near-surface permafrost; moderate to steeply sloping colluvial complexes.	Severe surface and gully erosion problems can be created when water is channelled onto or over these sites (major thermal erosion possible in areas of permafrost), particularly on cut slopes; erosion is commonly evident in natural conditions. If area not avoidable, minimize concentrated surface runoff in areas of permafrost, minimize extent and duration of soil exposure, and promptly stabilize soils with salvaged vegetation (e.g., moss) cover or appropriate erosion control measures.

4 Terrain Description

The following sections describe the main terrain units (Section 4.1) and geomorphological processes (Section 4.2) encountered within the study area.

4.1 Terrain Units

Terrain units are defined based on a particular combination of surficial material(s), texture(s), surface expression(s) and geomorphological process(es), as well as drainage class(es), permafrost conditions and slope class. The diversity of terrain characteristics within the study area can be organized into ten terrain units for descriptive (**Table 4-1**) and geostatistical analysis purposes (**Figure 4-1**). Each terrain unit is described below according to its typical distribution, material composition, landform characteristics, permafrost conditions and geomorphological processes, and summarized in table form with standardized photographic perspectives. The descriptions incorporate directly applicable characterizations of corresponding 'landform-soil types' (LSTs) established for the unglaciated Klondike Plateau (McKillop et al., 2013) (**Table 4-1**). Colluvial terrain is subdivided into several distinct units due to significant differences in their composition, stability classification and sensitivity to disturbance. **Table 4-2** identifies standardized textures assigned to distinct colluvial terrain units based on field observations and in accordance with regional surficial geology mapping (Lipovsky and Bond (compilers), 2014).

Table 4-1. Cross-reference between main terrain units within the study area and established 'Landform-Soil Types' (McKillop et al., 2013)

Report Section	Terrain Unit	Corresponding Landform-Soil Type (LST) Number and Name
4.1.1	Bedrock and Weathered Bedrock	LST1: intact and weathered bedrock
4.1.2	Mixed Weathered Bedrock and Colluvium	LST2: mixed weathered bedrock and colluvium
4.1.3	Colluvial Mantles without Permafrost	LST10, LST11 & LST12: clast-rich colluvial blanket, veneer & thin veneer
4.1.4	Colluvial Veneers with Permafrost	LST3 & LST4: loess-rich & landslide-affected colluvial veneer
4.1.5	Colluvial Blankets with Permafrost	LST5: loess-rich colluvial blanket
4.1.6	Colluvial Complexes with Permafrost	LST6: loess-rich colluvial apron
4.1.7	Fluvial Landforms	LST8: fluvial plain
4.1.8	Glaciofluvial Terraces	LST9: glaciofluvial terrace
4.1.9	Organic Terrain	LST7: organic plain
4.1.10	Anthropogenic Disturbances	n/a

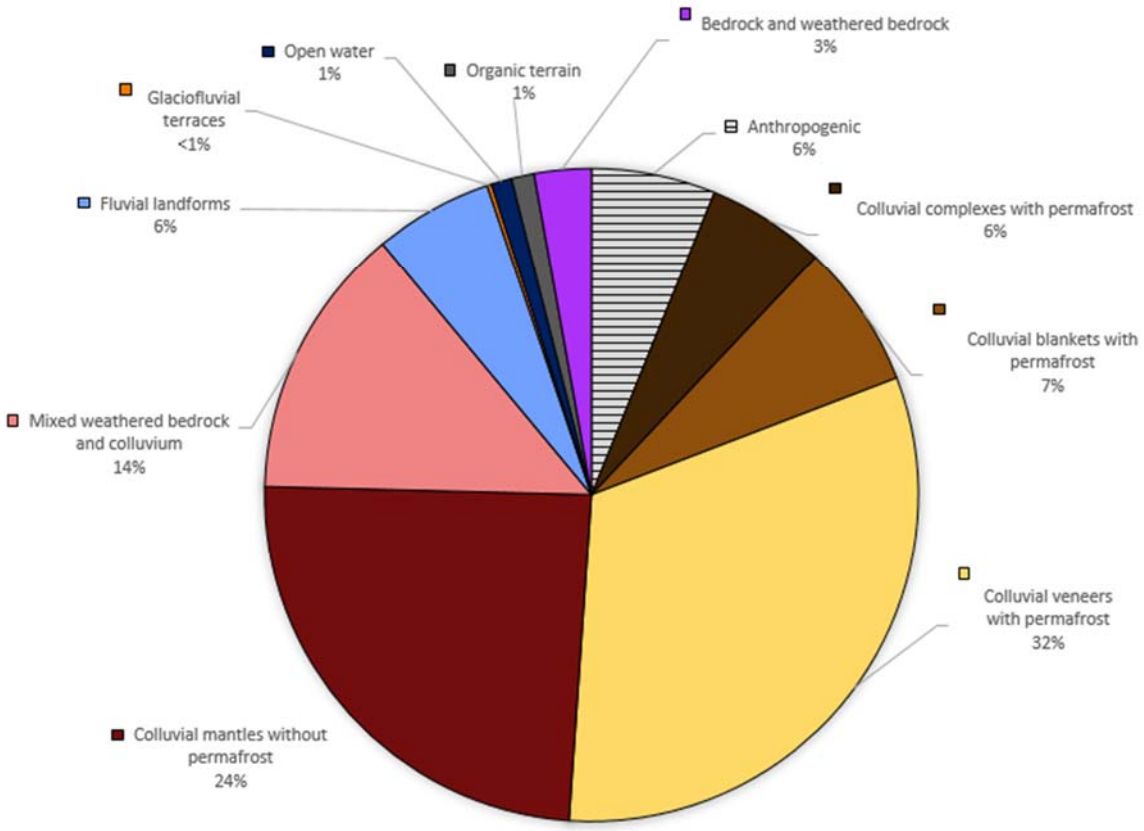

Figure 4-1. Areal proportion (%) of terrain units within the study area

Table 4-2. Standardized textures used for colluvial terrain units

Condition	Typical Texture and Landform
Colluvial mantles without permafrost	zsxCx; zsxCv; zsxCb
Colluvial veneers with permafrost	szxCv
Colluvial blankets with permafrost	sxzCb
Colluvial complexes with permafrost	xszC1a; xszC1b

Note: Lower-case letters preceding the colluvial surficial material (C) represent particular textures (i.e., z: silt; s: sand; x: angular fragments; d: mixed fragments); the lower-case letters that follow represent surface expressions (i.e., x: thin veneer; v: veneer; b: blanket; a: apron). Textural dominance increases from left to right. The replacement of x with d in the texture signifies the suspected incorporation of rounded clasts from an upslope or underlying source of water-transported deposits.

4.1.1 Bedrock and Weathered Bedrock

Intact (R) and weathered (D) bedrock is dominant within approximately 3% of the study area (**Figure 4-1**, **Table 4-3**). It is extensive on summits, ridges and spurs throughout the region, and small areas of it occur on isolated hills and over-steepened slope-toe scarps in some valley settings. It typically occupies crest and upper slope positions, with convex slope profiles and variable aspect and steepness.

Table 4-3. Typical characteristics of bedrock and weathered bedrock in the study area[6]

<table>
<tr><td colspan="2">Map example
  </td><td colspan="2">Oblique aerial view
  </td></tr>
<tr><td colspan="2" rowspan="8">Soil pit
  </td><td>General distribution</td><td>Summits; ridges and spurs; over-steepened valley sides</td></tr>
<tr><td>Common terrain units</td><td>zsxDv/Rh

<tr><td>Hazard considerations</td><td>Localized rockfall; thermokarst subsidence in saddles</td></tr>
</table>

The character of landforms and associated surficial materials within this terrain unit depends on local bedrock lithology and micro-topography. Summits and ridges underlain by intrusive (granitic) bedrock, such as within the mine site area, are commonly veneered with angular blocks of felsenmeer and punctuated by tors. Tors commonly occur in clusters, surrounded by a halo of angular, weathered blocks derived from rockfall. The residual soils that accumulate within areas of granitic bedrock tend to be pebbly to sandy

[6] Terrain labels and slope classes used in this and all other summary tables in Section 4.1 defined in Howes and Kenk (1997); drainage classes defined in BC Ministry of Forests and Range and BC Ministry of Environment (2010).

(grus), except where locally overlain or intermixed with loess. In contrast, areas underlain by finer-grained schists and gneisses are commonly featureless and rounded. These rocks are more susceptible to physical and chemical weathering, thus local relief tends to be lower. Residual soils that accumulate over metamorphic rocks tend to be sandy silt with traces of clay.

Permafrost may or may not be present within this terrain unit. Where present, the permafrost table is generally deep (>1 m), ice-poor and within intact or weathered bedrock, having little influence on ground stability. Exceptions occur in isolated fractures and hollows within the bedrock surface, and in gentle saddles along broad ridges, where enough loess has been preserved to maintain shallow permafrost that may contain segregated ice. Periglacial processes such as cryoturbation, cryoplanation and nivation are widespread in this terrain unit and have not been explicitly mapped. Soil drainage ranges from rapid to very rapid on bedrock outcrops, to well to poorly drained in silt-enriched hollows amongst weathered bedrock.

4.1.2 Mixed Weathered Bedrock and Colluvium

Mixed weathered bedrock (D) and colluvium (C) is dominant within approximately 14% of the study area (**Figure 4-1, Table 4-4**). It is predominant immediately below summit areas, on the shoulders of major ridges, and along rounded, steeper spurs. Most occurrences of this terrain unit are in crest and upper slope positions, with convex slope profiles and variable aspect and steepness.

Gentle slopes of this terrain unit, particularly in areas underlain by granitic bedrock, are commonly punctuated by subdued, bedrock-controlled steps formed by differential erosion. These ‘knickpoints’ may be recognized by conspicuous patches of boulder-sized felsenmeer with a slight slope-break. Over time, material originating from these knickpoints is transported downslope by a combination of soil creep and solifluction, typically forming veneers (<1 m) on underlying bedrock. In areas underlain by metamorphic bedrock, the soils tend to have smaller clasts and a finer-grained matrix, and knickpoints are rare. A jigsaw puzzle-like arrangement of clasts distinguishes *in situ* weathered bedrock from surrounding colluviated material. Silt-rich hollows and colluvial veneers may be susceptible to instability, particularly following wildfire.

Permafrost, where present, is most common in subalpine and alpine settings and on rounded spurs with northerly aspects, and may be indicated by ponded water at surface. Soils are well drained in areas of felsenmeer to poorly drained in finer grained colluvial soils with shallow, ice-poor permafrost.

Geomorphological processes are rare in permafrost-free occurrences of this terrain unit. Some higher elevation occurrences with deep permafrost exhibit conspicuously irregular micro-topography and patches of lichen-free, angular stones indicative of the process of rock creep. The potential for small active layer detachments is restricted to localized convexities with silty colluvium, most likely following wildfire.

</table>

4.1.3 Colluvial Mantles without Permafrost

Colluvial mantles without permafrost are the second most common terrain unit, dominant within about 24% of the study area (**Figure 4-1, Table 4-5**). This terrain unit is most commonly represented by a colluvial veneer (Cv). Less commonly, it is represented by a thin colluvial veneer (Cx), colluvial blanket (Cb) or colluvial mantle of variable thickness (Cw). It generally occurs in mid slope positions with moderate to steep gradients. This terrain unit can occur on all aspects but is dominantly found on southerly, convex or straight slopes.

Permafrost-free colluvium is typically derived from bedrock and dominated by angular clasts and a sandy to silty-sand matrix. It is locally overlain by a thin veneer of loess (Bond and Lipovsky, 2011). The thickness of colluvium in this terrain unit ranges from <0.2 m (thin colluvial veneer), to <1 m (colluvial veneer), to >1 m (colluvial blanket). Permafrost-free colluvial blankets rarely accumulate more than a few metres of material. Small outcrops are common, particularly at convex slope-breaks and on steep, south-facing slopes mapped as thin colluvial veneers (Cx).

Soil creep and sheetwash are the principal mechanisms transporting material downslope in this terrain unit and locally impart a crude stratification, although rockfall and debris slides also have rare occurrences in steep or gullied terrain. Soils are generally moderately well to rapidly drained.

</table>

4.1.4 Colluvial Veneers with Permafrost

Colluvial veneers (Cv) with permafrost are the most extensive terrain unit, dominant within about 32% of the study area (**Figure 4-1, Table 4-6**). They most commonly occur on gentle to steep slopes with convex upper-slope or straight mid-slope positions. This terrain unit occurs on slopes with all aspects, although it is dominantly on northerly aspects.

Table 4-6. Typical characteristics of colluvial veneers with permafrost in the study area

<table>
<tr><td colspan="2">Map view
  </td><td colspan="2">Oblique aerial view

<tr><td>Permafrost</td><td>Typically ice-poor and shallow</td></tr>
<tr><td>Other characteristics</td><td>Convex to straight slopes; dominantly stunted black spruce</td></tr>
<tr><td>Hazard considerations</td><td>Active layer detachments; slumping; slope wash; soil creep</td></tr>
</table>

The colluvium in this terrain unit is generally less than one metre thick (Cv), may contain isolated patches of weathered bedrock (Cw), and follows underlying topography. It is typically derived from detachment and entrainment of angular, weathered bedrock clasts, except below some terraces where it may contain rounded clasts of fluvial or glaciofluvial origin. Silt derived from loess is intermixed with the bedrock-derived material, with a decreasing concentration with depth (**Table 4-2**).

Permafrost within this terrain unit contributes to the higher silt content in comparison to permafrost-free colluvial veneers (Section 4.1.3) by inhibiting its erosion from regular surface runoff processes. Permafrost is typically shallow (0.4 to 1 m), but can be near-surface (<0.4 m) on poorly drained slopes with northerly aspects, or deep (>1 m) on convex rolls and spurs. Permafrost is generally ice-poor, containing little to no visible (segregated) ice, but may be ice-moderate and contain minor seams and lenses of ground ice on poorly drained slopes with northerly aspects. Soils are typically imperfectly to poorly drained, depending on the silt content and depth to permafrost.

A number of permafrost and periglacial processes commonly occur in association with this terrain unit, as described below in Section 4.2: active layer detachments, slumps, rock creep, slopewash and solifluction. Although active layer detachments can occur within all colluvial terrain units with permafrost, they are most common in colluvial veneers on moderate to moderately steep slopes.

4.1.5 Colluvial Blankets with Permafrost

Colluvial blankets (Cb) with permafrost are dominant within about 7% of the study area (**Figure 4-1, Table 4-7**). They typically occur in concavities in mid- to lower-slope positions. Although this terrain unit occurs on all aspects, it is most common on gentle to moderate slopes with northerly aspects.

Colluvial blankets with have a higher silt content than colluvial veneers with permafrost because they generally form in concavities that trap silt (**Table 4-2**). Blankets generally follow underlying bedrock topography and may be in the order of 10 m deep in concavities on gentle slopes. This terrain unit has a distinctly smooth surface expression, with no abrupt breaks-in-slope or gullies. Upper soil horizons are commonly dominated by loess-derived silt; the proportion of silt intermixed with bedrock-derived colluvium decreases with depth.

Permafrost within this terrain unit is generally shallow (0.4 to 1 m) or near-surface (<0.4 m). It typically exhibits moderate ice content in the form of pore ice and segregated seams and lenses, particularly in the siltier upper horizons. Soils are typically imperfectly to poorly drained, in some cases with discrete differences due to the presence of slopewash runnels, also known as water tracks. Dwarf willows growing along the runnels have a different appearance from the dwarf birches dominating the shrub cover, giving the slopes a distinct lineated, flow-like pattern. Active layer detachments occur, albeit less commonly than on steeper veneers.

</table>

4.1.6 Colluvial Complexes with Permafrost

Colluvial complexes (C1) occur mainly as blankets (b) and aprons (a), and represent an important, project-specific classification of terrain that occupies approximately 6% of the study area (**Figure 4-1, Table 4-8**). This terrain unit has a straight or concave profile and occurs on all aspects. Aprons and blankets predominantly occur in toe slope positions and lower-slope hollows, respectively. Commonly demarcating the upper limits of an apron is a conspicuous concave slope-break that typically coincides with an abrupt downslope reduction in soil drainage. In cross-section, aprons form a wedge, with the thickest portion in

the valley bottom and thinner material up-slope, while blankets generally conform to the underlying topography.

This terrain unit is well described by Huscroft (2002) as “colluvial eolian complexes”, owing to their complex sedimentology and origin, and represents the main occurrence of Klondike ‘muck’ (Tyrrell, 1917; Fraser and Burn, 1997). It is an aggradational landform, built up over time through the delivery of sediments from upslope by minor incremental and episodic colluvial and fluvial additions. These aprons consist of primary and redeposited loess, fluvial and slopewash sediments, bedrock-derived colluvium and organic material. Many, if not all, colluvial complexes are still active based on observation of the recent deposition of sediment and woody debris from upper valley sides.

The sedimentology of this terrain unit is highly variable, depending primarily on steepness and upslope drainage area. The slope of the aprons is an indicator of their internal composition. In general, colluvial complexes with gentler slopes in the lower portions of larger basins have higher silt and organic contents than slightly steeper ones in narrow headwater tributaries, where inclusions of mass movement deposits may be encountered (**Table 4-2**).

Aggradation of permafrost within the colluvial complexes generally kept pace with the deposition and accumulation of loess during the late Pleistocene (Fraser, 1995). A thick cover of mosses with high insulating value has enabled the permafrost to persist near-surface, even during the relatively warm Holocene. Surface organics in this terrain unit are relatively thick and commonly extend beneath the permafrost table. Soil drainage is imperfect to very poor, due to shallow or near-surface permafrost, loess-rich soil and gentle gradients.

This terrain unit typically contains ice-rich permafrost with ground ice in the form of excess pore ice, segregated seams and lenses, and massive bodies (Bond and Lipovsky, 2011). One such body of ground ice was observed during field reconnaissance in a recent placer mining excavation in a tributary to Maisy May Creek (**Photo 4-1**). Gentle colluvial complex aprons may have ice-rich permafrost up to 30 m thick, such as observed in boreholes within 20 km of the proposed mine area (J. Coates, Kryotek, 2015). Thermokarst activity occurs through both natural and anthropogenic disturbance in some of these ice-rich complexes.

</table>

4.1.7 Fluvial Landforms

Fluvial landforms, including channels and floodplains (FAp or Fp), terraces (Ft) and fans (Ff), occupy approximately 6% of the study area (**Figure 4-1**, **Table 4-9**). The characteristics of this terrain unit transition from headwater reaches to main branches. In headwater reaches within V-shaped valleys (i.e., first- to second-order streams), fluvial sands and subangular to subrounded clasts commonly veneer colluvial blankets. Along streams of intermediate size (i.e., second- to third-order streams), subrounded to rounded gravel forms the bed of the meandering channel, and banks may include sand and silt deposited during flood events. Floodplains are narrow and discontinuous. Along the largest meandering watercourses (i.e., third to fourth-order streams), bed material consists of rounded to well-rounded gravel and sand, and bank exposures indicate that the wide, continuous floodplains are composed of sand, silt and locally interbedded

organics. Organic deposits are commonly associated with broad floodplains alongside Yukon River and its major tributaries.

Fluvial terraces, commonly perched on bedrock terraces adjacent to some of the larger tributaries such as Indian River, Barker Creek and Coffee Creek, are a testament to the marked incision that occurred during the Pleistocene (Bond and Lipovsky, 2011). Many of these terraces are blanketed in loess and colluvium, making their recognition in the field challenging. However, the sharp break-in-slope formed by the terrace scarp is usually recognizable in aerial photographs and LiDAR-derived elevation models. Years of modification and downslope transport have resulted in a modification from planar to gentle slopes. The stream-deposited sediment in these fluvial terraces is generally a mixture of sand and rounded gravel.

Fluvial fans exist at the mouths of moderate to large tributaries, where they are less confined and channel gradients decrease abruptly. Where they exhibit steeper gradients than regular fluvial plains and terraces, they contain coarser-grained sand and gravel and less silt. Clasts may be subangular at the apices of the fans of small, steep drainages, due to the relatively short transport distance and duration. Some low-gradient fans exhibit similarities to the silt-dominated colluvial complexes describe above (Section 4.1.6).

Plains typically exhibit negligible slope with variable or no aspect, except along the bottoms of headwater tributaries with gentle to moderate slopes. The Stewart and Yukon rivers have the widest and most continuous fluvial plains within the region, but narrower, discontinuous fluvial plains also occur in association with its tributaries. In general, the width and continuity of fluvial plains increases proportionally with stream order (Strahler, 1952).

Most fluvial environments are subject to meander migration through progressive bank erosion or avulsion. Numerous oxbows alongside meandering streams indicate periods of instability; some enlarge through thermokarst processes. Areas of the floodplain farther from the active channel may be sufficiently stable that organic material can accumulate at the surface. Unless buried by flood sediments, these organics thicken and may promote the growth of underlying permafrost.

The depth to permafrost varies spatially and temporally within this terrain unit as a function of organic matter thickness and proximity to permanently flowing streams. Permafrost is generally absent or deep in frequently flooded sites, because an appreciable organic layer is unable to accumulate in areas prone to erosion and sedimentation. Sites with an intermediate flooding regime typically have no permafrost, or deep permafrost below the rooting zone of riparian vegetation. Stable terraces accumulate enough organics, which act as an insulator, that permafrost commonly aggrades (Viereck, 1973; Zoltai and Pettapiece, 1973).

Soils within this terrain unit are well drained in areas of active fluvial processes to very poorly drained in oxbows and areas of shallow or near-surface permafrost. An abrupt change in vegetation from a tall, dense canopy of trees to stunted or no trees commonly signifies the edge of shallow permafrost.

4.1.8 Glaciofluvial Terraces

Glaciofluvial terraces (FGt) are rare within the study area, representing less than 1% (**Figure 4-1**, **Table 4-10**). They only occur above the modern Yukon River, which was filled to varying elevations with a braided meltwater channel through most of the Pleistocene glaciations. Glaciofluvial terraces are distinguished from fluvial terraces based on their landscape position, thickness and the inclusion of well rounded cobbles with lithologies foreign to the local watershed.

Glaciofluvial terraces can be identified both in aerial photographs and during helicopter fly-overs. Glaciofluvial sand and gravel overlies some of the rock benches alongside the modern Yukon River, which formed in response to its flow reversal (Tempelman-Kluit, 1980; Jackson et al., 2008). Colluviation from

upslope areas and along the terrace scarp has made the terrace forms almost unrecognizable (oblique aerial view in **Table 4-10**). The subtle slope-break and linearity in vegetation patterns are the key diagnostic characteristics.

Broader glaciofluvial terraces parallel the Yukon River at lower elevations. The Coffee Creek airstrip is built on a terrace less than 10 m above the modern river level. Its coarse sand and gravel base is overlain by a discontinuous veneer of fine-grained flood deposits and loess. Although glaciofluvial terraces tend to be well drained, permafrost was encountered during gravel extraction at a depth of about 5 m.

Table 4-10. Typical characteristics of glaciofluvial terraces in the study area

</table>

4.1.9 Organic Terrain

Organic terrain, defined by its flat surface and infilling of shallow depressions with organic material (mostly peat moss), occupies only about 1% of the study area (**Figure 4-1**, **Table 4-11**). It exhibits different thicknesses – veneer (<1 m; Ov), blanket (>1 m; Ob) and plain (variable; Op) – depending on micro-topography, drainage and local disturbance history. Organic terrain is most commonly mapped on inactive portions of floodplains and terraces alongside the major watercourses. In this landscape, nearly all surfaces have some accumulation of organics; however, thin veneers (x) were not mapped.

Table 4-11. Typical characteristics of organic terrain in the study area

<table>
<tr><td colspan="2">Map view
  </td><td colspan="2">Oblique aerial view
  </td></tr>
<tr><td colspan="2" rowspan="8">Soil pit
  </td><td>General distribution</td><td>Floodplains and valley bottoms</td></tr>
<tr><td>Common terrain units</td><td>eOp-Xt</td></tr>
<tr><td>Dominant processes</td><td>Thermokarst subsidence; inundation</td></tr>
<tr><td>Drainage</td><td>Poor to very poor</td></tr>
<tr><td>Dominant slope range</td><td>Planar</td></tr>
<tr><td>Permafrost</td><td>Typically shallow and ice-rich</td></tr>
<tr><td>Other characteristics</td><td>Surface water common</td></tr>
<tr><td>Hazard considerations</td><td>Thermokarst subsidence; flooding</td></tr>
</table>

Organic terrain is commonly underlain by fine-grained flood deposits, typically overlying fluvial sand and gravel. The degree of decomposition of organic material within the study area varies, but is dominantly relatively low. Fibric organics are most common, and used as the standard texture (**Table 4-11**).

Permafrost is ubiquitous with organic terrain. It is commonly near-surface (<0.4 m) or shallow (0.4 to 1 m), and ice-rich. Natural and anthropogenic thermokarst subsidence within wetlands indicate massive bodies of ice are likely present. Drainage is poor to very poor throughout organic terrain due to the shallowness of permafrost and topographic position.

4.1.10 Anthropogenic Disturbances

Anthropogenic disturbance from placer mining activity is widespread along the valleys of the larger tributaries, occupying approximately 6% of the study area (**Figure 4-1**, **Table 4-12**). The access road has been proposed along these valleys to avoid disturbing and potentially impacting other, more pristine terrain. The severity of disturbance ranges from the stripping of surface organics to complete excavation (mining) and displacement of surficial materials down to bedrock. Linear disturbances such as roads and minor surface disturbances such as ATV tracks were not discretely mapped.

Alterations to the ground thermal regime in association with placer mining are deliberate and intended to promote thawing of silt-rich shallow permafrost to allow mining of underlying fluvial gravels. The process of placer mining and tailings pile formation so drastically alters the thermal and hydrogeological properties of the materials that permafrost is unlikely to re-establish itself under current climate conditions.

Notwithstanding the widespread removal of permafrost in association with placer mining activity, remnant areas of ground with ice-rich permafrost may occur in some areas, especially underlying sections of valleys that were less severely disturbed. Numerous ponds amongst the placer tailings are generally inferred to be present and controlled by local groundwater, which flows readily through the permeable gravels, but some may be prone to enlargement through thermokarst subsidence and gullying (TT-EBA, 2016b,c).

The unreliability of interpretations of material properties and permafrost conditions within areas of anthropogenic disturbance precludes assignment of terrain stability, hazard or soil erosion potential classes. Field investigation is required to properly assess ground conditions and their implications for road alignment and design. Therefore, such areas have been excluded from interpretive mapping and depicted with a neutral hatch pattern without a label (Maps 1 to 3, **Appendices A** to **C**).

4.2 Geomorphological Processes

A variety of geomorphological processes were mapped within the study area, including mass movement, erosional, fluvial and periglacial processes (Howes and Kenk, 1997). Subclasses of these primary processes were distinguished where necessary to more accurately represent different potential hazard characteristics and implications.

4.2.1 Rockfall (-Rb)

Rockfall is the rapid detachment, fall, rolling and bouncing of rock fragments (Hungr et al., 2014). Rockfall occurrences within the study area are restricted to bedrock bluffs (**Photo 4-2**) and steep colluvial slopes with bedrock outcrops. Active rockfall zones are recognized by the presence of an unweathered patch of bedrock bluff upslope and/or a pile of lichen-free rubbly debris at the base of the bluff. Rockfall is typically recurrent and most likely to occur during periods of freeze-thaw (frost shatter) or rapid and prolonged warming (thermal cracking).

Photo 4-2. Recent rockfall on bluff adjacent to proposed road alignment north of Stewart River

4.2.2 Debris Slides (-Rs)

A debris slide is the slow to rapid sliding of a mass of surficial material on a shallow, planar surface parallel with the ground (Hungr et al., 2014). Debris slides are distinguished from the more specific process of active layer detachment, which occurs only on slopes underlain by permafrost. Debris slides within the study area most commonly occur on steep, south-facing slopes at the over-steepened base of valley sides, typically in association with thin colluvial veneers.

4.2.3 Rock Slumps (-Fm)

A rock slump, or rotational slide, is the slow sliding of a mass of weak rock on a cylindrical or other rotational rupture surface that is not structurally controlled (Hungr et al., 2014). Rock slumps within the study area occur on slopes with and without permafrost, showing little relation to aspect or topographic characteristics. Rock slumps tend to occur as discrete, albeit slow, events, and they may advance upslope over time through retrogressive failures. Virtually all mapped examples of rock slumps appear old or dormant, and are likely no longer sensitive to disturbance. Occurring in areas without the potential to affect proposed infrastructure footprints, mapped rock slumps do not represent hazards to the project (as noted below in Section 5.3).

4.2.4 Rock Creep (-Fg)

Rock creep is the slow movement of angular debris under periglacial conditions (Howes and Kenk, 1997). Within the study area, rock creep occurs on the northerly shoulders of summits and ridges in subalpine to alpine settings with mostly ice-poor permafrost. It is recognized by a conspicuously irregular, undulating slope typified by patches of fresh talus amongst intact and weathered bedrock (**Photo 4-3**). Slopes prone to rock creep are likely only slightly sensitive to surface disturbance, due to their skeletal and typically ice-poor composition.

Photo 4-3. Henderson Ridge Road traversing a slope exhibiting rock creep

4.2.5 Gullying (-V)

Gullying is the modification of unconsolidated (surficial material) and consolidated (bedrock) surfaces by various processes such as surface runoff, mass movement and snow avalanching, resulting in the formation of parallel and sub-parallel long, narrow ravines (Howes and Kenk, 1997). The gullying process has been applied to terrain units (polygons) that exhibit such morphology to an extent that distinguishes them from surrounding, more uniform slopes. Gullies occur in all surficial materials and on bedrock slopes, typically elevating the potential for instability. Most gullies are formed through fluvial incision over millennia and, in this semi-arid, unglaciated setting, are not subject to debris flows (except in association with active layer detachments on slopes underlain by permafrost). The most conspicuous gullies are delineated on the maps with line symbols.

4.2.6 Solifluction (-S)

Solifluction is the slow, gravitational downslope movement of saturated, non-frozen overburden across a frozen or otherwise impermeable substrate. More accurately, in this study area, gelifluction is the form of solifluction that has been mapped due to the movement of material within the active layer on the permafrost table. Solifluction occurs most commonly on convex northerly slopes veneered or blanketed in colluvium in subalpine or alpine environments within the study area (**Figure 2-4**). The solifluction lobes that typify this form of mass movement may comprise silty material rich in organics or clast-rich material bound together by ground ice. Solifluction slopes have generally been mapped as having ice-moderate, shallow permafrost.

4.2.7 Active Layer Detachments (-Xf)

An active layer detachment, referred to more generically for mapping purposes by Howes and Kenk (1997) as a thaw flow slide, is a shallow form of debris slide that occurs within the active layer on top of the permafrost table (**Photo 4-4**). Active layer detachments typically occur in response to intense or prolonged rainfall or snowmelt, high air temperatures, or surface disturbances (e.g., wildfire, windthrow, anthropogenic ground alteration). Active layer detachments exhibit widespread coverage throughout the study area, but are restricted to initiation on slopes underlain by permafrost. They initiate on gentle to steep slopes, commonly just above a convex roll much like a snow avalanche. They have runout distances of up to several hundreds of metres and can transport woody vegetation and underlying colluvial material from ridge shoulders to slope-toe aprons. Following their initial occurrence, permafrost exposed on their sliding surface begins to thaw, and the active layer thickens. Continued slides, flows and gullying are common, until active layer thickening ceases. The headscarps of active layer detachments may migrate retrogressively upslope through gradual thawing and sloughing. The paths of former active layer detachments are commonly recognized by the anomalous stripe of deciduous trees (e.g., alder, birch) that colonize above the locally depressed permafrost table.

Terrain units (polygons) that exhibit a history of active layer detachments are assigned this process label (-Xf); discrete failures are also delineated with line symbols. Retrogressive thaw flows, also known as retrogressive thaw slumps (**Figure 3-2**), are commonly initiated by small active layer detachments and have been mapped with line symbols due to their small size within the study area.

Photo 4-4. Active layer detachments on recently burned east valley side of Barker Creek

4.2.8 Thermokarst Subsidence (-Xt)

Thermokarst subsidence is the formation of ground-surface depressions created by the thawing of ice-rich permafrost and associated soil subsidence (Howes and Kenk, 1997). Terrain units (polygons) inferred to have ice-moderate or ice-rich permafrost are generally susceptible to thermokarst, although the form and severity of such thermokarst also depends on material properties, depth to permafrost and the form of ground ice. The melting of massive ice bodies produces the most conspicuous thermokarst depressions, which may or may not contain standing water. Thermokarst occurs naturally, such as in response to windthrow or wildfire, but is accelerated through anthropogenic disturbance to surface organic cover and drainage patterns. Thermokarst subsidence is most common on planar to gentle slopes, but can occur on moderate slopes. Discrete thermokarst subsidence features, whether or not filled with water, are mapped using point symbols.

4.2.9 Thermal Erosion (-Xe)

Thermal erosion is the process of gully formation initiated by heat transfer from water bodies, typically flowing streams, to underlying permafrost. Thermal erosion can also occur due to heat transfer along the shorelines of standing water bodies. Thermokarst gullies are commonly distinguished by anomalously low width-to-depth ratios, indicative of relatively rapid incision into ice-moderate or ice-rich permafrost, and tension cracks along the crests of their side walls. Trees growing along the edges of such gullies gradually tilt inward toward the gully; straight trunks that have not had an opportunity to adjust their growth habitat

upward are indicative of relatively rapid gully enlargement (**Photo 4-5**). Retrogressive erosion of thermokarst gullies is common and can lengthen gullies that initiate on over-steepened slope toes by orders of magnitude upslope. Within the study area, thermokarst gullying is most commonly associated with ice-rich colluvial complexes and ice-moderate colluvial blankets. Natural and anthropogenic alterations in surface runoff patterns, especially where surface runoff becomes concentrated, can trigger thermokarst gullying. Significant thermokarst gullies are mapped using line symbols.

Photo 4-5. Thermokarst gully with inward-tilting trees on collapsing sidewalls

4.2.10 Slopewash (-Xs)

Slopewash, sometimes referred to as sheetwash, is the mobilization and redistribution of fine material by water flowing down the surface or within the shallow subsurface of smooth slopes that are typically underlain by permafrost. Slopewash exhibits widespread occurrence in permafrost terrain, but is most prevalent on slopes demarcated by downslope, parallel to sub-parallel runnels also known as water tracks. Such slopes that are distinguishable on the basis of these runnels have been mapped with this process label (-Xs) (**Figure 2-4**). The runnels are readily distinguished by the growth of dwarf willows, which contrast with surrounding dominance of dwarf birch. The concentration of surface runoff in slopewash runnels leads to local depression of the permafrost table, which in some cases can trigger thermokarst gullying. Slopewash runnels require consideration in drainage management strategies along roadways, as their thicker active layer allows seepage to continue well into winter, when icing can occur.

4.2.11 Pingo (-Xn)

Pingo development, in an 'open system' in this study area, is the process by which groundwater discharge (seepage) through permafrost freezes and accumulates at or close to the ground surface, forming an ice-cored and earth-covered mound (**Figure 2-4**). Intact and collapsed pingos, typified by a small pond enclosed by a hummocky rampart, are scattered throughout the study area and the broader Klondike Plateau region. They range in size from only several metres in diameter and less than a metre high, to several tens of metres in diameter and roughly ten metres high. They occur most commonly in the narrow valley bottoms of headwater tributaries infilled with silt-rich colluvium. The conditions that allow pingos to form – a continuous source of groundwater upwelling beneath and through permafrost – are best avoided by road construction. Pingos provide definitive evidence of locally ice-rich permafrost.

4.2.12 Meander Migration (-M or -I)

Much of the existing and proposed access road follows valley bottoms with meandering streams (-M) or irregularly sinuous channels (-I) and crosses the lowermost reaches of headwater drainages. Stream channels adjust their planform geometry naturally through bank erosion and meander processes including loop extension, down-valley migration and cut-off (avulsion). Where existing or proposed sections of road encroach within the meander belt of rivers and their major tributaries within the study area, they may be exposed to meander migration hazard. The rate of progression of meanders depends on a variety of factors, including stream power (a function of discharge and slope), meander geometry (e.g., radius of curvature) and the composition and topography of bank areas. Anthropogenic disturbances can accelerate bank erosion through perturbations to natural channel patterns. Segments of the proposed road centreline potentially subject to meander migration processes are identified in the mapping of terrain stability and hazards (Map 2, **Appendix B**).

5 Terrain Stability and Hazards

5.1 Terrain Stability

As discussed in Section 3.2.2, each polygon was attributed with an 'existing' or 'disturbed' stability class. The terrain stability mapping (Map 2) in **Appendix B** reveals that the majority (70%) of the study area has an existing terrain stability class[7] of 'generally stable' (Class II) (**Figure 5-1**). This is expected given the gentle to moderate slopes that predominate on lower valley sides and in uplands. Approximately 8% of the study area is considered 'potentially unstable' (Class IV, 1%) or 'unstable' (Class V, 7%), mostly represented by steep, gullied slopes and areas of permafrost with visible (excess) ground ice already exhibiting thermokarst activity.

The disturbed terrain stability class is defined in terms of the worst case scenario of ground disturbances in association with conventional cut-and-fill road construction, without any mitigation measures to address potential instabilities related to permafrost or sidecast on steep slopes. This allows for the establishment of improved baseline references, and better highlights areas that warrant special design consideration. This approach for communicating terrain hazard conditions enables engineers responsible for designing the mine facilities and access road to make more informed and site-specific decisions about appropriate construction techniques. Furthermore, it allows project risk assessments to be specifically tailored to different circumstances.

According to the disturbed terrain stability class, the proportion of terrain stability polygons with a 'generally stable' (Class II) rating drops from 70% (existing) to 33% (disturbed) (**Figure 5-1**). Many of these polygons become 'generally stable with minor potential for instability' (Class III, 30%) or 'potentially unstable' (Class IV, 16%) if disturbed without mitigation. This notable increase in terrain stability class reflects the sensitivity of permafrost terrain to active layer detachments and/or thermokarst following disturbance. The 13% areal coverage of 'unstable' (Class V) polygons in the disturbed condition is largely attributable to enhanced potential for thermokarst subsidence or gullying in areas with ice-rich permafrost.

The distinction between existing and disturbed terrain stability classes allows accurate representation of potential upslope (e.g., active layer detachments) or downslope (e.g., thermokarst gullying) hazards that are unaffected by proposed infrastructure footprints. This format of mapping distinguishes natural hazards, which may be triggered by occurrences such as wildfire, from those potentially exacerbated or initiated by project-related disturbance. For example, a particular polygon crossed by the proposed road may have a disturbed terrain stability class of IV (potentially unstable). Its existing terrain stability class, however, may only be II (generally stable). Therefore, the potential hazard posed by terrain conditions within this polygon could be recognized as being appreciably lower if the road passes beneath it than if it actually crosses it.

[7] The existing terrain stability class is included in the label, as shown in the legend, but the polygons are colour-symbolized according to the disturbed terrain stability class.

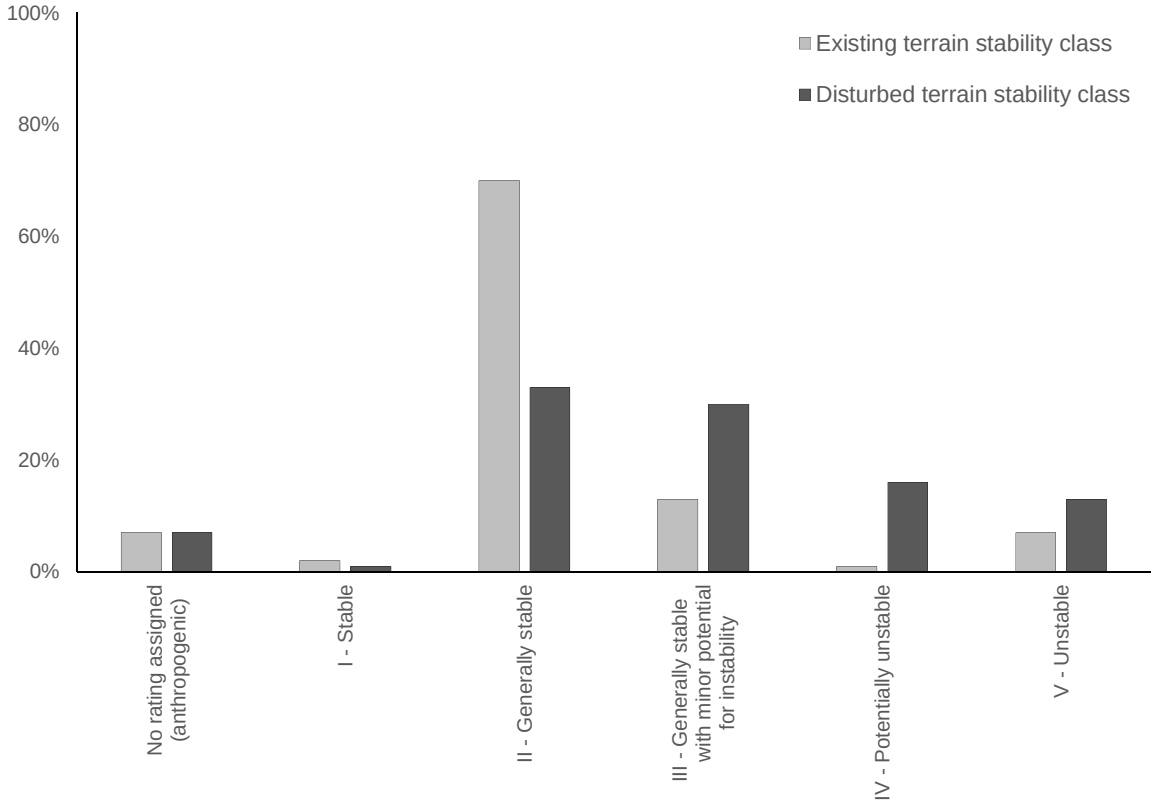

Figure 5-1. Histogram of existing and disturbed terrain stability classification in the study area

5.2 Hazards Overview

The mapping of terrain (Map 1, **Appendix A**) and terrain stability and hazards (Map 2, **Appendix B**), together, identify various forms of hazards through the assignment of geomorphological process codes (polygon-scale) and discrete geomorphological processes (point or linear features) in addition to the actual terrain stability classes. **Table 5-1** outlines the likelihood and potential magnitude of hazard occurrence over the mine life, generalized according to each of the identified hazards with the potential to affect proposed project infrastructure footprints[8]. Project considerations are also included in order to better communicate the implications of different processes for infrastructure design and future maintenance requirements. A geographic breakdown of hazard distribution within each of the 14 study area sections identified in **Figure 1-1** is provided in **Table 5-2**, followed by a descriptive summary of hazard distribution within main physiographic settings in sections 5.3.1 to 5.3.3.

[8] Only terrain characteristics and processes that may pose hazards to project infrastructure footprints are considered in this and following sections; rock slumps, which have only been mapped well beyond areas of proposed infrastructure (Map 1, **Appendix A**), are excluded.

Table 5-1. Generalized characteristics and considerations for hazards with the potential to affect proposed project infrastructure footprints

Hazard	Likelihood (over mine life)	Magnitude	Project considerations
Rockfall	High – typically recurrent and frequent, where present; freshness of talus at base of bluff indicative of recency	Moderate – generally small in volume, but rapid and dense	Plan for rockfall below bluffs, especially in areas of fresh deposits (avoid or mitigate), and on steep slopes with small bedrock outcrops
Debris slide	Moderate – most likely to occur on steep slopes exhibiting history of debris sliding, especially within or adjacent to recent scars	High – generally small to moderate in volume, but rapid and moderately dense	Avoid debris slide slopes and runout zones
Rock creep	High – periodic movement expected; freshness of patches of rock debris indicative of recency	Low – small volume, short distance, slow movements of angular rock debris	Expect increased maintenance and allow for minor settlement and shifting of rock debris
Gullying	High – periodic and localized gully erosion processes (e.g., fluvial incision, side wall mass wastage)	Low – generally incremental and localized incision, and minor surface sloughing	Minimize crossings of gullied slopes, especially where underlain by permafrost, and expect increased maintenance
Solifluction	High – near-continuous, incremental movement	Low – small volume, short distance, slow movements of silt-rich debris	Expect increased maintenance and allow for minor settlement and shifting of surficial material
Active layer detachment	Moderate – most likely to occur on recently disturbed or burned slopes, slopes with previous failures (including within existing scars), or in steep and/or gullied terrain especially downslope of any sites of newly concentrated surface runoff	Moderate – small to moderate in volume; generally rapidly transports organic-rich surficial material tens to hundreds of metres downslope	Avoid slopes that exhibit a history of active layer detachments, or otherwise accommodate their possible occurrence, minimize disturbance to surface organics and drainage, and expect increased maintenance for debris removal
Thermokarst subsidence	Moderate – gradual or periodic settlement, especially in areas of ice-rich permafrost	Low – isolated, slow deepening of ground surface depressions, formation and expansion of ringing tension cracks, and possible slow, inward slumping	Minimize disturbance to surface organics and drainage in areas of ice-moderate to ice-rich permafrost through appropriate gravel embankments/pads and water management, and expect increased maintenance that could involve localized road reconstruction; consider monitoring settlement
Thermal erosion	Moderate – gradual or periodic incision, especially in areas of ice-rich permafrost	Low – localized, slow, commonly retrogressive incision of rills or gullies, formation and expansion of adjacent tension cracks, and possible slow, inward slumping	Avoid or minimize concentrating surface runoff in areas of ice-moderate to ice-rich permafrost, especially into pre-existing gullies, and expect increased maintenance that could involve localized road reconstruction; consider monitoring incision
Slopewash	High – seasonal slopewash and transport of fine sediments within runnels; near-continuous seepage	Low – localized, slow transport of fine sediments, and seepage and icing especially in runnels	Accommodate seepage-induced icing accumulation especially within intercepted runnels, expect increased maintenance due to fine sediment delivery adjacent to road, and manage downslope drainage
Pingo	High – continuous upwelling and freezing of groundwater through permafrost forming ice-cored mound(s)	Moderate – isolated, slow heaving (growth) or subsidence (melting) of ice core, with potential for ringing tension crack formation and expansion, and possible slumping	Avoid the limits and immediate vicinities of pingos, due to the potential for long-term and locally severe ground instability if disturbed
Meander migration	High – episodic erosion of banks, mainly along the outside of meanders, in association with high flow events	Moderate – destabilization of road by incremental erosion or undercutting and slumping	Accommodate natural meander migration processes, where possible, by maintaining setbacks appropriate to the site; otherwise, proactively protect the road from erosion using appropriately sized riprap or alternative measures
Icing	High – annual formation of ice (aufeis), mainly in streams and seepage areas, from as early as October to as late as June	Low – incremental, seepage-induced accumulation and persistence of ice (aufeis) with maximum thicknesses of up to several metres and typical widths of tens of metres	Each year, accommodate at least six months of seepage-induced icing accumulation and persistence, especially at stream and slopewash runnel crossings, and across low-lying floodplains, and plan for associated maintenance

Note: Hazards within the broader study area but without the potential to affect proposed project infrastructure footprints (e.g., rock slumps) are not included

Table 5-2. Geographic distribution of hazards with the potential to affect proposed project infrastructure footprints

Geographic section (as identified in Figure 1-1)	Associated map sheets (Appendices A & B)	Hazard process with potential to affect project infrastructure footprints											Special considerations (mapping polygon ID referenced in parentheses)
		Rockfall	Debris slide	Rock creep	Gullying	Solifluction	Active layer	Thermokarst	Slopewash	Pingo	Meander migration	Icing	
Hunker Creek Valley[c]	1-4						x	x			x	x	Narrow section of valley with instability above road alignment (4446)
King Solomon Dome Area[u]	4-6					x		x	x			x	
Sulphur Creek Valley[c]	6-10							x			x	x	Tributary crossing affected by severe thermokarst gullying and icing (3993); parts of road along Sulphur Creek valley that cross ice-rich aprons have caused downslope thermokarst gullying
Indian River Valley[r]	10-12				x			x			x	x	
Eureka Creek Valley[c]	12,13							x			x	x	
Henderson Ridge Area[u]	13-18			x				x				x	
Maisy May Creek Valley[c]	18-21		x				x	x			x	x	Debris slide affecting road alignment (1681)
Stewart River Crossing[r]	21,22	x			x			x			x		
Barker Creek Valley[c]	22-25						x	x			x	x	Tributary crossing affected by severe thermokarst gullying and icing (1310,1311)
Barker-Ballarat Divide Area[u]	25,26						x	x	x			x	
Ballarat Creek Valley[c]	26-28		x					x		x	x	x	Debris slides initiated above road alignment (1681); road alignment very close to pingo (1598)
Yukon River Crossing[r]	28,29	x	x		x			x			x		Active rockfall and rock slides above road alignment (1816)

Thermokarst includes subsidence and related gullying

Hazards within the broader study area but without the potential to affect proposed project infrastructure footprints (e.g., rock slumps) are not included

5.3 Slope Failure and Thermokarst

As discussed in Section 3.4.1, each polygon was more broadly categorized according to its dominant potential hazard – slope failure, thermokarst or both – in order to highlight those areas where thermokarst activity is possible in addition to default instability related to slope failure. This hazard category is not intended to represent the existing or imminence of thermokarst (or slope failure); its aim is to rule out certain areas from the possibility of thermokarst activity. 'Thermokarst potential' dominates the applicable hazard category within approximately 15% of the study area (**Figure 5-2**). Such areas are generally characterized by planar to gentle topography with ice-moderate or ice-rich permafrost. The potential for thermokarst outweighs the remote possibility of slope failure in these areas. Approximately 4% of the study area has been categorized co-dominantly with 'slope failure and thermokarst potential'. Such areas are distinguished from those dominated only by thermokarst potential by their slope class of moderate (class 3) or higher. A category of 'slope failure potential dominant' applies to all other areas (74%), except anthropogenic and open water areas (not applicable, 7%), irrespective of the possibility of slope failure (e.g., fluvial plains).

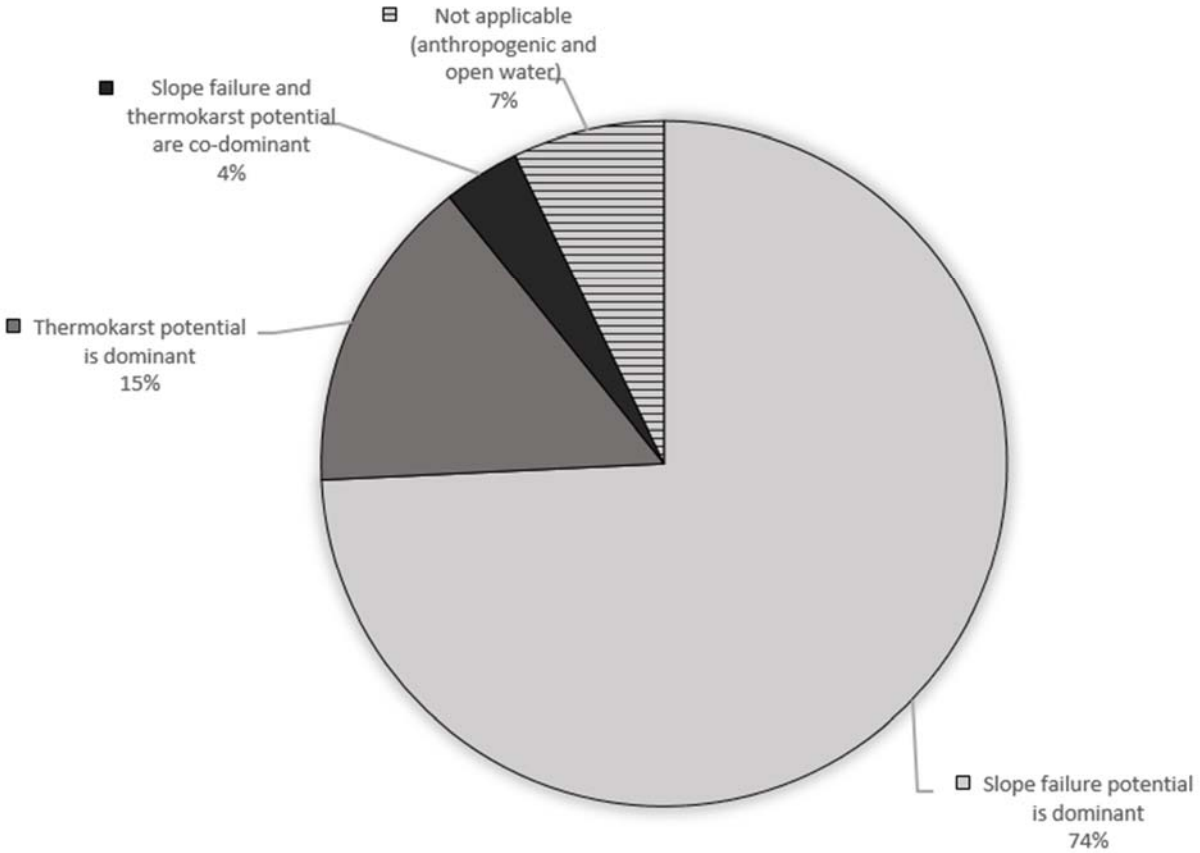

Figure 5-2. Areal proportion (%) of applicable hazard categories in the study area

The distribution of terrain hazards within and immediately surrounding the footprints of proposed project infrastructure is characterized below in relation to three physiographic settings: uplands (Section 5.3.1), creek valleys (Section 5.3.2) and river valleys (Section 5.3.3). A geographic breakdown (based on the sections defined in **Figure 1-1**) of the dominant geomorphological processes that may pose hazards to the footprints of proposed project infrastructure, including any special considerations, is provided in **Table 5-2**. This inventory specifically considers hazards with the potential to affect the footprints of proposed road or mine facilities due to their relative proximity and position. Hazards may affect the footprints locally (e.g., thermokarst subsidence), upslope (e.g., active layer detachment running out into or across footprint) or downslope (e.g., retrogressive erosion of thermokarst gullies) of the footprints. Hazards within the broader study area but without the potential to affect the proposed project infrastructure are not included.

5.3.1 Uplands

Uplands encompass summits, ridges and spurs that are generally composed of weathered and intact bedrock with colluvium in ridge-shoulder and upper-slope positions. Summits composed of granitic bedrock commonly exhibit tors, while metamorphic units generally form rounded smooth surfaces. Loess-derived colluvium becomes trapped within depressions and saddles along ridges resulting in a veneer of silt-rich colluvium. The fine-grained nature of these deposits commonly preserves permafrost with moderate ice content. Thermokarst subsidence is likely if disturbed. Rockfall commonly occurs from tors and steep-sided bedrock summits; however, no immediate rockfall hazards have been identified adjacent to the proposed road alignment in this physiographic setting. In general, uplands pose minimal hazards to infrastructure.

The following sections of the study area (**Figure 1-1**) exhibit terrain units, processes and hazards associated with upland settings:

- King Solomon Dome Area
- Henderson Ridge Area
- Barker-Ballarat Divide Area
- Latte-Yukon Divide Area
- Mine Area

5.3.1.1 Proposed Mine Facilities

A brief characterization of the specific terrain conditions and hazards in the vicinity of each of the main proposed mine facilities (Maps 1 and 2 in **Appendices A** and **B**, respectively) is provided below:

- **Open pit** – The open pit straddles the drainage divide separating the headwaters of Halfway Creek (north) and “Latte Creek” (south). It will be excavated mainly within terrain units in summit, ridge and spur settings, and will extend into colluvial veneers slopes with a southerly aspect. Most of the pit limits are within terrain with deep, ice-poor permafrost, which has little effect on ground stability or the ultimate rim of the pit. Portions of the pit will extend onto slopes with active rock creep (similar to solifluction) (northern limit), ice-moderate permafrost (western limit) and gullied terrain

(southern limit). Care will need to be taken in managing surface runoff and designing the rim of the pit in such areas, to avoid retrogressive gullying and settlement of the thin overburden cap.

- **Waste Rock Dumps** – Kaminak is proposing to dump waste rock in three primary areas known as the west, south and north waste rock storage facilities (WRSFs), and in a smaller dump farther west:
    - The West WRSF is proposed on a laterally-convex hillside veneered with colluvium above upper Halfway Creek. Permafrost is interpreted to be continuous throughout the area encompassing this facility, but ice-poor and shallow to deep. The southwestern portion of the facility extends into a terrain unit subject to minor gullying and a fringing colluvial complex blanket with shallow, potentially ice-rich permafrost. The design of the lower toe of the West WRSF will need to consider the possibility of several metres of ice-rich permafrost in the draw at its southwestern limit.
    - The South WRSF is proposed to fill the upper portion of a small, first order tributary valley with an overall southerly aspect. The design of this facility will require careful planning and site preparation, as the western valley side has shallow, ice-moderate permafrost, although slopewash is the only active geomorphological process mapped. The eastern valley side exhibits subdued gullies with permafrost suspected in some of their lower portions.
    - The North WRSF is proposed to partly fill a moderately sloping, north-facing headwater basin. Although most of the footprint is within colluvial veneer terrain units, some areas have thicker colluvium and all have permafrost, some of which is ice-moderate. Site preparation will need to be conducted carefully given the localized potential for thermokarst, rock creep and slopewash.
    - A much smaller, unnamed waste rock dump is proposed on an east-southeasterly aspect opposite the West WRSF. It is situated mostly on weathered bedrock or a colluvial veneer with shallow to deep, ice-poor permafrost, except at its southern limit where it extends into the bottom of a draw infilled with fluvial and colluvial material that may contain some ground ice at depth.
- **Heap Leach Facility (HLF) Area** – The HLF Area, which includes the heap leach pad and event pond, is proposed to be situated on a gentle, broad ridge separating the headwaters of Halfway Creek and “Latte Creek”. The footprint is dominantly within weathered bedrock that transitions to gentle colluvial slopes along its margin; permafrost is shallow to deep and mostly ice-poor. Small portions of the footprint exhibit evidence of solifluction and related rock creep, which will need to be factored into the design. The northwestern corner of the footprint extends onto a gentle colluvial blanket inferred to have ice-moderate permafrost. A small active layer detachment occurred recently on this gentle slope.
- **Stockpiles** – Two main ore stockpiles are proposed, mainly on rounded ridges or their shoulders. The eastern stockpile is situated on the shoulder of a rounded ridge, where permafrost is inferred to be shallow but ice-poor. The stockpile immediately north of the HLF straddles a colluvial veneer exhibiting evidence of solifluction and a colluvial blanket dissected by a headwater draw with minor fluvial deposits, all of which is inferred to be underlain by ice-moderate permafrost. Solifluction is a slow (mm to cm/yr) process through which material moves downslope on the permafrost table, but its presence warrants consideration in the site preparation for this stockpile.

- **Plant Site Area** – The processing plant is proposed on the crest of a broad, near-level section of ridge dividing Halfway Creek and "Latte Creek". The ground is a veneer of weathered bedrock and colluvium, with shallow to deep, ice-poor permafrost. There are no significant stability concerns within its footprint.

5.3.2 Creek Valleys

Creek valleys can be divided into valley side and valley bottom positions. Valley sides are dominantly composed of colluvial mantles. Convex slopes are typically mantled by veneers, whereas convex slopes are mantled by blankets. Draws occurring on valley sides typically contain colluvial blankets overlain by a veneer of fluvial material. On southerly aspect slopes (i.e., permafrost free), the dominant hazards are associated with rockfall, debris slides and gullying. Northerly aspect slopes (i.e., permafrost) are prone to active layer detachments, especially after fire or anthropogenic disturbance. Downslope movement of material may also occur through solifluction and slopewash. Draws are susceptible to thermokarst subsidence and may pose an icing hazard when roads are constructed across them.

Creek valley bottoms are typified by colluvial complexes that overlie fluvial deposits, active and inactive fluvial deposits with varying amounts of organic covers, and anthropogenic material. Disturbance of colluvial complexes without explicit regard for the protection of ice-rich permafrost may trigger thermokarst subsidence or gullying. Steeper complexes may additionally be susceptible to active layer detachments. Active fluvial units may be subject to bank erosion and meander migration. Fluvial units covered by organics can have significant amounts of ground ice, making them susceptible to thermokarst subsidence.

The following sections of the study area (**Figure 1-1**) exhibit terrain units, processes and hazards associated with creek valley settings:

- Hunker Creek Valley
- Sulphur Creek Valley
- Eureka Creek Valley
- Maisy May Creek Valley
- Barker Creek Valley
- Ballarat Creek Valley

5.3.3 River Valleys

River valleys are distinguished from creek valleys based on their larger size (width and depth) and more benched topography. Similar to creek valleys, river valleys can be separated into valley sides and bottoms. Valley sides are typically high and locally steep. Southerly aspects are prone to rockfall, rock slides, debris slides and gullying. Active layer detachments can occur on slopes with northerly aspects, although such hazards are not posed to proposed infrastructure footprints.

River valley bottoms are dominantly composed of wide fluvial plains, large fans aggraded from the mouths of tributaries, and colluvial complexes. Thick organic deposits and organic mantles are common on flood plains and fans, and typically signify ice-rich permafrost and increased potential for thermokarst subsidence or erosion. Fluvial deposits in the toe-slope position are commonly overlain by ice-rich colluvial complexes and are also at risk of thermokarst subsidence or erosion. Fluvial deposits closer to the rivers do not typically contain extensive permafrost and are not susceptible to subsidence; however, they may be subject to bank erosion.

The following sections of the study area (**Figure 1-1**) exhibit terrain units, processes and hazards associated with river valley settings:

- Indian River Valley
- Stewart River Crossing
- Yukon River Crossing

5.4 Meander Migration

A total of 44 meander-road encroachment sites constituting meander migration hazards were identified along the proposed access road (Map 2, **Appendix B**). Some of these sites already exhibit undercut and collapsing road embankments in need of maintenance and erosion protection. The results of the more detailed assessments of each of the three river crossings are provided in the following sections and in **Figure 5-3**.

5.4.1 Indian River Bridge

Indian River exhibits a tortuous meander pattern within a broad, flat valley with widespread disturbance from placer mining (**Figure 5-3**). Its meander pattern in the vicinity of the existing bridge crossing was altered sometime between 1977 and 2009 through local channel realignment, presumably to accommodate different stages of placer mining within the valley bottom. The river encroaches alongside the existing road at two locations upstream of the crossing (a and b in **Figure 5-3**), where previous riprap placement or maintenance appears to have inhibited erosion of the road embankment. The historical channel overlays at these two locations do not indicate any systematic migration of the meanders. Immediately upstream of the crossing, at the apex of another meander (c in **Figure 5-3**), the historical channel overlays reveal bank erosion occurring with a southeastward trajectory at an average rate of 0.3 m/yr (between 1961 and 2015). Without intervention, this trend could result in undermining or outflanking of the southern abutment of the existing bridge. The position, span and abutment protection of the crossing structure should account for the erosion hazard posed by this actively migrating meander. An allowance should also be made for flooding and scour caused by ice jam failure.

5.4.2 Stewart River Barge Crossing

Stewart River exhibits a sinuous channel pattern in the vicinity of its proposed barge crossing, immediately upstream of the confluence with Barker Creek (**Figure 5-3**). The northern bank is defined by a relatively stable bedrock bluff east of the proposed northern barge landing. The amount of bank erosion suggested by the historical overlay analysis is negligible and within the error of georeferencing the historical aerial photographs on which the overlays are based. Minor deposition and stabilization of a side bar occurred between 1949 and 2015 a few hundred metres downstream of the proposed northern barge landing (d in **Figure 5-3**). The proposed southern barge landing is situated along the edge of a low fluvial terrace, or inactive portion of floodplain (e in **Figure 5-3**). Although field reconnaissance documented at least some erosion along this southern bank, based on leaning trees and localized undercutting and slumping, the coincidence of historical bank positions with that delineated based on the 2015 aerial photography indicates that observed bank instability is localized and has not resulted in systematic erosion. Given the size of the river, and the erodibility of the bank materials, some degree of localized bank failure and retreat should be accommodated in the design of the southern barge landing. An allowance should also be made for flooding and scour caused by ice jams, which form annually.

5.4.3 Yukon River Barge Crossing

Yukon River exhibits a sinuous to anastomosing channel pattern in the vicinity of its proposed barge crossing, just upstream of the confluence with Coffee Creek (**Figure 5-3**). The river has numerous side and mid-channel bars, exhibiting varying degrees of stability, as well as back channels that may only convey water during floods. The existence and distribution of bars along the main channel affect bank erosion patterns through their localized deflection and/or splitting of the thalweg. The persistence and slight growth of a relatively large mid-channel bar at the proposed barge crossing (f in **Figure 5-3**), since at least 1948, may have contributed to the systematic erosion of the northern river bank that is documented through the historical overlay analysis. Erosion of the northern bank immediately upstream of the proposed northern barge landing (g in **Figure 5-3**), which is situated at the interface between fluvial deposits and the toe of a steep, rocky hillside, has occurred at an average rate of 1.3 m/yr between 1948 and 2015. Depending on the exact positioning and design of the proposed northern barge landing, continued erosion of this bank may necessitate proactive riprap placement to mitigate the hazard. No significant erosion appears to have occurred along the southern bank in the vicinity of the proposed barge landing, likely due to partial protection afforded by the adjacent vegetated bar (h in **Figure 5-3**) from the more erosive thalweg. An allowance should also be made for flooding and scour caused by ice jams, which form annually.

5.5 Icing

Icing, locally known as ‘glaciation’, is the accumulation of ice (aufeis) during winter along streams and large slopewash runnels that receive near-continuous groundwater seepage from unfrozen portions of active layers or adjacent permafrost-free ground (**Photo 5-1**). Icings form through the accretion of layers of ice, attaining thicknesses of up to several metres and widths of several tens of metres. Icings within the study area locally initiate in October and may persist until early June where thickest and most shaded. Lorax Environmental Services Ltd.’s (2015) wintertime monitoring of ice along streams draining the proposed mine area confirm that thicknesses of more than 1 m are common, particularly along headwater reaches.

Photo 5-1. Example of icing spanning the bottom of a headwater drainage in the Klondike Plateau

A total of 77 sites known or inferred to be prone to wintertime icing were identified along the proposed access road (Map 2, **Appendix B**). Some of these sites, as reported by Yukon Highways and Jim Coates (Kryotek), require significant efforts to break up and remove the ice in the spring before the road is drivable by regular vehicles. Large accumulations of aufeis along stream beds and low-lying areas of floodplains can also increase the width (and height) of flooding if intense rainfall or snowmelt occurs before the ice has thinned and broken up. Allowances should be made in the design of crossings of icing-prone drainages for both the formation and failure of aufeis, as well as potential flooding in excess of that predicted by regular hydrological analysis.

5.6 Other Hazard Considerations

Several other processes were noted as potential hazards through the mapping process, but delineation of their limits requires site-specific investigation and analysis of detailed hydrological and topographic data beyond the scope of this assessment:

- **Flooding** – Sections of road crossing or traversing low-lying areas alongside modern streams may be subject to temporary flooding (inundation) during intense or prolonged rainfall or snowmelt. Ice jams, which can also significantly raise water levels, are common along the rivers and their major tributaries. Riparian vegetation patterns and soil profiles provide indicators of the approximate limits and frequency of flooding.

- **Ice Jams and Scour** – Virtually continuous covers of ice form during the winter months along creeks and rivers within the study area. Thicknesses vary spatially and temporally, but locally can exceed one metre. Small areas of open water that punctuate otherwise continuous ice cover occur in areas of sustained groundwater discharge, along the toes of terraces or valley sides. Open water commonly also persists locally in the Stewart and Yukon rivers, in areas of hyporheic exchange near the downstream limits of large gravel bars. During the winter, the ice flexes and buckles, continually shifting under the hydraulic influence of water flowing beneath. Ice jams form in local constrictions within the channel, or at abrupt bends, commonly at similar locations each year. Water impounded by ice jams can flood extensive areas of the valley bottom not normally exposed to flooding due solely to meteoric (hydrologic) events. In the spring, the ice jams break up and release thick slabs of ice downstream. Depending on the size of the ice jams, and the timing, duration and mechanisms of ice jam failure, breaches can result in widespread scour and ice block stranding along banks and riparian zones downstream.
- **Degradation and Aggradation** – Degradation, also known as channel down-cutting, is the lowering of stream bed elevation due to erosion overwhelming deposition at a reach scale. Aggradation, or channel infilling, is the raising of stream bed elevation due to deposition outpacing erosion at a reach scale. Both degradation and aggradation along streams may pose hazards to crossing structures (e.g., culverts or bridges) if not recognized and accommodated in the design. Degradation can lead to undermining of abutments, potentially destabilizing crossing structures, and perching of culverts, forming barriers to upstream fish migration. Aggradation can reduce the hydraulic capacity of the channel or crossing structures by partial infilling, which in turn can increase the frequency of overbank flooding and the potential for road overtopping.

5.7 Soil Erosion Potential

Soil erosion potential was an attribute interpreted in association with terrain and terrain stability mapping, as outlined above in Section 3.5. Nearly half (49%) of the study area was assigned a soil erosion potential ranking of moderate (**Figure 5-4**), which reflects the counterbalancing effects of silt within the soil (i.e., highly erodible) with the predominantly gentle to moderate slopes (i.e., less prone to erosion). Approximately 13% of the study area exhibits high or very high soil erosion potential, due to their ground ice contents and appreciable proportions of silt intermixed with organics. Thermal erosion was considered in association with areas of ice-moderate or ice-rich permafrost.

The management of surface runoff and sediment during the construction of the proposed mine facilities and access road will be particularly important in areas directly upslope of fish habitat. Consideration will also need to be given to swales or gullies with the potential to transport sediments into downstream fish-bearing watercourses. Erosion and sediment control measures should be designed, implemented, monitored and maintained with the greatest attention given to erosion-prone slopes upslope of fish habitat.

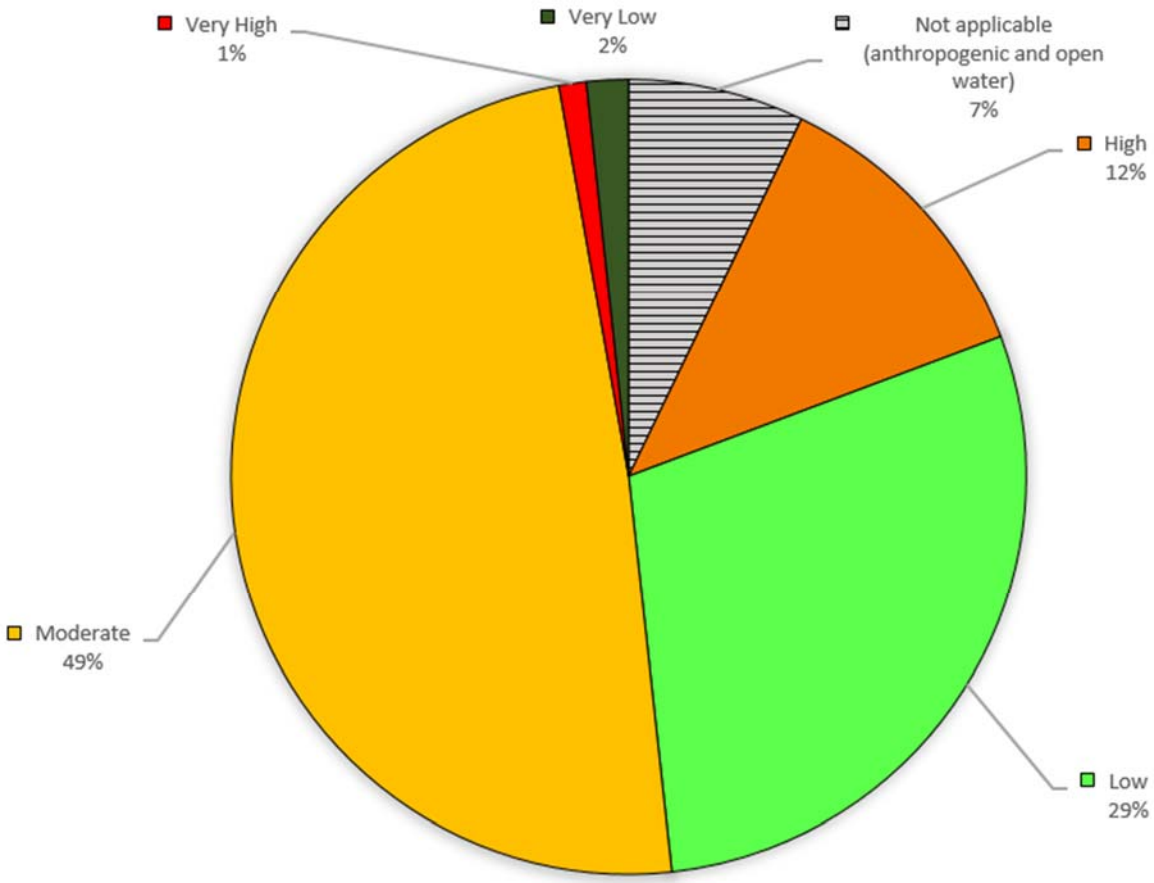

Figure 5-4. Areal proportion (%) of soil erosion potential

6 Project Design Considerations

The information presented in this report and its accompanying maps (**Appendices A** to **C**) provides a basis for planning, designing, constructing and maintaining project infrastructure in ways that minimize long-term costs and potential effects on the environment. It also informs rehabilitation practices during and following operations. The identification and characterization of geomorphological processes and the potential hazards they pose to the Project facilitate assessment of site-specific risks and measures to avoid or mitigate these risks. The following two sections highlight opportunities to avoid or minimize risks based on advance knowledge of terrain and permafrost conditions.

6.1 Hazard Avoidance

Hazard avoidance is a guiding principle Kaminak has embraced in the siting and routing of its mine facilities and access road, respectively. The final footprints of the proposed mine facilities and access road should be located to avoid areas prone to mass movement, slope erosion or fluvial processes, where feasible. Project infrastructure should avoid crossing, or upslope and downslope exposure to, areas mapped as having an existing terrain stability class of V due to past or imminent slope failure. Careful site preparation and design will be required in areas where project infrastructure unavoidably crosses areas with an existing terrain stability class of V due to existing thermokarst activity (as described further below in Section 6.2). Such terrain occurs locally in some valley bottoms along which the access road is proposed. Similar attention should be given to areas with a disturbed terrain stability class of V but with a lower existing terrain stability class (e.g., gentle colluvial complex apron with ice-rich permafrost), in order to avoid triggering instability.

In some cases, hazard avoidance may also be achieved through careful site preparation that eliminates or alters the conditions responsible for the hazard. For example, in rare situations where key mine facilities cannot reasonably avoid encroachment into areas with ice-rich permafrost, thawing and excavation of the ice-rich surficial material could be considered prior to construction.

6.2 Effective Hazard Mitigation

In areas where hazard avoidance is not possible or practicable, Kaminak will apply hazard mitigation measures applicable to site-specific conditions and commensurate with associated risks to the Project. Examples of general strategies for mitigating the main forms of hazard within the study area, if and where subsequent risk assessment establishes the need, are identified in the following sections.

6.2.1 Slope failure

Reducing the likelihood or magnitude of slope failures may or may not be possible in areas where the hazard cannot be avoided. The management of surface runoff will be critical on slopes underlain by permafrost; unnatural concentrations can quickly saturate the active layer and reduce its effective shear strength resulting in active layer detachments, or cause subsidence in ice-moderate or ice-rich settings. In addition, consideration could be given to modifying slope geometry to lessen initiation potential, altering

surface and groundwater drainage patterns in an attempt to reduce the water content of the surficial material, or introducing active or passive external forces to increase shear strength. Monitoring changes to the morphology of disturbed slopes is recommended at locations of suspected instability.

Opportunities to limit and manage the runout of potential slope failures should also be considered where the hazard is likely and unavoidable. Measures exist for controlling the trajectory of the mass movement, such as deflection berms. In order to help control the runout limits, passive or active measures could be considered individually or in combination. For example, ditching alongside a section of road exposed to rockfall represents a passive measure to accommodate (and accumulate) rockfall debris. Constructing physical barriers to intercept rockfall debris, such as an earthen berm, represents more active mitigation.

Considerations for addressing minor hazards posed by geomorphological processes such as solifluction and slopewash are included above in **Table 5-1**.

6.2.2 Thermokarst

Minimizing the potential for initiating or exacerbating thermokarst is one of the most important engineering objectives in the routing and design of the proposed access road. The over-arching principle is to protect the integrity of the core of the road embankment through the maintenance of the local ground thermal regime (McGregor et al., 2010). Specific design, construction and maintenance techniques aimed at maintaining or minimizing change to the ground thermal regime are available for areas where ice-moderate or ice-rich permafrost cannot reasonably be avoided. Below is a summarized list of effective mitigation measures from the technical memorandum prepared for this project by TT-EBA (2016a) (**Appendix E**):

- Avoiding cuts and ditches wherever possible to limit disturbance to the active layer;
- Restricting the movement of equipment used to clear the right-of-way, in order to minimize disturbance to surface organics;
- Removing snow cover prior to construction of the road embankment, if constructed in winter, to reduce settlement during the thaw period;
- Using an end-dumping method to construct the road embankment to avoid unnecessary damage to vegetation;
- Avoiding high fills and side-slopes wherever possible to limit potential for mass movement within the road embankment;
- Constructing a road embankment with a thickness sufficient to maintain or even slightly decrease existing active layer thickness;
- Avoiding concentration and ponding of water alongside the road embankment, by doing so, if necessary, a reasonable distance from the embankment (in order to avoid degrading permafrost at the edge of the embankment); and
- Preventing snow accumulation on the lee side of the embankment, which can inhibit cold penetration during winter and increase active layer thickness.

Careful planning of road maintenance is required. Judgment must be used to determine when routine maintenance will suffice, and when to escalate activities to rehabilitation (McGregor et al., 2010). If localized thermokarst subsidence or gullying becomes particularly severe, consideration may need to be given to thawing and removing the underlying ice-rich permafrost and reconstructing the section of road. This technique, although not preferred, is commonly used by placer miners in the region.

6.2.3 Meander migration

Sections of the proposed access road exposed to meander migration hazards may require erosion protection in order to avoid impact to the embankment. Riprap is the most common and straightforward measure to inhibit the erosion of a road embankment, although other more proactive measures such as in-stream flow 'training' (e.g., rock veins or steam barbs to shift thalweg position) or local channel realignment are options worth considering, especially if riprap continues to be undermined and collapse. Banks should be stabilized prior to impingement along the road embankment, although additional riprap placement may also be required following major floods.

The exact positioning and design of the barge landings at proposed crossings of the Stewart and Yukon Rivers should account for the trajectories and rates of bank erosion documented above in sections 5.4.2 and 5.4.3. Consideration should also be given to the implications of ice formation, jamming, scouring and break-up in the vicinity of the landing sites.

6.2.4 Icing

The design of crossing structures along the proposed access road at streams and seepage areas prone to icing should accommodate ice accumulation and springtime flooding before or during break-up as best as possible. Pre-construction monitoring of the stream crossings of greatest concern would valuably inform crossing design, providing insight on site-specific icing thickness and extent. Measures to mitigate potential effects of icing may include locally enlarged entrance areas to culverts; installation of multiple culverts, some raised relative to the others; and local drainage diversions. Considering the implications of any contemplated measures to underlying or adjacent ice-rich permafrost will be necessary.

7 Conclusions

Terrain stability and hazard mapping completed for the Coffee Gold Project depicts the distribution and characteristics of terrain units, processes and hazards within a 526 km^2 study area that encompasses the proposed mine area and its access road from Dawson. This report and its accompanying maps support engineering and environmental studies being completed as the project advances its proposal submission to YESAB. Several key results warrant highlighting:

1. The siting and design of proposed mine facilities and the access road should account for the widespread occurrence of permafrost in valley bottoms, on northerly aspects and within hillside hollows;
2. The primary mass movement hazards that may affect the footprints of the proposed mine facilities and access road, where not avoided, are rockfall, debris slides, active layer detachments and thermokarst;
3. Disturbance to the ground thermal regime of colluvial complexes rich in silt, organics and segregated ground ice, as well as silty mantles with excess ground ice in saddles and on concave slopes, should be minimized in order to inhibit thermokarst;
4. Active layer detachments commonly initiate on moderate slopes, just above a convex slope-break, with increased likelihood after fire or other surface disturbances;
5. The potential for thermokarst gullies to retrogressively erode upslope should be accommodated in the road alignment and design;
6. Erosion protection (e.g., riprap) will likely be required along sections of the proposed access road where a meandering channel encroaches, including at the three proposed river crossings; and
7. Special consideration is needed in the design of drainage crossings along the proposed access road that are prone to icing, which can form as early as October and persist as late as June.

8 Statement of Limitations

This report (including its appended maps) has been prepared by the Consultant (Palmer Environmental Consulting Group Inc. (PECG)) for the benefit of the Client (Kaminak Gold Corporation) in accordance with the agreement between Consultant and Client, including the scope of work detailed therein (the "Agreement"). The report and the information it provides may be used and relied upon only by Client, except (1) as agreed to in writing by Consultant and Client, (2) as required by-law, or (3) to the extent used by governmental reviewing agencies for the purpose of obtaining permits or approvals.

The extent of this study was limited to the specific scope of work for which we were retained and that is described in this report. PECG has assumed that the information and data provided by the client or any secondary sources of information are factual and accurate. PECG accepts no responsibility for any deficiency, misstatement or inaccuracy contained in this report as a result of omissions, misinterpretations or negligent acts from relied-upon data. Judgment has been used by PECG in interpreting terrain stability and hazards based on desktop-based interpretation calibrated by field observations at sites representative of the diversity of conditions within the study area. Ground conditions may differ from those interpreted at a polygon scale, even where investigated in the field, due to inherent variability in terrain characteristics.

PECG is not a guarantor of the terrain, permafrost or hazard conditions within each of the mapped polygons, but warrants only that its work was undertaken and its report prepared in a manner consistent with the level of skill and diligence normally exercised by competent geoscience professionals practicing in Yukon. Our findings, conclusions and recommendations should be evaluated in light of the limited scope of our work.

Textures

Symbol	Name	Size (mm)	Description
a	blocks	>256	Angular particles.
b	boulders	>256	Rounded and subrounded particles.
k	cobbles	64 - 256	Rounded and subrounded particles.
p	pebbles	2 - 64	Rounded and subrounded particles.
s	sand	2 - .062	
z	silt	.062 - .002	
c	clay	<.002	
d	mixed fragments	>2	Mix of rounded and angular particles.
g	gravel	>2	Mix of boulders, cobbles and pebbles.
x	angular fragments	>2	Mix of rubble and blocks.
r	rubble	2 - 256	Angular particles.
e	fibric		Well-preserved fibre (40% or more) that can be identified as to botanical origin upon rubbing.

Surficial Materials

Symbol	Name	Assumed status	Description
A	anthropogenic	(A)	Artificial materials, or geological materials so modified by human activities that their original physical properties (e.g. structure, cohesion, compaction) have been drastically altered. Typically related to placer mining activity in valleys, where the extent and severity of disturbance varies from stripping of surface organics to complete excavation of material to bedrock.
C	colluvial	(A)	Materials that have reached their present position as a result of direct, gravity-induced movement. Generally consists of massive to moderately well-stratified, non-sorted to poorly sorted sediments. Veneers are dominantly composed of angular fragments with lesser amounts of silt and sand, while blankets and aprons that most commonly form in concave or slope toe positions generally have higher contents of silt.
C1	colluvial complex	(A)	A mixture of sand, silt, organic materials and minor amounts of angular fragments that has reached its present position as a result of direct, gravity-induced movement. Typically forms aprons or blankets along the base of valley sides and valley bottoms, and consists dominantly of sandy silt with ice-rich permafrost. Locally known in the Klondike region as “black muck”.
D	weathered bedrock	(A)	Bedrock decomposed or disintegrated *in situ* by mechanical and/or chemical weathering processes. Generally consists of angular rock fragments ranging in size from coarse sand to blocks. Typically occurs on ridge crests and gentle upper slopes.
F	fluvial	(I)	Materials transported and deposited by streams and rivers. Generally consists of rounded gravels with interstitial sand and silt. Thick deposits typically occur on valley bottom floodplains/fans and terraces. Thin deposits occur within draws or on slopes where water is flowing over the permafrost table.
FG	glaciofluvial	(I)	Materials transported and deposited by glacial meltwater. Deposits range from non-sorted, massive gravels to well-sorted, stratified gravels, and only occur as terraces alongside the Yukon River.
O	organic	(A)	Organic materials resulting from the accumulation and decay of vegetative matter. Contains at least 30% organic matter by weight. Saturated deposits of accumulated mosses, sedges, or other hydrophytic vegetation are typical. Accumulations of leaf litter, twigs, branches and mosses are found in drier areas. Thin organic deposits are widespread in the area, occur in many different environments, and are only included in the map label where they influence the physical properties of the unit.
R	bedrock	n/a	Intact rock outcrops that may be covered by a thin mantle (<10 cm thick) of unconsolidated or organic materials. Typically occur on ridge crests (e.g. tors) and along the base of over-steepened slopes.

Qualifiers

Symbol	Name	Description
A	active	Used to qualify surficial materials and geomorphological processes with regard to their current states of activity
I	inactive	

Surface Expressions

Symbol	Name	Description
a	moderate slope	A unidirectional surface with a slope of 27-50%; longitudinal profile is either straight, or slightly concave or convex; relief of local surface irregularities is less than 1 m.
b	blanket	A mantle of unconsolidated materials >1 m thick; blankets are thick enough to mask minor irregularities of the underlying surface, but still conform to general underlying topography.
c	cone	A cone-shaped accumulation of sediment with a relatively smooth surface and a slope steeper than 26%; longitudinal profile is either straight, or slightly concave or convex.
f	fan	A relatively smooth sector of a cone exhibiting a slope gradient less than or equal to 26%; longitudinal profile is either straight, or slightly concave or convex.
a	apron (colluvium only)	Complex of coalescent cones, fans or constructional sloping surfaces, usually in a slope toe position.
h	hummocky	Steep-sided hillocks and hollows with multidirectional slopes, dominantly between 26 and 70%, and relief greater than 1 m; bedrock slopes may be locally steeper.
j	gentle slope	A unidirectional surface with a slope of 6-25%; longitudinal profile is either straight, or slightly concave or convex; relief of local surface irregularities is less than 1 m.
k	moderately steep slope	A unidirectional surface with a slope of 50-70%; longitudinal profile is either straight, or slightly concave or convex; relief of local surface irregularities is less than 1 m.
p	plain	A level or very gently sloping unidirectional surface with a gradient of 0 to 5%; longitudinal profile is either straight, or slightly concave or convex; relief of local surface irregularities is less then 1 m.
r	ridged	Assemblage of parallel or sub-parallel elongate hillocks with slopes dominantly between 26 and 70% and relief greater than 1 m; bedrock slopes may be locally steeper.
s	steep slope	A unidirectional surface with a slope of >70%; the longitudinal profile is either straight, or slightly concave or convex; local surface irregularities have a relief less than 1 m.
t	terraced	A single feature or assemblage of step-like forms where each step consists of a scarp face and a horizontal or gently inclined surface above it.
u	undulating	Gently sloping hillocks and hollows with multidirectional slopes up to 26% and relief greater than 1 m.
v	veneer	A layer of unconsolidated material 10 cm to 1 m thick; too thin to mask the minor irregularities of the surface of the underlying material.
w	mantle of variable thickness	A layer or discontinuous layer of surficial material of variable thickness (0 to about 3 m) that fills or partially fills depressions in an irregular substrate. It is generally too thin to mask prominent irregularities in the underlying material.
x	thin veneer	Similar to veneer; 2 to 20 cm thick.

Geomorphological Processes

Symbol	Name	Assumed Status	Description
F	slow mass movements	(A)	Slow downslope movement of masses of cohesive or non-cohesive surficial material by creeping, flowing, or sliding.
I	irregularly sinuous channels	(A)	A clearly defined main channel displaying irregular turns and bends without repetition of similar features. Back channels may be common, and minor side channels and a few bars and islands may be present, but regular and irregular meanders are absent.
M	meandering channels	(A)	A clearly defined channel characterized by regular patterns of bends.
R	rapid mass movements	(A)	Rapid downslope movement by falling, rolling, sliding or flowing of dry, moist or saturated surficial materials and/or bedrock.
S	solifluction	(A)	Slow gravitational downslope movement of lobate forms composed of saturated surficial materials across a frozen or otherwise impermeable substrate.
V	gully erosion	(A)	Parallel/subparallel long, narrow ravines due to erosion by various processes.
X	permafrost	(A)	Processes controlled by the presence of permafrost.

Geomorphological Process Subclass

Symbol	Name	Description
"	initiation zone	Polygon includes sites or zones where mass movement processes initiate; used to distinguish initiation zones from runout zones.
Permafrost Processes		
e	thermal erosion	Gullies and depressions created by melting of permafrost due to heat transfer from water bodies, typically flowing streams.
f	thaw flow slides	Shallow slope failures within the active layer caused by the thawing of permafrost.
n	pingos	A mound of earth-covered ice where groundwater discharge (seepage) through permafrost freezes and accumulates at or close to the ground surface.
s	sheetwash	The mobilization and redistribution of fine material by water flowing down the surface or within the shallow subsurface of smooth slopes, typically underlain by permafrost.
t	thermokarst subsidence	Surface depressions created by thawing of permafrost, typically containing standing water.
Mass Movement Processes		
b	rockfall	Descent of masses of bedrock by falling, bouncing and rolling.
g	rock creep	Slow down-slope movement of angular debris under periglacial conditions.
m	slump in bedrock	Sliding of internally cohesive masses of bedrock along a slip plane that is concave upward or planar.
r	rockslide	Descent of large masses of disintegrating bedrock by sliding.
s	debris slide	Sliding of disintegrating mass of surficial material.
u	slump in surficial material	Sliding of internally cohesive masses of surficial material along a slip plane that is concave upward or planar.

Map 2 – Terrain Stability and Hazards

Coffee Gold Project Terrain Stability and Hazards Map Code Definitions

Terrain Stability Class

Symbol	Class	Condition	Interpretation		Common terrain characteristics	
			Existing (current conditions)	Disturbed (following disturbance to ground conditions from road/facility construction without mitigation)	Existing (current conditions)	Disturbed (following disturbance to ground conditions from road/facility construction without mitigation)
I	stable	permafrost	No significant stability problems.		Planar to gently sloping bedrock and weathered bedrock; active fluvial units.	Planar to gently sloping bedrock, weathered bedrock and active fluvial units with deep, ice-poor permafrost.
		no permafrost			Planar to low sloping bedrock and weathered bedrock; active fluvial units.	
II	generally stable	permafrost	Very low likelihood of slope instability.	Very low likelihood of slope instability; no thermokarst subsidence or erosion expected.	Colluvial mantles on gentle slopes; gently sloping colluvial complexes; gently sloping fluvial units; organic deposits; moderately steep bedrock and weathered bedrock.	Colluvial mantles on gentle slopes with deep, ice-poor permafrost; gently to moderately sloping fluvial units with deep, ice-poor permafrost.
		no permafrost	Very low likelihood of slope instability.		Gently to moderately sloping colluvial mantles and fluvial units; moderately steep bedrock and weathered bedrock.	
III	generally stable with minor potential for instability	permafrost	Low to moderate likelihood of slope instability.	Low to moderate likelihood of slope instability and/or minor thermokarst subsidence or erosion possible.	Poorly drained colluvial mantles on moderate slopes; moderately sloping colluvial complexes; imperfectly drained colluvial mantles on moderately steep slopes; ice-poor to ice-moderate permafrost.	Poorly drained colluvial mantles on gentle slopes; imperfectly drained colluvial mantles on moderate slopes; ice-poor to ice-moderate permafrost.
		no permafrost	Low to moderate likelihood of slope instability.		Colluvial mantles on moderately steep slopes.	
IV	potentially unstable	permafrost	Expected to contain areas with a high likelihood of slope instability.	Expected to contain areas with a high likelihood of slope instability and/or moderate thermokarst subsidence or erosion.	Poorly drained colluvial mantles on moderately steep slopes; moderately steep colluvial complexes.	Any surficial unit thicker than a veneer with ice-moderate permafrost; poorly drained colluvial mantles on moderate slopes; imperfectly drained colluvial mantles on moderately steep slopes.
		no permafrost	Expected to contain areas with a high likelihood of slope instability.		Colluvial units on moderately steep to steep slopes.	
V	unstable	permafrost	Expected to contain areas with a very high likelihood of slope instability and/or thermokarst; may or may not exhibit evidence of previous slope failure and/or thermokarst.	Expected to contain areas with a very high likelihood of slope instability and/or major thermokarst subsidence or thermal erosion; typically exhibits evidence of previous slope failure and/or thermokarst.	Any unit with evidence of slope failure and/or thermokarst subsidence or thermal erosion.	Any unit with evidence of slope failure or ice-rich permafrost; poorly drained colluvial mantles on moderately steep slopes.
		no permafrost	Expected to contain areas with a very high likelihood of slope instability; typically exhibits evidence of previous slope failure.		Any unit with evidence of slope failure; typically occur on moderately steep to steep slopes.	

Applicable Hazard Category

Symbol	Class	Description
s	slope failure potential is dominant	Dominant hazard potential category related to gravity induced slope failure. May or may not include existing failures. Represents default category.
t	thermokarst potential is dominant	Dominant hazard potential category related to thermokarst subsidence or erosion. May or may not include existing failures.
b	both slope failure & thermokarst potential are co-dominant	Hazard potential category related to gravity induced slope failure and thermokarst subsidence or erosion. May or may not include existing failures.

Appendix C

Map 3 – Soil Erosion Potential

Coffee Gold Project Soil Erosion Potential Map Code Definitions

Soil Erosion Potential Class

Symbol	Class	General criteria	Common terrain characteristics	Management implications
VL	very low		Bedrock; planar weathered bedrock; planar fluvial deposits without permafrost.	No or only very minor surface erosion within small areas of exposed soil on locally steeply sloping ground (e.g., creek banks); conventional surface runoff management appropriate.
L	low		Gently to moderately sloping weathered bedrock; gently to moderately sloping, permafrost free colluvial mantles; gently to moderately sloping, permafrost-free fluvial deposits.	Expect minor erosion of fine sediments along ditch lines, cut slopes and across disturbed soils; avoid channelling water toward more sensitive downslope units.
M	moderate		Planar to gently sloping organic material; gently to moderately sloping colluvial veneers with shallow or near-surface permafrost; gently sloping colluvial blankets with shallow or near-surface permafrost; moderately steep to steeply sloping, permafrost-free veneers and thin veneers; fluvial deposits with shallow or near-surface permafrost.	Expect moderate erosion when water is channelled down road surfaces or ditches (minor thermal erosion possible in areas of permafrost); plan for preventative and remedial actions in disturbed areas, including measures to minimize concentrated surface runoff in areas of permafrost and to trap sediments.
H	high		Moderately steeply sloping colluvial veneers; moderately to moderately steeply sloping colluvial blankets with shallow to near-surface permafrost; gently sloping colluvial complexes; ridgetop saddles with silt-rich colluvial veneer.	Significant erosion problems are expected when water is channelled onto or over exposed soil on these sites (moderate thermal erosion possible in areas of permafrost), particularly on cut slopes; plan for preventative and remedial actions in disturbed areas, including measures to minimize concentrated surface runoff in areas of permafrost and to trap sediments.
VH	very high		Steeply sloping colluvial mantles with shallow or near-surface permafrost; moderate to steeply sloping colluvial complexes.	Severe surface and gully erosion problems can be created when water is channelled onto or over these sites (major thermal erosion possible in areas of permafrost), particularly on cut slopes; erosion is commonly evident in natural conditions. If area not avoidable, minimize concentrated surface runoff in areas of permafrost, minimize extent and duration of soil exposure, and promptly stabilize soils with salvaged vegetation (e.g., moss) cover or appropriate erosion control measures.

Tetra Tech EBA Technical Memo: Road Design Considerations in Areas of Permafrost

TETRA TECH EBA

TECHNICAL MEMO

ISSUED FOR REVIEW

To:	Robin McKillop, P. Geo.	**Date:**	March 3, 2016
c:	K. Jones, P. Eng., VP Arctic Development	**Memo No.:**	3
From:	V. Roujanski, P. Geol.	**File:**	704-ENG.EARC03004-01
Subject:	Geotechnical Considerations for Road Design in Areas Underlain by Permafrost		

This 'Issued for Review' document is provided solely for the purpose of client review and presents our interim findings and recommendations to date. Our usable findings and recommendations are provided only through an 'Issued for Use' document, which will be issued subsequent to this review. Final design should not be undertaken based on the interim recommendations made herein. Once our report is issued for use, the 'Issued for Review' document should be either returned to Tetra Tech EBA or destroyed.

1.0 INTRODUCTION

Tetra Tech EBA Inc. (Tetra Tech EBA) is pleased to submit this Memo to Palmer Environmental Consulting Group (PECG) regarding geotechnical considerations for the proposed all-season access road design in areas underlain by permafrost.

The proposed Kaminak access road route runs approximately 214 km from the Klondike Highway junction (Bear Creek) near Dawson City southward to the Coffee Property mine area.

2.0 PERMAFROST ALONG THE PROPOSED KAMINAK ROAD ALIGNMENT AND IN THE MINE AREA

2.1 Permafrost Distribution, Temperatures, Ice Content, and Related Geohazards

According to the Permafrost Map of Canada (Heginbottom, 1995) the proposed Kaminak road alignment is located within the zone of extensive discontinuous permafrost, in which 50 to 90% of the area is expected to be underlain by permafrost. Our calculations of permafrost distribution within the 200 m-wide proposed road corridor using ArcGIS technology show that approximately 56% of **the corridor area** is underlain by permafrost (9% - by very ice-rich permafrost, 12% - by permafrost with visible excess ice, and 17% - by predominantly ice-poor permafrost). Approximately 18% of **the corridor are**a is covered by placer tailings deposits and may include pockets of ice-rich material buried by the tailings and where the ground thermal regime was affected by mining. Approximately 44% of **the corridor area** is therefore estimated to be permafrost-free.

Permafrost thicknesses were measured with thermistor cables at the south end of the proposed access road, within the Coffee Mine area. The results are highly variable, ranging from approximately 30 m to 165 m thick.

Active layer thickness varies spatially and temporally. In areas with thicker insulating organic cover, it is usually thin (approximately 0.3 m to 0.6 m), whereas it can be several metres thick within partially exposed bedrock or within coarse surficial material with a high clast content.

At the south end of the proposed Kaminak road alignment, within the Coffee Mine area, permafrost temperatures were measured with thermistor cables, as well as with temperature sensors on vibrating wire piezometers. At the

Tetra Tech EBA Inc.

Edmonton, AB T5V 1B4 CANADA
Tel 780.451.2121 Fax 780.454.5688

depth of zero seasonal temperature variation, ground temperatures range from -0.6ºC to -2ºC. The permafrost classification for the road within the Coffee Mine area is thus “warm”.

Ground ice content (percent by volume) of the perennially frozen surficial materials along the proposed road alignment is highly variable, i.e. ground ice that is predominantly:

- not visible (Nf, Nbn, Nbe): This is generally ice-poor permafrost;
- visible excess ice (Vx, Vc, Vr, Vs): This moderately to ice-rich permafrost is well-bonded but rarely includes large ground ice bodies; or
- forming significant accumulations, such as ice wedges and other massive ice bodies: This is very ice-rich permafrost.

Warm permafrost temperatures along the proposed road alignment mean that areas underlain by ice-rich perennially frozen ground are sensitive to any kind of natural or manmade disturbance. As a consequence, one of the permafrost-related geohazards within the project area is thermokarst, which could be triggered by construction activities or by natural processes, such as forest fires. Development of thermokarst can be accompanied by thermal erosion, subsidence, and mass wasting of thawing ice-rich organic and fine-grained mineral soils.

2.2 Permafrost and Geotechnical Considerations for Road Design and Construction

Although every effort was made to avoid areas of thaw-sensitive perennially frozen soils when selecting the proposed road route, in some cases this was not possible and some sections of the selected road alignment cross areas underlain by warm ice-rich permafrost as shown on the Map of Permafrost Distribution Along Proposed Kaminak Road Alignment (Roujanski and McCuaig, 2016). Approximately 14 km of the 214 km-long road is founded on very ice-rich permafrost and approximately 24 km – on ice-rich permafrost. Road construction in such areas can cause a change in heat exchange at the ground surface and a change in the existing thermal regime of the ground. This may lead to thaw degradation of ice-rich permafrost in the subgrade, i.e. gradual melting of ground ice beneath the road. The resulting differential settlement may cause sharp dips in the road surface, progressively widening cracks and, less commonly, sinkholes where massive ice bodies previously existed. Thawing and settlement may continue for years until the ice has melted, thawing has stopped, or road fill bridges the resulting voids (Andersland and Ladanyi, 2004).

Within the areas of active or recent placer mining in the valley bottoms, the proposed alignment often follows existing mining access roads or crosses extensive areas covered by placer mining tailings. The ice-rich material within these disturbed sections has been mostly removed and the road maintenance costs are expected to be low. However, pockets of the ice-rich material may exist and will require special consideration for design.

In general, there are two approaches for the design of roads in permafrost areas (Johnston, 1981; Crory, 1991, McGregor et al., 2010):

1. **Passive Approach**: Provide full thermal protection to maintain permafrost in its frozen condition; or
2. **Active Approach**: Provide for limited thaw penetration into the underlying subgrade where preservation of permafrost is not possible or practicable and the consequences of thaw are allowed for in the design.

Both approaches may be employed on any appreciable length of the proposed road alignment.

A passive approach should be employed along those sections of the proposed road alignment that cross areas underlain by ice-rich permafrost, such as bottoms of creek valleys infilled with perennially frozen very ice-rich silt

(loess), interbedded with, and/or overlain by, organic material, known as “black muck”. Geotechnical considerations for the road design within such sections are as follows:

- Cuts and ditches are avoided wherever possible;
- Movement of equipment used for clearing the Right-of-Way (ROW) should be controlled or prohibited to keep the terrain disturbance to a minimum and to preserve the organic mat;
- The snow cover is carefully removed before construction of the embankment in a winter operation to reduce settlement of the fill during the thaw period;
- The embankment should be constructed by the end dumping method so that the vegetation cover will not be damaged by hauling equipment;
- High fills and sideslope alignments are avoided wherever possible;
- For conceptual design purposes, embankment thickness should be at least 2.0 m, placed on heavy weight, non-woven geotextile, to protect the subgrade from thawing;
- Flat horizontal and vertical curves and gradients not exceeding 8% are highly desirable;
- Drainage should be controlled to prevent water ponding along the toe of the embankment. This will allow the thermal regime of the frozen subgrade to be maintained. If runoff water must be collected and channelized, it should be done at a reasonable distance from the embankment (>10 m); and
- Snow accumulation should be prevented on the lee side of higher sections of the road embankment to maintain thermal regime of the frozen subgrade.

Basic principles for thermal design of embankments to preserve the permafrost include the following (McGregor et al., 2010):

- Favourable thermal conditions should be imposed and maintained underneath the structural core of the embankment; and
- Thermal design is required to ensure raised or at least maintained permafrost levels beneath the core of the embankment.

3.0 CONCLUSIONS

The proposed Kaminak access road route runs approximately 214 km across the zone of extensive discontinuous permafrost, in which approximately 21% of **the corridor area** is underlain by ice-rich to very ice-rich permafrost. Approximately 14 km of the 214 km-long road founded on very ice-rich permafrost and approximately 24 km – on ice-rich permafrost. Sections of the proposed alignment crossing thaw sensitive permafrost terrain will require special geotechnical considerations.

These include adequate thermal protection of ice-rich permafrost in the subgrade by avoiding cuts and ditching, minimizing terrain disturbance during clearing ROW, preserving the insulating organic mat, using special road construction methods (the end dumping), removing snow, and drainage control along the embankment.

Executive Summary

Newmont™
COFFEE

Executive Summary

The prevailing climate conditions at the Project site are typical for central Yukon. Average annual temperature at the proposed undertaking (~1,300 m above sea level) is -2.6 °C, with average monthly air temperatures that range from -15°C (December) to +14°C (July). Locally, the Project site experiences notable temperature inversions in the winter months, with observed ridgetop temperatures up to 10°C higher than measurements recorded at valley bottom locations.

Mean annual precipitation at 1,300 m is estimated to be 504 mm, with rainfall comprising 67% of this total precipitation during the months of April through mid-October, and the remaining 33% occurring as snow from late-October through March. Precipitation gradients were ascertained by inspecting site and regional precipitation data and were established as follows: 4%/100 m elevation gain for rainfall; and 7%/100 m elevation gain for snow.

Annual potential evaporation (PE) for the Project area is estimated to be approximately 460-480 mm, with monthly rates highest in May, June, July, and August (roughly 70 to 110 mm per month) and considerably lower for autumn, winter, and spring months. Consistent with other studies in the Yukon, the evapotranspiration estimate for the Coffee Gold site is roughly 40% of the assumed PE value or 170 mm per year. Results for other climate/weather parameters, including wind speed and direction, relative humidity, solar radiation, and atmospheric pressure are presented in Section 4 of this report.

Local patterns of streamflow are dominated by a snowmelt freshet that typically occurs between late April and early June. Following freshet, patterns of streamflow are punctuated by several rainfall-induced runoff events which occur throughout the summer and autumn. In general, these high flow events are short duration, persisting usually for a 1 or 2-day time period. Flows in local creeks and streams abate in October in response to freezing temperatures and it is notable that local watersheds typically experience zero flow conditions throughout the winter (*i.e.,* November through end March). Aufeis (*i.e.,* frozen groundwater seepage that accumulates within, and adjacent to, local watercourses) is pervasive in creeks and streams at the Project site and melts during the freshet but can persist into the early summer.

Based on measurements at Coffee Creek hydrometric stations, average unit yields across the Project site are 10.6 L/s/km^2 for the open water season (May to October) and range from 4 to 16 L/s/km^2, with specifics of the runoff regime for each monitoring station being dependent on drainage characteristics (*i.e.,* basin area, shape, mean elevation, extent of

permafrost, *etc.*). Unit yields range from 2.0 - 5.1 L/s/km^2 in October and decrease steadily to annual minima in March (*i.e.,* 0 - 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rains. At Coffee Creek, instantaneous peak flows, expressed as unit yields, are typically between 120 and 200 L/s/km^2, but measurements vary widely across the site (from 60 to >300 L/s/km^2).

As part of the baseline study, site-specific and regional hydrometric data were analyzed in combination to: (1) place the relatively short period of record for Coffee Creek into a broader context; (2) generate long-term (*i.e.*, 30+ year) synthetic climate and discharge records for the Project area; and (3) to compute robust climate and flow metrics (*e.g.*, extreme rainfall depths; instantaneous peak flows; low flows for various return periods) from the combined site and regional information. Methods related to these hydrometeorological analyses are presented in Section 2 and Section 3. Results are presented in Section 4 and Section 4.5 of the report and are carried forward to inform engineering and design studies related to the mine and water management plan and to construct and calibrate a site-wide water balance and water quality model for the Coffee Gold Project.

1. Introduction

Newmont™
COFFEE

1. Introduction

1.1 Project Background

Newmont Corporation (Newmont) is in the process of developing and permitting the Coffee Gold Project (the "Project"), a proposed heap leach operation located in west-central Yukon, approximately 130 km south of Dawson City (Figure 1-1). The Project is located in the Yukon-Tanana Terrane (YTT), an accreted pericratonic rock sequence that covers a large portion of the Omineca Belt in the Yukon and extends into Alaska and British Columbia. The Project has undergone a detailed Feasibility Study (Coffee Gold 43-101 FS) with project engineering and mine design progressing forward with full consideration of the environmental conditions at the property.

The Coffee Gold Project is amenable to development as an open pit mine with gold recovery recommended by heap leach mining methods. The general arrangement for the Coffee Project, includes the following major infrastructure: primary and secondary crushing facilities; a carbon adsorption plant; a gold refinery; the heap leach facilities; waste rock storage facilities (WRSF); open and backfilled pits; water drainage structures and storage ponds; haul roads; an accommodations complex; and an all-weather airstrip.

The open pits associated with the Project are the Latte, Double, Supremo and Kona pits (Figure 1-2). Waste rock associated with the undertaking is proposed to be placed in one main facility (Alpha WRSF), with additional backfill of waste in Latte, Double, Kona, and Supremo (SU1) pits. Proposed pits and WRSFs are all situated at high elevation (*i.e.*, median drainage basin elevations range from 945 to 1,220 m asl), and are proposed to be situated either on, or adjacent to, headwater tributaries of the Halfway Creek, Latte Creek and YT-24 (an unnamed tributary of the Yukon River) watersheds.

In parallel to exploration activities and feasibility studies, Newmont has resourced a full suite of baseline programs (*e.g.*, meteorology, hydrology, surface water quality, groundwater, soils, air, fish and fish habitat, wildlife) to support the preparation of an already submitted Project Proposal and related regulatory submissions to the Government of Yukon. Each year since 2010, monthly site visits have been undertaken that focus on the core activities comprising the baseline climate and hydrology monitoring programs, including: downloading data from automated weather stations; completing snow course surveys; collecting stage and discharge measurements to validate and enhance rating curves; undertaking hydrometric station data download and maintenance tasks; completion of benchmarking and levelling surveys; and, expanding the monitoring programs over time to include new stations, as required.

1.2 Climate and Streamflow Study Objectives

The objectives of the baseline meteorology and surface hydrology studies are as follows:

- To collect high-quality climate/streamflow data from a representative suite of Project area watersheds/locations;
- To describe runoff generation processes in the context of local climate conditions (*e.g.,* snow accumulation, timing of snowmelt, basin response to summer rainfall) and physiography (*e.g.,* basin size, basin storage, the influence of permafrost, land cover, elevation, and aspect).
- To present relevant metrics for local watersheds including low flow, peak flow, and unit yield estimates for Project site streams; annual and monthly precipitation depth summaries, including snow survey results; and annual and monthly air temperature records and typical rates of evaporation.
- To combine site-specific climate/hydrometric data with regional data sources (*i.e.,* Alaska/Yukon climate and flow monitoring data) to estimate inter-annual streamflow variability, recurrence intervals for low and peak flows, and to quantify extreme precipitation depths (*e.g.*, 1:100 year, 24-hour rainfall event).
- To generate the climate/hydrology datasets that will inform economic/engineering studies (*e.g.*, heap leach facility design) and be used to construct and calibrate the site-wide water balance and water quality model (Lorax, 2021) developed to advance Project permitting.

1.3 Overview of the Climate and Streamflow Monitoring Networks

The baseline surface hydrology monitoring study was initiated at Coffee Creek in autumn 2010, with the baseline meteorology study commencing later, in July 2012. These two monitoring programs remain fully operational, with data collection scheduled to continue through the assessment and licensing phases of the Project timeline. As of December 2021, Newmont possesses 9+ years of climate data and more than eight years of hydrometric data from the Project site.

Prior to 2014, baseline data collection for the meteorology and hydrology disciplines was led by Access Consulting Group, an environmental services firm operating out of Whitehorse, YT. Access Consulting Group established a high-elevation automated weather station (975 m asl), established snow courses at various elevations/aspects around the study site and selected eleven surface monitoring stations for flow and water quality measurement.

In spring of 2014, Lorax Environmental Services Ltd. (Vancouver) and Laberge Environmental Services (Whitehorse) assumed responsibility for the baseline meteorology and hydrology programs. Lorax and Laberge enhanced the existing baseline hydrology study by adding five new hydrometric stations to the monitoring network and by upgrading several of the flow monitoring stations with instrumentation to estimate continuous stream. The monitoring stations added to the network gauge streamflow from headwater tributaries, with several of the gauges sited at locations downstream of proposed open pits, waste rock storage and heap leach facilities.

In 2015, several additional flow monitoring sites were added on Halfway Creek, on YT-24 tributary and on Upper Latte Creek. Sampling of these sites was initiated to further refine the apparent chemical attenuation of certain parameters along these reaches, as well to determine whether reaches were gaining (streamflow increases from groundwater inputs) or losing (streamflow reductions due to infiltration to groundwater) tributaries. Monthly water quality samples and manual flow measurements (when possible) were taken from 2015 through present at these stations. In the summer of 2016, staff gauges, benchmarks, stilling wells and continuous water level recorders were installed at two of the stations.

As a complement to the automated station weather station installed in 2012, Newmont installed a second weather station adjacent the proposed heap leach facility in autumn 2018. The new weather station includes a full suite of climate sensors (*e.g.*, air temperature, relative humidity, wind speed and direction, precipitation, atmospheric pressure, solar radiation) and is situated at an elevation of approximately 1,340 m asl.

Given the large volume and long duration of the baseline hydrometeorological datasets, and due in part to the onset of the COVID-19 pandemic, site visits were scaled back to quarterly trips in the winter of 2020 and have continued at this frequency throughout 2021.

1.4 Report Structure

Sections of the report that follow build upon and update the baseline hydrometeorology report submitted in March 2017 as part of the Project Proposal submission (Lorax, 2017). The layout of the report is as follows:

- Sources of information, monitoring methods and any discussion related to derived outputs for the meteorology and hydrology disciplines are presented in Section 2 and Section 3 of the report, respectively.
- Section 4 and Section 4.5 presents baseline study results for the climate and streamflow disciplines, respectively.
- Main findings and a summary are presented in Section 6.

- Appended to the report are several technical memos and data summaries (see Appendix A through Appendix E) that contain the following information:
  - Appendix A presents summaries of the synthetic climate data assembled for the Project site, derived by combing site- and regional data sources. These synthetic climate data are direct inputs to the site-wide water balance and water quality models for the Project.
  - Climate change scenario data and results relevant to the Project site are summarized in Appendix B.
  - Appendix C is the primary repository for measured hydrometric data and associated metadata collected at the Project site.
  - Appendix D presents synthetic streamflow data for eleven baseline monitoring stations at the Project site.
  - Summaries of regional streamflow data relevant to the Coffee Gold Project are summarized in Appendix E.

2. Climate Monitoring and Methods

Newmont™
COFFEE

2. Climate Monitoring and Methods

2.1 Site Meteorological Data

The locations of automated weather stations, standalone tipping bucket rain gauges and snow courses at the Coffee Gold Project are summarized by Figure 2-1 and Table 2-1. At present, there are two active- and continuously recording climate stations, and two standalone tipping bucket rain gauge stations, the latter two gauges being in operation until 2018. There is also a comprehensive network of snow course stations at the property, with sample stations positioned to capture variability in snow accumulation with elevation and aspect change.

2.1.1 Automated Weather Stations and Rainfall Gauges

Details related to the automated weather station installations at the Coffee Gold Project include the following:

- A weather station was installed adjacent to the mine acess road, between Camp and the proposed heap leach facility in July 2012. Referred to as the Km 11 weather station, this installation is situated at elevation 975 m asl (Figure 2-2).
    - Climate monitoring at this station includes sensors deployed to measure air temperature (min, max, avg), relative humidity (min, max), wind speed (average, gust) and direction, incoming solar radiation, barometric pressure, and precipitation.
        - Rainfall data are measured at the station using a tipping bucket rain gauge.
        - In the winter, a snowfall conversion adaptor is deployed at the gauge to measure snowfall. An alter shield surrounds the precitation gauge to minimize wind turbulence and reduce gauge undercatch.
    - Climate sensors are sampled at 10-second frequency with observations recorded to the central Campbell Scientific datalogger at an hourly time step.
- Two standalone tipping bucket rain gauges were installed at the property in 2015 and operated through 2018. The gauges were installed at Coffee Camp (elevation 450 m asl) and adjacent to the high-elevation laydown (approximately 1,250 m asl) for the purpose of collecting supplementary rainfall depth data (May-October) and quantifying rainfall gradients (*i.e.*, percent increase in rainfall per 100 m elevation gain) at the mine site.

- A second automated weather station was installed at high elevation (~1,340 m asl) and adjacent the proposed heap leach pad footprint (*i.e.*, ~400 m to the northwest of the HLF) in October 2018. This station is equipped with a satellite transmitter, which uploads the climate data to a web server on an hourly basis. This will allow real-time assessment of station performance (*e.g.*, battery health and reliable sensor behaviour) and upper elevation climate conditions in support of exploration and mining operations.
    - Measured parameters at the Kona climate station include air temperature, relative humidity, wind speed/direction, precipitation, snow depth, solar radiation and barometric pressure (Table 2-2, Figure 2-3).
    - The central datalogger is equipped with a satellite transceiver, which enables real-time communication with the climate station.

Newmont intends to operate the Kona weather station in parallel with the original baseline climate station for several years. Overlapping climate data from these two weather stations, as well as any supplementary precipitation data collected at standalone rain gauges and snow courses, will be used to update the characterization of the site climatic regime, and refine the water balance models accordingly.

2.1.2 Snow Course Sampling

Each year of the baseline meteorology study snow course measurements were carried out at the property following Territory protocols. As shown in Figure 2-1, site snow courses were established at various elevations (*i.e.*, low, mid and high elevation) and oriented to discern effects of aspect on local snow accumulation (Table 2-3).

Sampling involves recording measurements of snow depth and snow water equivalent (SWE) along a 10-point transect (Figure 2-4). Snow courses were surveyed at, or near, peak seasonal accumulation (*i.e.*, Feb. 1, Mar. 1, Apr. 1) with surveys timed to coincide with regional monitoring undertaken by agencies in Alaska and Yukon. Field measurements are taken using a Federal Snow Sampling kit, which is comprised of several sampling tubes, a driving handle, calibrated spring scale (with graduated units in centimeters of water) and weighing cradle.

As a complement to the baseline snow monitoring stations, short duration but intensive snow sampling studies have been undertaken at Project area. Data collection of this nature typically informs specific engineering or modelling assumptions related to mine/water management facilities. For example, five snow course stations were established and sampled in 2018 and 2019 to resolve the spatial variability of snowpack conditions in the Halfway Creek drainage near the proposed footprint of the Alpha waste rock storage facility (WRSF; Table 2-4).

2.2 Regional Climate Data

Climate data relevant to the Coffee Gold Project is available from a suite of monitoring networks operated by both Federal and State/Territorial governments in the Yukon and Alaska (refer to Table 2-5 and Figure 2-5). For example, weather stations operated by Environment Canada in the Yukon and the National Oceanic and Atmosphere Administration (NOAA) in Alaska were assessed to verify site measurements of precipitation and conduct frequency analyses (*e.g.*, recurrence interval estimates of 24-hr rainfall). Additionally, snow data from stations operated by the Yukon Snow Survey Network and the SNOTEL network operated by the Natural Resources Conservation Service (NRCS) in Alaska were used to provide context and validate site data; conduct frequency analyses and resolve average and extreme snowpack melt rates.

Table 2-5:

PROJECT:

Coffee Gold Project

TITLE: Regional Precipitation Stations

PROJECT #: A362-3 | *FIGURE:* 2-5

P:\@Drafting\Coffee Gold\Drafting Figures\MxDs\Baseline Report\Regional Precipitation Stations_20160302.mxd

Several gridded climate re-analysis products are also available for the Coffee Gold Project area, providing information about the historic, contemporary, and future (climate change) climate conditions of the mine site:

- Outputs from the ClimateWNA program (v7.20; see Wang *et al.*, 2016) are utilized in this assessment to provide a check and verification on the site-specific precipitation and orographic gradients derived from measured data at the Project site.

  https://cfcg.forestry.ubc.ca/projects/climate-data/climatebcwna/#ClimateWNA.

- Data and outputs provided by the Scenario Network for Alaska and Arctic Planning (SNAP), were the main information source utilized to frame the future water balance conditions for the Project site under a changed climate.

  https://www.snap.uaf.edu/

The previous baseline report (Lorax 2017) included a climate change analysis for the Coffee Gold Project. The analysis, appended to this report (Appendix B), was prepared by Dr. Thomas Pedersen. The main findings and recommendations of Appendix B remain unchanged. However, new air temperature and precipitation results specific to the Representative Concentration Pathway (RCP) scenarios are presented in Section 4.5, since the RCP scenarios now supersede the SRES (Special Report on Emissions Scenarios – IPCC, 2000) vintage scenarios used prior.

2.3 Climate Analysis Methods

This section outlines the methodology used to analyse site-specific and regional climate records to derive representative metrics for use in engineering design and modelling efforts (*e.g.*, heap leach facility and site-wide water balance models). In addition to the site-specific and regional data sources outlined below, gridded outputs from the ClimateWNA tool (Wang *et al*., 2016) were used to supplement analyses where necessary.

2.3.1 Air Temperature and Precipitation

Temperature and precipitation (solid and liquid phase) data were summarized for the Project site and regional climate stations. Monthly average daily- minimum, average and maximum temperatures were computed, as well as extreme minimum and maximum temperatures for the period of record, for each station. Daily and monthly precipitation totals were also computed for the AK and YT stations near the Project. For extremes, values for air temperature and precipitation were gleaned from the Canadian climatic normal database or analogous databases for Alaskan climate stations.

2.3.2 Snow Water Equivalent (SWE) Measurements

Winter precipitation data are subject to several types of error which make reliable winter measurements difficult to obtain:

- Gauge undercatch resulting from turbulence effects around the gauge orifice (*e.g.*, Yang *et al*., 2005);
- Gauge capping due to snow falling at or near the triple point temperature that bridges the orifice and effectively seals the gauge; and,
- High spatial variability of snowfall (and subsequent redistribution) in mountainous areas (Pomeroy *et al*., 1999).

Furthermore, sublimation losses (from the existing snowpack) form an important component of the water balance in sub-arctic environments, with losses occurring predominantly from forest canopy interception and wind suspension and re-distribution (*e.g*., Hedstrom and Pomeroy, 1998).

The use of the maximum winter SWE value (*i.e.,* a value measured by the April 1st snow survey) effectively integrates sublimation losses up to the time of measurement, and thus winter snow course readings are highly informative with regard to total potential water available for melt (*i.e.*, SWE) and therefore freshet generation. More than twenty snow survey sites have been sampled with varying frequency at Coffee Gold from 2012 to present (Table 2-3) with five stations (Table 2-1) selected at the Project site to characterize SWE in this context.

Additionally, the Government of Yukon maintains an extensive snow survey network for flood and water supply forecasting purposes (http://www.env.gov.yk.ca/air-water-waste/snow_survey.php). The nearest territorial stations to the Coffee Gold Project are Casino Creek (elevation 1,065 m) and Pelly Farm (elevation 472m asl), with the two regional stations providing high-elevation (Casino Creek) and valley bottom (Pelly Farm) context for the Project site (Table 2-6).

The regional snow course records have long-term data (>30 years in length) and provide context to assess long-term variability in SWE at the Project site. The site and regional snow course data can also be combined to compute annual recurrence intervals for snowpack variables using standard frequency analysis techniques.

Table 2-6:
Regional Snow Survey Sites

Station Name	ID	Elevation (m asl)	Dist. From Project (km)	Record Period	Territory/ State	Latitude (°)	Longitude (°)	Mean Annual SWE (mm)
CASINO CREEK	09CD-SC01	1,065	32	1977-2021	YT	62.7333	-138.8	142
PELLY FARM	09CD-SC03	472	81	1986-2021	YT	62.8167	-137.3667	82

2.3.3 Synthetic Temperature and Precipitation Record

The development of a synthetic climate series for the Project Proposal was originally detailed in Appendix 8-A of the YESAB submission (Lorax, 2017) and was based on a site climate record that spanned 2012-2014 and the McQuesten regional climate station. Critical parameters that must vary in concert are:

- Air temperature (daily maximums, means and minimums). In particular, the winter inversions that result in higher ridgetop temperatures than valley bottom must be accurately reproduced.
- Daily precipitation totals, the annual distribution of precipitation between snow and rain, and the duration and magnitude of multi-day events and trace (<1 mm) events, must be well represented.
- Evaporation, on an annual and daily scale (*i.e.*, lower on days with precipitation, higher on warm days with additional wind and radiation inputs).
- Correspondence of wet- and dry-years between site and regional stations.

The synthetic climate record described below builds upon the Project Proposal submission and remains a foundational input to both the heap leach and site-wide water balance models. The additional site climate data collected since 2015 allows for more robust comparisons to be made between site and predictor stations. Further, the additional monitoring data provide the opportunity to confirm and revise assumptions related to winter temperature inversions, seasonal orographic precipitation gradients, maximum annual snowpack, and the importance of gauge undercatch of winter precipitation and snowpack sublimation.

2.3.3.1 Screening of Regional Stations

The first screening step involved correlating the monthly average temperatures and precipitation from the regional stations with the site record. The six closest stations to the Coffee Gold Project were assessed in the initial screening.

The second step involved correlating both monthly and daily variables to determine which regional stations best represented the intra-annual and sub-monthly variability in Project site climate. In addition to the correlation coefficients, the completeness of the regional record was taken into consideration as well. Preference was given to stations with the most complete records to reduce the need to infill missing data using other regional stations. Finally, those stations deemed to be most representative of the Project area were given priority (*i.e.*, similar elevation, comparable longitude, situated close to the Coffee Gold property).

Since the initial Project Proposal submission, two factors now require that this synthetic climate record be updated: an additional 4.5 years of site climate data are now available; and the McQuesten climate station was decommissioned by Environment Canada in September 2014. Based on the initial screening process described above, the Dawson A climate record (1897-2021) was selected as the predictor to derive the updated synthetic climate record.

The Dawson A station is located 130 km to the north of the Project site at an elevation of 370 m (Table 2-5, Figure 2-5). Over the corresponding period of record between the Project site and Dawson A records (2012-2021), the Dawson A climate station has recorded wetter than average (105% of MAP; 1945-2021) conditions.

2.3.3.2 Estimating Missing Data – Regional Record

The Dawson A daily air temperature record is 99.9% complete (37 missing days) over the period from January 1, 1945, to November 2021. Missing temperature data largely consisted of single day occurrences and these missing values were estimated with an average of the preceding and following days' values.

The precipitation record is mostly complete for the period of 1945 to 2002, but the subsequent years have more frequent data gaps. The 2002-2021 period is missing precipitation data for 7% of all days in this period. Missing winter precipitation values were infilled using the daily snowfall totals and assuming a fresh snow density of 10%. Any remaining missing values were infilled using the data from the nearby Pelly Ranch climate station.

2.3.3.3 Site Climate Data Adjustments

The issue of gauge undercatch for solid phase precipitation in cold regions is well documented in the primary literature and can account for up to 5-20% loss of the actual precipitation amount (Goodison *et al*. 1998; Yang *et al*. 2005;). This undercatch is largely attributed to high wind speeds transporting lower density snow particles away from the

gauge orifice, and thus the primary correction for this process requires reliable wind speed data. During the period of 2012-2014, the wind speed data collected at site were unreliable, due largely to the development of rime ice on the sensor. Thus, it was not possible to apply the gauge undercatch procedures outlined in Yang *et al.* (2005) and described in detail in Goodison *et al*. (1998).

Instead, the SWE data from the snow course co-located with the Km 11 meteorological station (975 m) were used to benchmark the winter precipitation data recorded by the gauge. Snowfall was calculated by summing gauged precipitation if hourly average air temperature < 0°C. Melt events were assumed to be negligible between October and the end-of-March, based on the air temperature record. An update of this comparison is presented in Table 2-7. Note that the gauge data for the period of Oct. 2014 to Mar. 2015 are considered unreliable and were excluded from this analysis.

Table 2-7:
Comparison of annual maximum measured SWE and estimated cumulative snowfall depths based on undercatch corrected precipitation record for elevation 975 m.

Station	Year	April 1st SWE (mm)	SWE corrected for sublimation (mm)	Oct-Mar precipitation (mm)
Km 11 (975 m)	2012[1]	110	132	--
	2013[1]	117	141	121
	2014	88	106	147
	2015	104	125	46
	2016	98	118	92
	2017[2]	68	82	81
	2018	115	138	99
	2019	72	86	*46*
	Average	100	120	97
Kona (1,340 m)[3]	2019[2]	60	72	58
	2020[2]	69	83	130
	2021[2]	113	136	110
	Average	81	97	99

Notes:
[1]KAM-SS-WX snow course not active, values provided are average of all high-elevation measurements.
[2]Value is from March snow survey

The wind sensor issues were satisfactorily resolved in autumn 2015, which allowed the effect of wind speeds on gauge undercatch to be calculated following Goodison *et al.* (1998). For the purposes of this analysis, wind speed was assumed to be the primary

determinant of gauge undercatch, and correction for wetting losses and evaporation were assumed to be negligible. When applied to the average annual snowfall total (assumed to be all gauged precipitation that fell from October to March), this correction provided an average snowfall estimate of 97 mm for elevation 975 m, and 99 mm for elevation 1,340 m. While a true maximum SWE value is not available for the climate station snow course (due to the monthly sampling interval), the average April 1st value is 100 mm, which is comparable to the gauged precipitation estimate. The same analysis was conducted with the precipitation and snow survey data collected at the Kona climate station (1,340 m), noting that there is only a single year of overlap between the two precipitation records due to gauge malfunction at the Km 11 station. Notably, the maximum annual SWE values were lower at the higher elevation station (on average), but the average winter precipitation accumulations are comparable, noting again the limited overlap in the two datasets.

On average, the undercatch corrected snowfall amounts were comparable to the maximum annual SWE measured at the snow course (Table 2-7). The snow course data are also likely biased low due to sublimation losses, which can result in an average SWE loss of 20% over the course of the winter season (*e.g.*, Janowicz *et al.*, 2004), comparable to the estimated magnitude of gauge undercatch. However, for the purposes of the water balance models, it is the volume of water contained in the snowpack available for melt that is the primary parameter of interest. Therefore, any estimate of sublimation is applied to the gauged precipitation adjusted for undercatch, and the reasonable benchmark for comparison is the measured SWE data from the snow course. As a result, the endpoint (volume of water available for melt during freshet) would be expected to be approximately the same.

2.3.4 Extreme Precipitation and Snowmelt

Design of water management infrastructure necessitates an understanding of the volume of water that might be delivered by a storm of given frequency and duration (*e.g.*, 1:100 year, 24-hour rain event). A detailed analysis was undertaken of the long-term precipitation records available from the regional climate networks, and the resulting frequency-duration storm magnitude estimates were scaled to the Project site using local precipitation gradients. The full analysis and results of this effort was originally presented in Lorax (2017) and is updated and summarized in Section 4.4.1.

To inform the required design capacity for the heap leach facility event ponds an estimate was also required of the probable maximum precipitation (PMP) for a 24-hour period. The probable maximum precipitation is defined as the greatest depth of precipitation for a given duration meteorologically possible for a design watershed or a given storm area at a particular location at a particular time of year, with no allowance made for long-term climatic trends (WMO, 2009). The statistical procedure used follows the methodology

presented in Hershfield (1961) and WMO (2009) and results are presented in full in Section 4.4.2.

2.3.5 Evaporation Estimates

Hourly potential evaporation rates were computed using Coffee Gold weather station data and the Ref-ET calculator – a compiled, stand-alone computer program that calculates reference evapotranspiration (ASCE, 2005). For the period of available record, an hourly climate input file was prepared from the Coffee Gold weather station database. The input variables required by Ref-ET are: Maximum air temperature, minimum air temperature, relative humidity, incoming solar radiation, atmospheric pressure, and wind speed.

From the assembled climate inputs, Ref-ET returned potential evaporation (PE) computations at hourly and daily time-steps based on an array of evaporation models (*e.g.,* Penman-Monteith model, Priestley-Taylor formulation; Section 4.1.7). An additional check on the derived PET estimates was run using the Hargreaves-Samani method (Hargreaves and Samani, 1985), which requires daily minimum, mean and maximum air temperatures and station latitude as inputs.

3. Hydrology Monitoring and Methods

Newmont™ COFFEE

3. Hydrology Monitoring and Methods

3.1 Baseline Monitoring Network at the Project Site

Table 3-1 and Table 3-2 summarize station nomenclature and drainage characteristics for the sixteen stations which comprise the existing baseline hydrology network for the Coffee Gold Project. Figure 3-1 shows the location of these monitoring stations with respect to proposed Project infrastructure and mine site footprints. Gauged watersheds at the Coffee Gold site range in size from ~3 to >500 km^2, noting that nine of the watersheds being monitored have drainage areas of less than 25 km^2. Furthermore, gauged watersheds differ in elevation characteristics (*i.e.,* mean catchment values for drainage basins range from 800 to 1,300 m asl).

The naming system for flow and water quality stations established at Coffee Gold in 2010 is not intuitive. Accordingly, new station IDs were recently prescribed for stations and utilized throughout this version of the baseline report (Table 3-1) as follows:

i. The station name begins with two or three letters which are based on the name of the drainage basin the station is situated within (*e.g.*, Latte Creek drainage basin = LC);

ii. If the gauge is on a tributary of the drainage basin mainstem, the tributary is given a number (even number for river left and odd number for river right *i.e.*, looking downstream), with numbers beginning at the confluence with the downstream watercourse (*e.g.*, the first tributary on Latte Creek above the confluence with Coffee Creek on river left looking downstream is LCT2); and,

iii. Numerical designations for stations that follow reference a distance in kilometres upstream from the confluence with the next largest stream (*e.g.*, for a station established 100 m above the LCT2 confluence with LC mainstem is LCT2-0.1).

3.2 Drainage Basin Characteristics

To place the streamflow dataset into the broader context of the Project site and to assist with the attribution of various physiological drivers of the streamflow regime in each basin, several spatial analyses were carried out. Specifically, the area and elevation characteristics (*i.e.*, drainage area, aspect, area-elevation relationships) of local drainages were described.

- Drainage areas for surface water monitoring stations were delineated using Surfer 12. The 1:50,000 Grid NRCAN Canadian Digital Elevation Model was used as the source of topographic data utilized for drainage basin delineations.

- Aspect, which is the measure of the direction that a slope faces, was computed with Global Mapper 12 using the NRCAN Canadian DEM as the elevation grid input. Aspect was calculated for each cell in the raster dataset, with output reported for each watershed counter clockwise in degrees from 0 (due north) to 360. Cells with no slope were assigned a value of -1. The proportion of each drainage comprised of the four cardinal direction aspects (North, 315°-45°; East, 45°-135°; South, 135°-225°; West, 225°-315°) is presented in the hydrometric station summaries in Appendix C.
- A hypsometric curve for a drainage basin summarizes the relative proportion of drainage area below (or above) a given elevation. Topographic relief within a drainage basin is commonly summarized in this format, with plots allowing easy comparison of topographic data between adjacent basins. For the Project area watersheds, hypsometric curves were generated using Scripter BASIC programming language and Surfer 12. For each basin, areas were calculated per 10 m interval from the minimum to the maximum elevation. These areas were standardized as the percentage of the basin area below that elevation (out of 100%) for plotting purposes. Hypsometric curves are presented for each station in Appendix C.

Table 3-1:
Cross reference table summarizing new and previous names for streamflow monitoring stations at Coffee Gold.

Drainage Basin	Watercourse	New Station Name	Previous Station Name
Coffee Creek	Coffee Creek (CC)	CC-3.2	CC-4.5
		CC-11.6	CC-0.5
	Latte Creek (LC)	LC-0.1	CC-3.5
		LC-11.4	CC-1.5
		LC-15.5	CC-6.0
	Latte Creek Trib 20	LCT20-0.1	CC-1.0
YT-24	YT-24 (YT24)	YT24-0.1	YT-24
		YT24-4.9	YT-24-2
Halfway Creek	Halfway Creek (HC)	HC-0.1	HC-5.0
		HC-6.8	HC-2.5
Independence Creek	Independence Creek (IC)	IC-2.7	IC-4.5
		ICT15-0.1	IC-2.5
		IC-16.1	IC-1.5
	Kona Tributary (KT)	KT-0.3	IC-3.0
	Independence Creek Trib 14 (ICT14)	ICT14-0.4	IC-0.5

Notes:
Station nomenclature for tributaries is as follows: numbering begins at confluence with next larger stream, and moves upstream, with even numbers on river left, and odd numbers on river right (looking downstream).
All numerical designations for stations are the distance in kilometres upstream from the confluence with the next largest stream.

Table 3-2:
Coffee Gold Project, Surface Hydrology Stations and Drainage Basin Characteristics

Station ID	Drainage	UTM N*	UTM E*	Drainage Area (km^2)	Frequency	Record Period
LCT20-0.1[w]	Small tributary to Latte Creek draining proposed South WRSF	6,971,733	584,890	3.4	Flow - continuous	June 2014 - present
LC-11.4	Latte Creek downstream of CC-1.0 drainage	6,971,654	585,071	23.1	Flow - continuous	Oct. 2010 - present
LC-0.1	Latte Creek immediately upstream of confluence with Coffee Creek	6,970,375	594,319	69.8	Flow - continuous	Oct. 2010 - present
LC-15.5	Upper Latte Creek	6,970,960	581,317	9.6	Flow - continuous	June 2014 – Aug. 2019
CC-11.6	Coffee Creek immediately upstream of confluence with Latte Creek	6,970,225	594,719	385.6	Flow - continuous	Oct. 2010 - present
CC-3.2	Coffee Creek	6,975,084	598,330	484.0	Flow - monthly	Oct. 2010 - present
HC-6.8	Halfway Creek - midway	6,976,548	584,089	14.8	Flow - continuous	Oct. 2010 - present
HC-0.1	Halfway Creek - mouth	6,980,536	588,823	27.0	Flow - continuous	Oct. 2010 - present
ICT14-0.4[s]	Independence Creek – unnamed large tributary	6,976,911	572,012	68.9	Flow - monthly	Oct. 2010 - present
IC-16.1	Mainstem of Independence Creek	6,976,835	572,260	81.1	Flow - continuous	Oct. 2010 – Aug. 2019
ICT15-0.1	Unnamed small tributary to Independence Creek	6,978,044	572,771	17.3	Flow - continuous	Oct. 2010 – Aug. 2019
KT-0.3[s]	Kona Creek, small tributary to Independence Creek	6,979,357	575,334	18.3	Flow - monthly	October 2010 - present
IC-2.7	Independence Creek - mouth	6,983,237	579,358	222.3	Flow - continuous	October 2010 - present
YT24-0.1	Mouth of YT-24, small tributary to Yukon River and draining North WRSF	6,979,073	589,526	11.8	Flow - continuous	June 2014 - present
YT24-4.9	YT-24 tributary – midway	6,976,472	585,922	4.0	Flow - continuous	June 2016 - present

3.3 Hydrometric Data Collection Methods

3.3.1 RISC Standards

The methods adopted for the baseline hydrology study are aligned with standards and procedures outlined in the Manual of British Columbia Hydrometric Standards - Version 2.0 (RISC, 2018). This document defines standards and detailed procedures for the acquisition of streamflow data and provides specific direction on the following topics: monitoring site selection; station construction and benchmarking; recording discharge measurements; developing stage-discharge relationships; and reporting and presenting hydrometric data. The BC RISC standards also summarize best practices and minimum requirements for stage (Table 3-3) and discharge (Table 3-4) measurements in order to achieve acceptable data capture, or data grades (Grade A, Grade B, Grade C) for the hydrology discipline.

Table 3-3:
Summary of BC RISC Standards for Stage (or Level) Data

Data Quality Indicator	Standard Grade for Stage/Level data				
	Grade A	**Grade B**	**Grade C**	**Grade E (estimated)**	**Grade U (unknown)**
Instrumentation					
Water level gauge reading/sensor accuracy	Greater of either 3 mm or 0.2% of effective stage	Greater of either 5 mm or 0.2% of effective stage	1 cm or better	See notes below	Undefined
Field Procedures					
Minimum number of benchmarks	3	3	3	See notes below	Undefined
Number of benchmark checks per year	2 or more, or at least once per year, if gauge is stable	2 or more, or at least once per year, if gauge is stable	1 or more	See notes below	Undefined
Data Calculation and Assessment					
Data and calculations reviewed for anomalies	Yes	Yes	Yes	See notes below	Undefined
Results compared to other station and years for consistency	Yes	Yes	Yes	See notes below	Undefined

Notes:
Hydrometric data should be graded as "E" (Estimated) if stations are operated using RISC standards (targeting Grade A, B or C), but data were estimated because of instrument anomalies, shift correction issues, missing data, or rating-curve extrapolation beyond maximum or minimum validated discharge level. Hydrometric data should be graded as "U" (Unknown data quality) when RISC standards not followed for data collection and/or data quality is not known.

Table 3-4:
Summary of BC RISC Standards for Discharge Data

Data Quality Indicator	Standard Grade for Discharge Data					
	Grade A/RS	**Grade A**	**Grade B**	**Grade C**	**Grade E (estimated)**	**Grade U (unknown)**
Instrumentation						
Meter calibration (when applicable)	*n/a*	Valid calibration confirmed	Valid calibration confirmed	Valid calibration confirmed	Valid calibration not confirmed	Undefined
Meter field verification (when applicable)	*n/a*	At least annually	At least annually	Less often than annually	See notes below	Undefined
Water level gauge reading/sensor accuracy	Greater of either 3 mm or 0.2% of effective stage	Greater of either 3 mm or 0.2% of effective stage	Greater of either 5 mm or 0.2% of effective stage	1 cm or better	See notes below	Undefined
Field Procedures						
Minimum number of benchmarks	3	3	3	3	See notes below	Undefined
Number of verticals in manual flow measurements when current meter used	*n/a*	20 or more, if channel width sufficient and not more than 10% of flow in any panel	20 or more, if channel width sufficient and not more than 10% of flow in any panel	10 or more, if channel width sufficient and not more than 10% of flow in any panel	See notes below	Undefined
Number of manual flow measurements per year	Minimum of one field measurement for rating verification	5 or more over adequate range of flow conditions	3 or more over adequate range of flow conditions	2 or more over adequate range of flow conditions	See notes below	Undefined
Number of benchmark checks per year	2 or more, or at least once per year, if gauge is stable	2 or more, or at least once per year, if gauge is stable	2 or more, or at least once per year, if gauge is stable	1 or more	See notes below	Undefined
Data Calculation and Assessment						
Discharge rating accuracy/ rating curve shift deviation threshold	<5%	<7%	<15%	<25%	See notes below	Undefined
Data and calculations reviewed for anomalies	Yes	Yes	Yes	Yes	See notes below	Undefined
Results compared to other station and years for consistency	Yes	Yes	Yes	Yes	See notes below	Undefined

Notes:
Hydrometric data should be graded as "E" (Estimated) if stations are operated using RISC standards (targeting Grade A/RS, A, B or C), but data were estimated because of instrument anomalies, shift correction issues, missing data, or rating-curve extrapolation beyond maximum or minimum validated discharge level. Hydrometric data should be graded as "U" (Unknown data quality) when RISC standards not followed for data collection and/or data quality is not known.

3.3.2 Station Instrumentation

Coffee Gold Project hydrometric stations are instrumented with metric staff gauges which are surveyed to three nearby benchmarks (Figure 3-2). At most stations, continuously recording water level recorders (*i.e.,* Solinst Levelogger Edge, Solinst LTC) are housed inside protective stilling wells to record continuously (*i.e.,* 15-minute frequency). Direct read cables are attached to the Solinst Leveloggers to minimize disturbance of sensors when monthly data downloads are scheduled.

Since Leveloggers are not vented to atmosphere and collect the combination of water level and atmospheric pressure change, it is necessary to collect an independent record of atmospheric pressure such that raw water level data can be pressure adjusted. Three Solinst Barologger recorders are deployed at the property for the collection of this information. Leveloggers and barologgers utilized in the baseline hydrology program are programmed for data collection at 15-minute frequency.

Relevant technical specifications for Solinst Leveloggers and Barologgers are provided in Table 3-5.

Figure 3-2: A typical hydrometric station installation at the Coffee Gold Project (LC-11.4) including metric staff gauge, stilling well, direct read cable attached to a water level recorder. Angle iron and bracing is used to anchor and secure the station.

Table 3-5:
Summary of Sensor Specifications for Solinst Leveloggers and Solinst Barologgers

Level Sensor	
Sensor Type:	Piezoresistive Silicon with Hastelloy Sensor
Accuracy:	±0.05% FS (Barologger Edge: ±0.05 kPa)
Resolution:	0.001% FS (M5)
	0.002% FS (Barologger)
Normalization:	Automatic Temperature Compensation
Temperature Compensation Range:	0 to 50 °C (M5)
	-10 to 50 °C (Barologger)
Submergence Range (m)	M5 (5 m), Barologger (air only)
Temperature Sensor	
Temperature Sensor Accuracy:	± 0.05 °C
Temperature Sensor Resolution:	0.003 °C
Datalogger Specifications	
Battery Life:	10 years based on 1 reading/minute
Clock Accuracy:	±1 minute per year
Operating Temperature:	-20 to 80 °C
Maximum Number of Readings:	40,000 readings typically, but up to 120,000 using linear data compression
Memory Modes:	Slate and Continuous
Communication:	Optical Infrared Interface (pedestal and direct read cable)
Sampling Modes:	Linear, Event, Future Start, Future Stop, Real-time View
Measurement Rate:	From 0.125 seconds to 99 hours
Barometric Compensation:	Solinst Software
Warranty:	3 years under normal use

Note: Barologger placement recommended to be within 30 km radius of Levelogger installations and within 300 m elevation.

3.3.3 Field Measurements of Stage and Discharge

Measurements of stage are recorded manually at station staff gauges during monthly site visits, with the point and continuous water level measurements used eventually to create a detailed record of stage height fluctuation at each monitoring location over time. Coinciding with manual stage readings, spot measurements of discharge are collected at Project hydrometric stations primarily by wading with a current meter and salt dilution gauging, while other measurement methods (*e.g.*, bucket-stopwatch tests, slope-area approach) were utilized upon occasion in the baseline study.

3.3.3.1 Discharge Measurements by Wading with Current Meter

The mid-section method is a widely used technique for calculating stream discharge that involves wading with a current meter to measure discharge in individual measurement cells or panels across a section (Figure 3-3, Figure 3-4). Using a top-setting wading rod and current meter, depth (m), width (m) and velocity (m/s) readings are used to compute a component discharge for each panel. Ultimately, total discharge (Q) is computed by summing the individual panel discharges.

The bullet points below outline monitoring methods utilized at the Coffee Gold Project with respect to this method:

- At each site visit, the measurement section is assessed to ensure the reach remains a suitable location for the measurements (*i.e.*, a straight section of the river, free of large boulders and other obstructions, stable banks, relatively even distribution of streamflow across the watercourse).
- The section is photographed. Photos are taken looking upstream and downstream to document site conditions and section/reach controls governing flow at the measurement location.
- Next, a measuring tape is secured across the section, perpendicular to the flow. The wetted width and maximum depth across the section are noted.
- If the watercourse is wide (*e.g.*, >2 m), the wetted width is divided into approximately 20 sections (between 16 and 24 being optimal to achieve a high grading in terms of measurement quality (Table 3-4).
    - The concept of panels (or verticals) for a mid-section method discharge measurement is shown in Figure 3-3. At each vertical across the stream a depth, width and velocity are recorded.
    - For narrow streams, velocity measurements are completed at a minimum distance of about 10-15 cm from one another, or at a distance that is practical to ideally establish 20 panels across the channel.
- Since local watercourses are generally shallow (*i.e.*, less than 1.0 m deep), the 0.6-depth mid-section method (*i.e.*, velocity readings are made at 0.6 of the depth below the water surface in the vertical is used as the mean velocity in the vertical) when water depths of <1.0 m are encountered.
    - If stream depth exceeds 1.0 m, a two-point method of measuring velocities is adopted with velocity measurements recorded at 0.2 and 0.8 of the depth below the surface – then averaged to a composite reading.

- Once the step of recording depth and velocity readings across the measurement section is complete, field staff then record a stage height reading from the manual staff gauge, so the station rating curve can be updated.

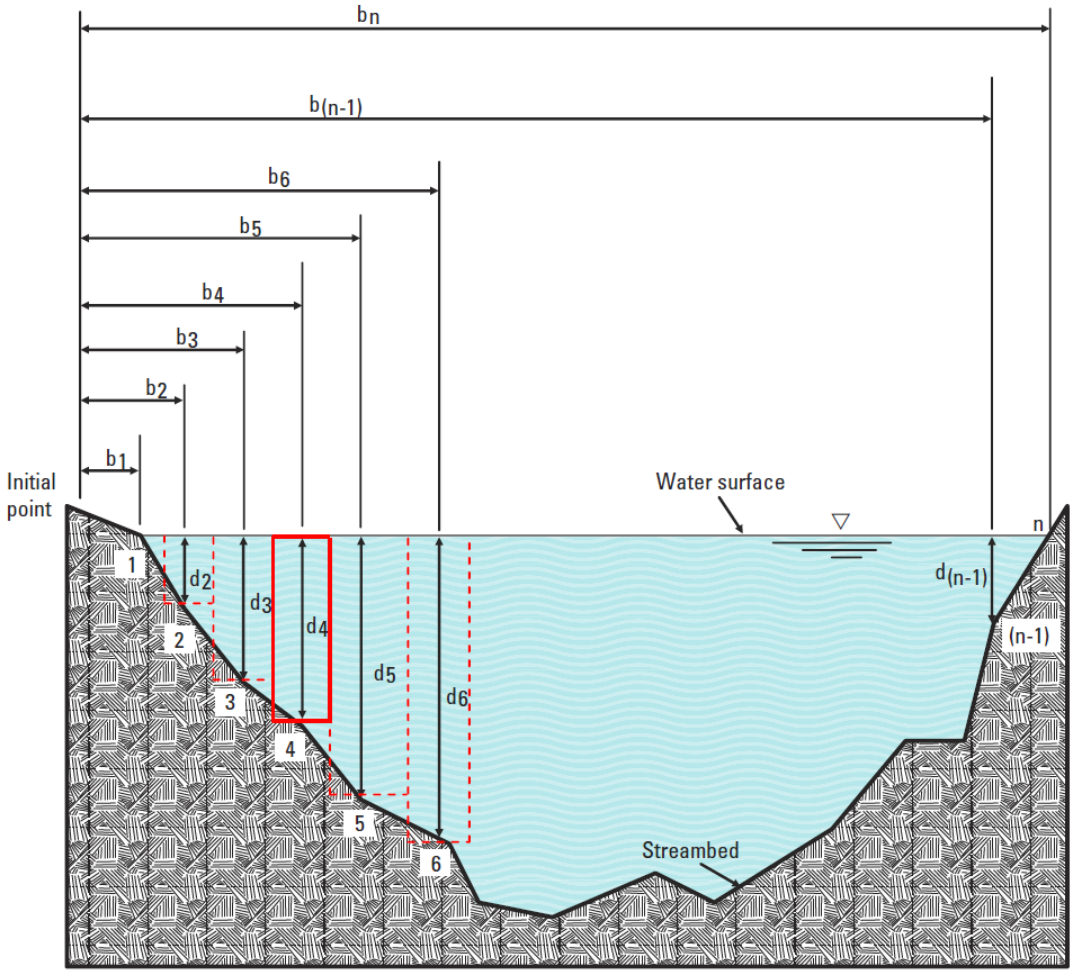

Figure 3-3: Definition sketch of the mid-section method of measuring stream discharge by current meter and wading (modified from USGS 2010) at a stream section by a hydrometric station. Terms b, d and n refer to widths, depths, and number, respectively.

Figure 3-4: Discharge measurement by wading using a current meter and top-setting wading rod at LC-0.1.

3.3.3.2 Discharge Measurements by Salt Dilution Gauging

Another common method of stream gauging involves the injection of a chemical tracer (*e.g.*, table salt, rhodamine dye) into a stream and determining its dilution following complete mixing into the flow. In concept, the injection of tracer creates a peak or wave that dissipates to background (pre-injection) levels with time as shown in Figure 3-5. By recording background conductivity, the mass of salt introduced and calculating the area under the tracer wave, an estimate of stream discharge can be computed very accurately using this method. Field methods for this measurement approach are well documented in the open literature (*e.g.*, Fraser and Hudson, 2002; Moore, 2004; Moore 2005).

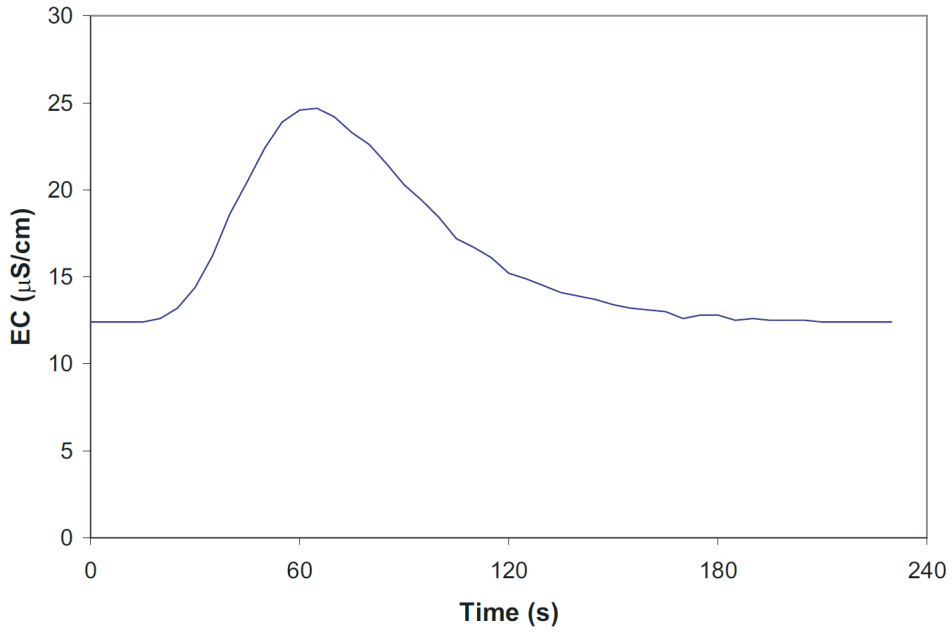

Figure 3-5: Example of a salt wave or 'peak' following injection of tracer to a watercourse.

3.3.4 Data Processing

3.3.4.1 Determining Points of Zero Flow

It is standard hydrometric practice to extend the rating curve through the zero-flow point (h_0) on the plot to ensure that the rating equation accurately estimates streamflow values that fall below the lowest measured discharge on record. This is particularly important since accurate definition of the low-flow condition plays a critical role in determining the available dilutive capacity in the receiving streams during ecologically sensitive periods (*i.e.*, summer low flows), and the use of open water season low flows as a calibration target for the numerical groundwater model developed in support of the Project Proposal effects assessment. In the absence of field measurements documenting zero flow stage, curve fitting and survey approaches were used to establish zero-flow stages for rating curve development.

Surveys to the benchmarks established at each hydrometric station are undertaken on an annual basis. Appendix C provides a detailed accounting of benchmarks per site and annual surveys conducted over the baseline study period. Using a level and survey rod, a typical survey involves tying into BM #1 at the hydrometric station. A 10 m arbitrary elevation is assumed for BM #1. Next, the relative elevation of the staff gauge, the water surface, and the creek bottom (including at the deepest section) are measured. The level is then repositioned, and relative elevations are taken to BM#2, the staff gauge, the water surface,

the creek bottom, and BM#1 – with closing of the survey aimed to be within 3 mm. With a frame of reference established between staff gauge readings and the lowest elevation in the creek (theoretical zero-flow stage), rating curve data may be adjusted (horizontal, x-axis transformation) to a theoretical zero-flow stage using survey data.

As illustrated in Figure 3-6 below, a graphical technique for determining the gauge height for zero flow is outlined in RISC (2018). As shown in the figure, field measurements of stage (Y axis) and discharge (X axis) are plotted and three discharges in geographic progression are selected. Horizontal and vertical lines plotted through selected discharges create points of intersection, and diagonal lines drawn through points of intersection indicate a zero-flow stage. This curve fitting approach was applied to field measurements collected per hydrometric station and zero flow stages were isolated. As a final step and subsequent to curve fitting, available stage data were appropriately adjusted to a new frame of reference and rating curve equations were computed per station using the SigmaPlot 12.0 software package.

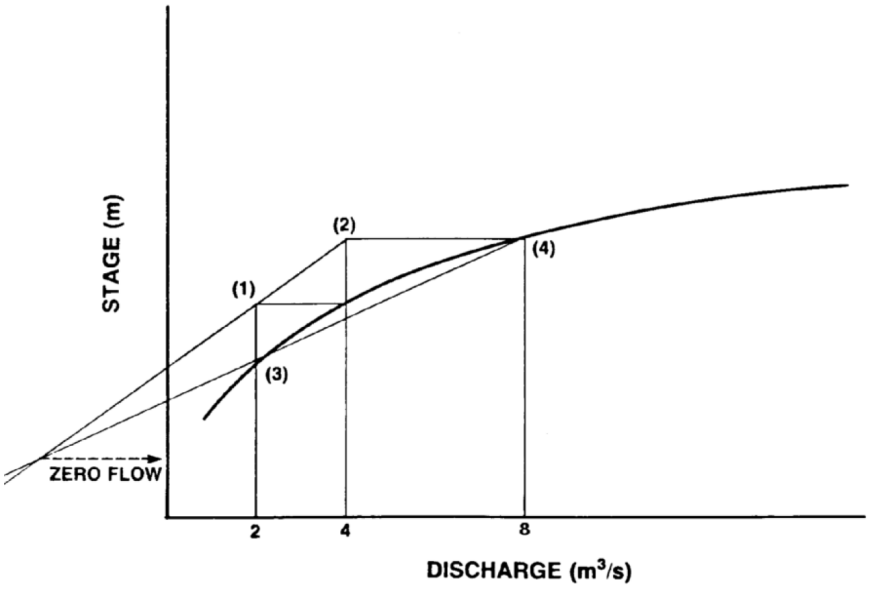

Figure 3-6: Conceptual diagram illustrating a curve-fitting approach to assign zero flow stage (from RISC, 2018).

Zero-flow fit curves were applied to the full stage data record for applicable hydrometric stations, and it is these estimates of discharge that are carried forward for the subsequent analyses. An example of the zero-flow fit rating curve for the LC-11.4 (previously CC-1.5) hydrometric station is presented in Figure 3-7. All manual measurements, rating curve error calculations and rating curve plots for baseline hydrometric stations are provided for review in Appendix C.

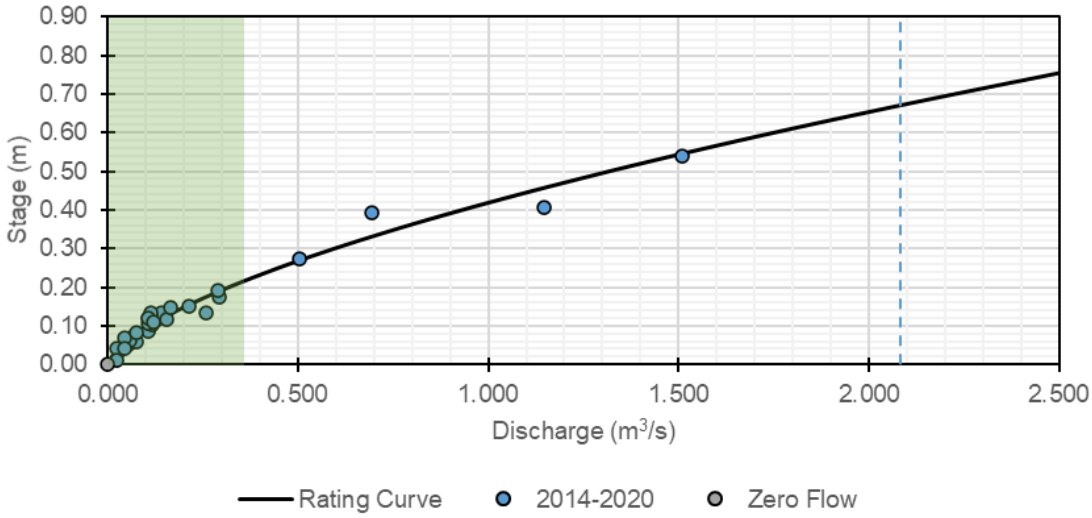

Figure 3-7: Zero-flow fit rating curve for the HC-6.8 hydrometric station. Dashed line indicates highest continuous discharge value estimated from rating curve, and green shaded area indicates 90th percentile of all calculated discharge values.

3.3.4.2 Rating Curves

Given the substantial amount of effort required to make manual measurements of streamflow, it is common practice to measure water level (stage height) on a continuous basis and convert these level readings to a discharge value. This requires that a relationship between stage height and discharge be developed that is unique to each hydrometric station, as this relationship is defined by the channel geometry.

Rating curves were developed for Coffee Gold hydrometric stations using the standard rating equation, and the coefficient, offset and exponent were selected to conform to hydraulic theory (*e.g.*, Maidment, 1993) and the stream channel properties.

$$Q = C(h - h_0)^n$$

Where:

Q = discharge (m^3/s)
C = coefficient (function of channel geometry)
h = stage (m)
h_0 = stage at point of zero flow, offset (m)
n = exponent (function of channel geometry)

The term C is usually 0.5 to 2.5 times the channel width at the control section, and n is often between 1.6 and 3 for moderate gradient streams. The BC RISC standards (RISC, 2009) state that ideally a rating curve will be based on a minimum of 10 stage-discharge measurements. Given the long duration of monitoring activities at the Project site, all Coffee Gold hydrometric stations meet this guidance criteria, with all station rating curves

based upon a minimum of 13 measurements. Average rating curve errors range from -11% to 3%, but generally fall between -4% and 3% (Table 3-6).

Table 3-6:
Summary of Project area hydrometric station rating curves

Station	Measurements (n)	2021 Rating Equation	Average Error (%)	Standard Error (%)
CC-11.6	16	$17.508*(h-0.22)^{1.664}$	-4%	13%
LC-11.4	24	$13.559*(h-0.27)^{2.536}$	3%	32%
LC-0.1	41	$5.390*(h-0.11)^{1.628}$	-11%	39%
LC-15.5	21	$2.488*(h-0.075)^{1.612}$	-1%	26%
HC-6.8	30	$3.889*(h-0.29)^{1.562}$	0%	33%
HC-0.1	36	$2.873*(h-0.2)^{1.345}$	-4%	21%
IC-16.1	14	$8.107*(h-0.36)^{1.721}$	-1%	14%
ICT15-0.1	18	$2.122*(h-0.22)^{1.696}$	3%	20%
KT-0.3	20	$7.000*(h-0.22)^{2.100}$	0%	46%
IC-2.7	21	$9.148*(h-0.06)^{2.302}$	-1%	19%
YT24-0.1	27	$6.081*(h-0.33)^{2.040}$	-4%	22%
YT24-4.9	13	$5.400*(h-0.220)^{2.100}$	-11%	33%
Average	23	--	-2%	26%

3.3.4.3 Computing Final Discharge Series

To acquire continuous discharge data, paired stage and discharge measurements are used to develop a stage-discharge relationship specific for each hydrometric station. A continuous discharge record is then computed from the stage-discharge relation and a continuous water level record.

To assemble discharge records, the following data processing steps were followed:

- Stage measurements from staff gauges and corresponding discharge measurements were assembled into site-specific rating curves (Appendix C).
- Compensated water level records were plotted alongside independent measurements of stage recorded at each monitoring station. Because the staff gauges were carefully benchmarked, these independent readings were assumed fixed and true, and water level records were adjusted as required to best fit the staff gauge record time series.
- Once adjusted to an elevation reference consistent with staff gauge measurements, site-specific rating curves were used to compute continuous discharge estimates from the continuous water level readings.

Plots and tabular summaries of all hydrometric information collected at Coffee Creek are presented by Station ID in Appendix C. Data for the LCT20-0.14 hydrometric station have not been compiled and tabulated in this report, as the rating curve is not well defined. Further, the YT24-4.9 station was destroyed in the July 2017 flood and had to be rebuilt; thus, the record is not sufficiently continuous to warrant inclusion at this point.

3.3.5 Regional Hydrometric Data

As a complement to the hydrometeorological datasets available for the Coffee Gold Project site, there are several regional flow monitoring stations near the mine site (Table 3-7; Figure 3-8). Several of these regional stations show extended period of record (*i.e.*, >30 years of daily streamflow data) and situated in close proximity (*i.e.*, within 75 km) to the Project site.

Site climate and hydrometric data overlap with regional climate and streamflow monitoring activities, and therefore, regional data sources are summarized in this baseline study. Overall, regional data are well suited for the following: to verify the reasonableness of site measurements; to characterize the period of baseline study in terms of range of natural variability and long-term trends; and, to create synthetic climate records by generating site-regional station relationships and then computing long-duration site datasets using these relationships and a predictor station(s). Regional streamflow data for ten representative Water Survey of Canada (WSC) hydrometric stations are presented in Appendix E.

3.3.5.1 Regional Streamflow Statistics

To obtain the input data required for the regional streamflow analyses (peak and low flows, annual runoff, trend analyses, *etc.*), the daily time-series (in m^3/s) from the hydrometric stations listed in Table 3-7 were run through a customized routine to extract the relevant metrics. Extracted metrics included the following:

- Average annual (calendar year and water year [October to September]) discharge;
- Annual maximum and minimum daily discharge;
- Annual and June-September minimum 7-day average discharge;
- Average monthly discharge (m^3/s) and runoff (mm);
- Date of freshet initiation (pulse date; after Cayan *et al.*, 2001);
- Date of freshet peak discharge, and;
- Date of centre of hydrograph mass (calendar year; after Stewart *et al*., 2005).

Summaries of extracted metrics from regional datasets are provided in table format in Appendix E.

Table 3-7:
Regional Hydrometric Stations near Coffee Gold Project. Stations highlighted in gray are summarized in Appendix E.

Station ID	Station Name	Drainage Area (km^2)	Period of Record	Data Frequency	Agency	Comments, Notes
09EB003	Indian River above the Mouth	2,210	1981 to 2018	Daily	WSC	Used as the regional predictor station to generate long-term, site-specific synthetic discharge records for the Project area, and in the regional peak and low flow analyses
09DD003	Stewart River at the mouth	51,000	1951 to 2018	Daily	WSC	This station is situated ~35 km downstream of the proposed barge location across the Stewart River, and was used in the regional peak and low flow analyses
09CD001	Yukon River above White River	149,000	1956 to 2018	Daily	WSC	This station is situated ~45 km downstream of the proposed barge location across the Yukon River, and was used in the regional peak and low flow analyses
09AH003	Big Creek near the Mouth	1,800	1974 to 2018	Daily	WSC	Used as the regional predictor station to generate long-term, site-specific synthetic discharge records for the Project area, and in the regional peak and low flow analyses
09CA003	Donjek River below Kluane River	12,400	1979 to 1994	Daily	WSC	Used for the regional peak and low flow analyses
09DD004	McQuesten River near the Mouth	4,750	1979 to 2018	Daily	WSC	Used for the regional peak and low flow analyses
09CA006	Nisling River below Onion Creek	7,910	1995 to 2018	Daily	WSC	Used for the regional peak and low flow analyses
09AH004	Nordenskiold River below Rowlinson Creek	6,410	1982 to 2018	Daily	WSC	Used for the regional peak and low flow analyses
09EA004	North Klondike River near the Mouth	1,090	1974 to 2018	Daily	WSC	Used for the regional peak and low flow analyses
09BC001	Pelly River at Pelly Crossing	48,900	1951 to 2018	Daily	WSC	Used for the regional peak and low flow analyses
09EB004	Sixty Mile River near the Mouth	3,060	1996 to 2018	Daily	WSC	Used for the regional peak and low flow analyses
09DD002	Stewart River at Stewart Crossing	35,000	1960 to 1973	Daily	WSC	Used for the regional peak and low flow analyses
29CD001	Thistle Creek above Yukon River	210	1981 to 1996	Daily	YHN	Used for the regional peak flow analyses
29DD003	Scroggie Creek above Stewart River	730	1981 to 1997	Daily	YHN	Used for the regional peak flow analyses
29DD002	Clear Creek above Barlow Creek	340	1980 to 2011	Daily	YHN	Used for the regional peak flow analyses
29EC001	Clinton Creek above Fortymile River	206	1978 to 1991	Daily	YHN	Used for the regional peak flow analyses

PROJECT:

Coffee Gold Feasibility Study

TITLE: Regional Hydrometric Stations

PROJECT #: A362-3 | *FIGURE:* 3-8

P:\@Drafting\Coffee Gold\Drafting Figures\MxDs\Regional Hydrology Stations_20160126.mxd

3.3.5.2 Regional Peak Flow Analysis

A frequency analysis was previously conducted to estimate the recurrence of discharges of a particular magnitude for all regional hydrometric stations within a 200 km radius of the Project (Lorax, 2017). In a frequency analysis, a time-series of annual flow events are viewed as being a set of events sampled from a population of all events that is infinitely long and therefore continuous. Continuous probability distributions (*e.g.*, Log Pearson 3, Generalized Extreme Value, Log Logistic 3P) are then fitted to the observations and future and/or extreme events (*e.g.*, 1:200-year flood) are estimated from best fitting probability distributions. Statistical tests (*e.g.*, Kolmogorov Smirnov; Anderson Darling) can be used to isolate the probability distributions that best fit the observations or return a conservative result (Meylan *et al.*, 2012). Alternatively, results of the frequency analysis may be based a priori on a probability distribution conventionally applied in hydrology studies (*e.g.*, Log Pearson Type III).

At the time Lorax (2017) was prepared, annual time-series of instantaneous maximum discharge values from the regional stations listed in Table 3-7 were compiled for all years with data to 2014. Where the instantaneous maximum value was missing, the maximum daily discharge for that year (assuming a complete record was available) was scaled by the average ratio of instantaneous to daily peak flow from the other years in the station record (*per* Ahmed and Jackson, 2013). This ratio ranged from 1.01 to 1.17.

Final datasets were then input to the EasyFit Professional (v5.5) software to fit a range of distributions. The Log Pearson (Type III) distribution was used for most stations, with the Log Logistic 3P distribution providing the best fit (using the Anderson Darling test) for several of the smaller drainage basins. Best fitting probability distributions were then fitted to the unit discharge values and the following recurrence intervals were estimated: 1:2-year, 1:5-year, 1:10-year, 1:20-year, 1:50-year, 1:100-year and 1:200-year floods. To complete the analysis, peak flow estimates for each station and recurrence interval were plotted against drainage area. Best fit and conservative fitting envelope curves were then derived from the data with the information plotted in this format.

For this updated analysis, annual extreme discharges were obtained for regional stations through to the end of 2020. Data for 2015, 2016 and 2017 were then compared to values utilized in the previous frequency analysis to determine whether recent extreme events fall within (or outside) the range of variability presented in Lorax (2017). Since recent extreme values were all low magnitude compared to the annual extreme discharge series of the earlier dataset, it was concluded the results of the previous peak flow analysis remain valid. Data for Big Creek near the Mouth (09AH003) are shown in Figure 3-9 to illustrate the low magnitude of extreme discharges recorded in recent years in Yukon.

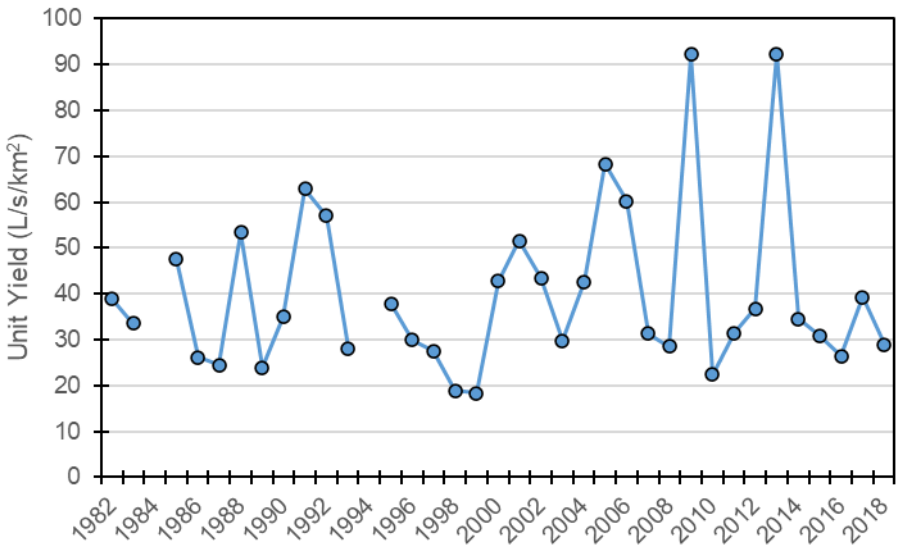

Figure 3-9: Maximum annual peak discharge series for Indian River above the Mouth (09EB003).

3.3.5.3 Regional Low Flow Analysis

The same set of regional stations (Table 3-7) were also assessed in a low flow analysis. To process datasets for the low flow analysis, daily discharge data from eleven of the selected regional hydrometric stations were downloaded from the Water Survey of Canada data portal and seven-day rolling averages were computed from the daily discharge data. Next, annual minima time-series of the winter and June-September 7-day average low flows were assembled for each station. These data were then exported to the EasyFit software for further evaluation.

Through an inspection of the statistics and ranking data output by EasyFit, no single probability distribution could be identified that consistently provided a best fit to the station observations of low flow. However, the Log Pearson (Type III), Weibull and Log Normal distributions were, in general, high-ranking distributions for each hydrometric station inspected. Furthermore, estimated low flows based on these three probability distributions were very similar. Consistent with guidance from the BC Ministry of Environment (see BC MOE, 2012), low flow values returned by the Log Pearson (Type III) distribution are reported in Section 3.2, noting that recurrence interval estimates were derived for the $7Q_2$ (median), $7Q_5$, $7Q_{10}$ and $7Q_{20}$ events. Where the Log Pearson (Type III) distribution did not provide a good fit to the data, the Weibull distribution was used following the guidance provided in WMO (2009).

As a final step in the low flow analysis, estimated low flows for each station were plotted against their respective drainage areas. This plot in effect allows a low flow metric to be

estimated for a location of interest based on drainage area information alone. Summer and winter manual low flow measurements collected from the Project area drainages were added to these regression plots, to validate the low flow-drainage area relationship for the smaller spatial scale (*i.e.*, drainage areas on the order of 10 to 400 km^2).

3.3.5.4 Synthetic Streamflow Records

The high-quality discharge records available for the Project site allowed synthetic discharge time series to be constructed for eleven Project hydrometric stations using regional streamflow data as a driver. Synthetic streamflow records allow the site-specific characteristics of the Project basins to be retained in long-term record, while preserving any regional inter-annual variability in discharge. This allows for more robust recurrence interval estimates of critical discharge regime metrics (*e.g.*, mean annual runoff, seasonal runoff distribution, June-September $7Q_{10}$, *etc*.), and maintains the regional inter-annual variability in streamflow resulting from multi-decadal climate cycles (*e.g.*, PDO, AO) and trends (*e.g.*, increasing winter low flows).

Following the Empirical Frequency Pairing (EFP) methodology described by Butt (2013), the overlapping periods of record were selected for the site station and the representative regional stations. Data were discretized by month, and all available daily average flows for each month were ranked. For example, if there were data available for the month of April over five years, then the number of paired observations was 150. The paired and ranked observations were then plotted, with the regional station set as the predictor variable (x-axis). Due to the limited availability of continuous winter flow data, all data for the months of October through April were grouped to represent the winter low-flow regime. Additionally, all available spot flow measurements were included in the analysis.

The methodology described in Butt (2013) was modified to improve the predictive power of the EFP method. A piece-wise linear regression approach was employed to estimate flow values that fall between each site-regional data pair. For cases where the minimum/maximum daily flow in the record fell outside of the site data record, the relationships were extrapolated using a linear relationship between at least 10 data pairs, and an understanding of the regional peak and low flow unit yields. An example of the EFP relationship for the LC-11.4 hydrometric station is provided in Figure 3-10 for the month of May.

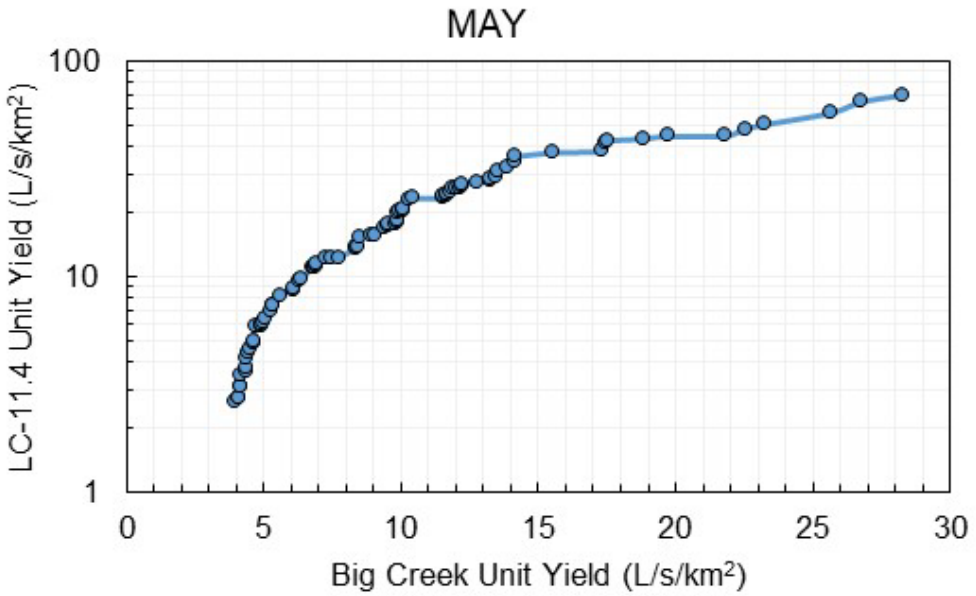

Figure 3-10: Example of an empirical frequency pairing relationship for May at hydrometric station LC-11.4.

Based on the streamflow data available when the Lorax (2017) baseline hydrometeorology report was prepared, the hydrometric record from the Indian River above the Mouth WSC gauge (09EB003) was originally used as the predictor basin for all synthetic hydrographs. This station was selected based on the following criteria:

- The drainage basin is situated north of Coffee Creek, but south of Dawson City.
- Record period of sufficient length and completeness to capture the full-range of inter-annual streamflow variability over the last 30 years;
- The record provides a reasonable representation of all relevant components of the site hydrographs (*i.e.*, rapid freshet, multiple rainfall driven peaks during the summer and early fall, and extended winter base flows of <1 L/s/km^2).

The Big Creek near the Mouth regional hydrometric station also meets the above criteria with the added benefit of several more years of site hydrometric data that overlap with regional values so the regional predictor station for the synthetic streamflow update was switched to the Big Creek station. Plots of all monthly and low flow EFP relationships are provided in Appendix D for all Project hydrometric stations. Also included in Appendix D are flow duration curves for the overlapping period of record (site and synthetic time-series), the full synthetic daily streamflow time-series, plots of annual runoff anomalies and tables summarizing the monthly average synthetic discharge values.

3.3.5.5 Supplementary Recurrence Interval Analyses: Annual Runoff Recurrence Intervals and June-September 7Qmin Flows

The synthetic streamflow time series created using the EFP method were used to estimate several metrics for the 11 Project site stations analysed. The full synthetic time-series for the Project stations are presented in time series format and as standardized anomalies in Appendix D. Standardized anomalies relating to synthetic hydrometric data were calculated as follows:

$$k=\frac{\mu-\bar{X}}{\sigma} \qquad \text{[Equation 5]}$$

where k is the standardized anomaly (dimensionless);

μ is the annual runoff value in mm;

σ is the standard deviation of the annual runoff series in mm;

$\bar{X}$ is the mean annual runoff in mm for the period of record.

Similarly, to the regional data, time series of June-September minimum 7-day average streamflow (*i.e.*, 7Qs) were analysed using the EasyFit 5.6 statistical package. Annual runoff recurrence interval estimates were derived for the 1:2 (median), 1:10, 1:25, 1:50, 1:100 and 1:200 wet and dry years using the Generalized Extreme Value (GEV) distribution. June-September 7-day minimum streamflow recurrence interval estimates were derived using the Log-Pearson (Type III) (LP3) distribution for the $7Q_2$ (median), $7Q_5$, $7Q_{10}$ and $7Q_{20}$ events as recommended by MOE (2012). Where the LP3 distribution did not provide a good fit to the data, the LogNormal distribution was used instead (WMO, 2009). The synthetic data were not used for the peak flow analyses, as the extrapolation procedure used for the upper end of the regional-site relationship may introduce bias into the results.

4. Climate Regime Characterization

Newmont™
COFFEE

4. Climate Regime Characterization

The sections below provide a summary of site and regional climate data relevant to the Coffee Gold Project. Period of record data are presented for the Km 11 weather station, the Kona weather stations, standalone tipping bucket rainfall gauges (Camp, Laydown), local snow courses and the nearest regional climate stations. In addition to the information presented in Section 4, supporting information in the form of data tables and plots is presented in the following data appendices: Appendix A (synthetic climate data), and Appendix B (climate change scenario data and trends for the Project site).

The prevailing climate conditions at the Project site are typical for central Yukon. Average annual temperature is approximately -2.2 °C at 1,000 m asl, with average monthly air temperatures that range from -16.0°C (December and January) to +14.0°C (July). Locally, the Project site experiences notable temperature inversions in the winter months, with observed ridgetop temperatures up to 10°C higher than measurements recorded at valley bottom regional stations. With the installation of the second climate station in autumn 2018, the occurrence and permanence of temperature inversions between the Km 11 (975 m) and Kona (1,340 m) monitoring station can now be evaluated at hourly, daily and monthly timestep.

Mean annual precipitation (MAP) at the Project site (~1,300 m above sea level) is estimated to be 504 mm over the 1991-2020 climate normal period, a value consistent with precipitation depths reported by Brabets (2000) and ClimateWNA (Wang *et al*., 2016). Approximately 68% of the annual precipitation is expected, on average, as rainfall during the months of May through September, with the remaining 32% expected as snow reporting between October and April. Site-specific precipitation gradients were ascertained through an inspection of site- and regional precipitation data with the analysis returning the following orographic gradients for the Coffee Gold Project: 4% increase in precipitation per 100 m elevation gain for rainfall (4%/100 m); and 7%/100 m elevation gain for snowfall.

Annual potential evaporation (PE) for the Project area is estimated to be ~500 mm which is roughly equal to the MAP estimate for the Project site. On an annual basis, monthly evaporation rates are highest in May, June, July, and August (*i.e.*, 70 to 110 mm per month). In contrast, potential evaporation rates for autumn, winter and spring months are generally low or negligible. Consistent with other studies in the Yukon, the evapotranspiration estimate for the Coffee Gold site is roughly 40% of the assumed PE value, or roughly, 190 mm per year.

4.1 Project Site Climate Records

This section presents tabular and graphical summaries of key climatic records collected at the two Project site climate stations, including:

- Air temperature;
- Precipitation;
- Relative humidity;
- Wind speed and direction;
- Atmospheric pressure;
- Solar radiation;
- Potential evapotranspiration; and,
- Snow depth and snow water equivalent.

With the exception of the occasional winter riming event which affects climate station sensors (*e.g.*, anemometer, wind vane), the instrumental record for Km 11 climate station now exceeds 9 years in duration and is essentially continuous, while the Kona climate record is approximately 3-years in duration.

4.1.1 Air Temperatures

Mean annual air temperature (MAT) for the bulk of the regional climate stations near Coffee Gold range from -5 to -2°C (Table 2-5). At the Km 11 station, record period MAT is -2.2°C, and -2.6°C at the Kona climate station (Table 4-1). On a monthly basis, average air temperatures for the Project site also show similar patterns and magnitude as the nearest regional climate stations (Figure 4-2). Minimum (maximum) recorded temperatures are -38.2°C (29.7°C) and -36.2°C (23.7°C) at the Km 11 and Kona climate stations, respectively (Table 4-1). Average monthly air temperature ranges are as follows (with reference to Figure 4-1):

- Minimum monthly air temperatures range from -32.6 to 6.0°C at the Km 11 station, and -31.6 to 4.1°C at the Kona station;
- Mean monthly air temperatures range from -16.8 to 13.9°C at the Km 11 station, and -15.4 to 11.7°C at the Kona station; and
- Maximum monthly air temperatures range from -2.0 to 25.3°C at the Km 11 station, and -1.8 to 22.9°C at the Kona station.

Table 4-1:
Monthly minimum, mean and maximum air temperatures at the Km 11 and Kona climate stations. All values are in °C.

Note: All values calculated from hourly data.

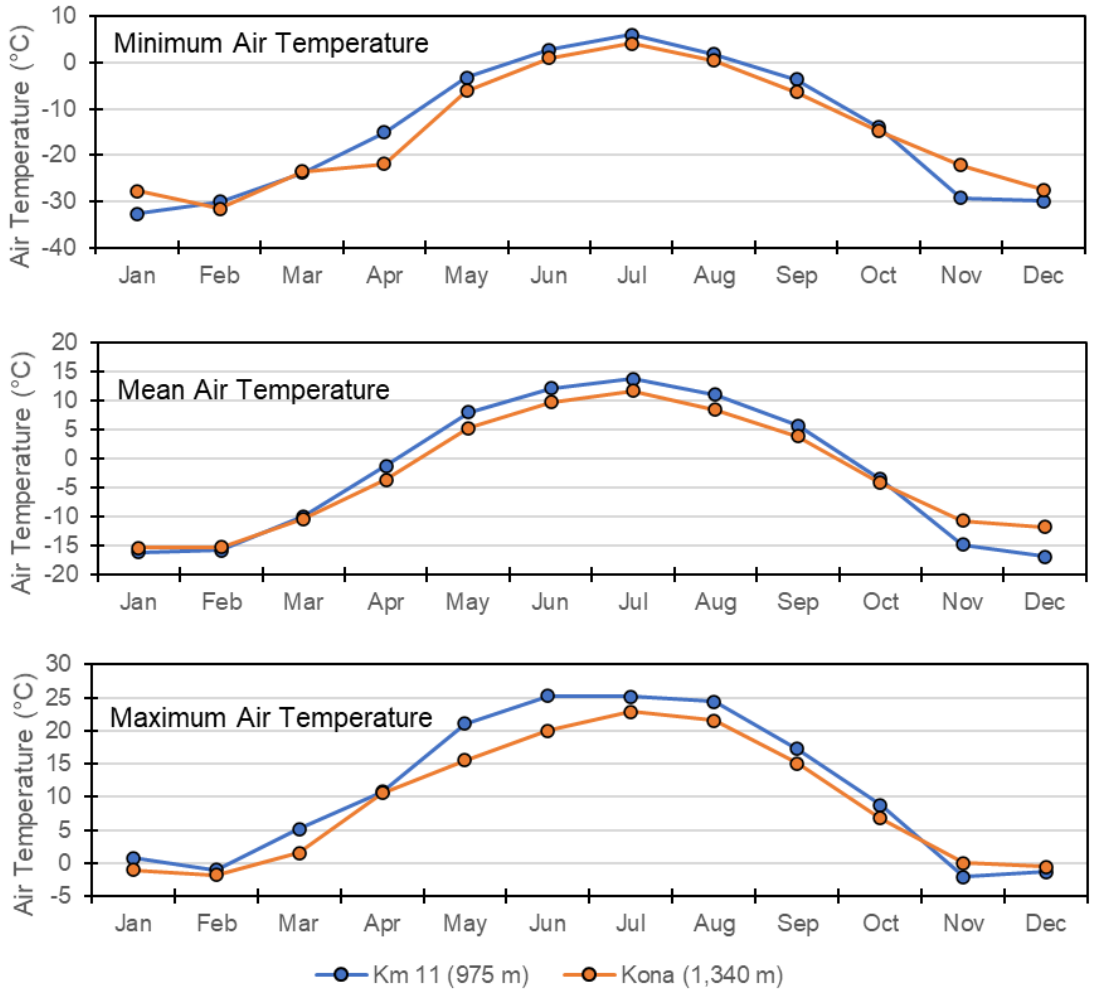

Figure 4-1: Mean monthly minimum (top panel), mean (middle panel) and maximum (bottom panel) air temperature records for the Km 11 and Kona climate stations.

The lowest air temperatures are often experienced in December through February, while the highest air temperatures usually occur in July at both stations, noting that there is evidence of inversion events during the winter months (see Section 4.1.1.1).

4.1.1.1 Air Temperature Inversions

At the upper elevations of the Project site, a notable departure from the regional temperature signal occurs during winter months (Figure 4-2). Valley bottom temperature inversions occur during winter months and ridgetop temperatures may be 10°C higher than measurements recorded at valley bottom stations. These inversions result in a reversal of the normal lapse rate (decreasing temperature with increasing elevation) and are typically caused by cold Arctic air masses pooling in the valley bottoms from late October to early March.

Wahl (1987) reports that during a temperature inversion, lapse rates can range from 3-5°C/1000 m of elevation gain. Based on a comparison of data between nearby Pelly Ranch (elevation 445 m) and Km 11, the average lapse rate is 5.8°C/1000 m over the winter (October through April). During summer months (June, July, August), the local lapse rate is -3.3°C/1000 m which is similar to the standard adiabatic lapse rate (-6.4°C/1000 m) and the saturated adiabatic lapse rate (-5.0°C/1000 m). These site:regional lapse rates are supported by values calculated from the two Project site air temperature records, with lapse rates averaging 5.5°C/1000 m during the winter months, and -5.8°C/1000 m during the summer. Note that air temperature inversions at the Project site appear to be most pronounced during the months of November and December (Figure 4-2).

Much of the annual precipitation total for the Project site reports as rainfall during summer months. The occurrence of warmer and wetter air masses at the Project (versus lower elevation) may explain the difference in lapse rate noted for the summer months.

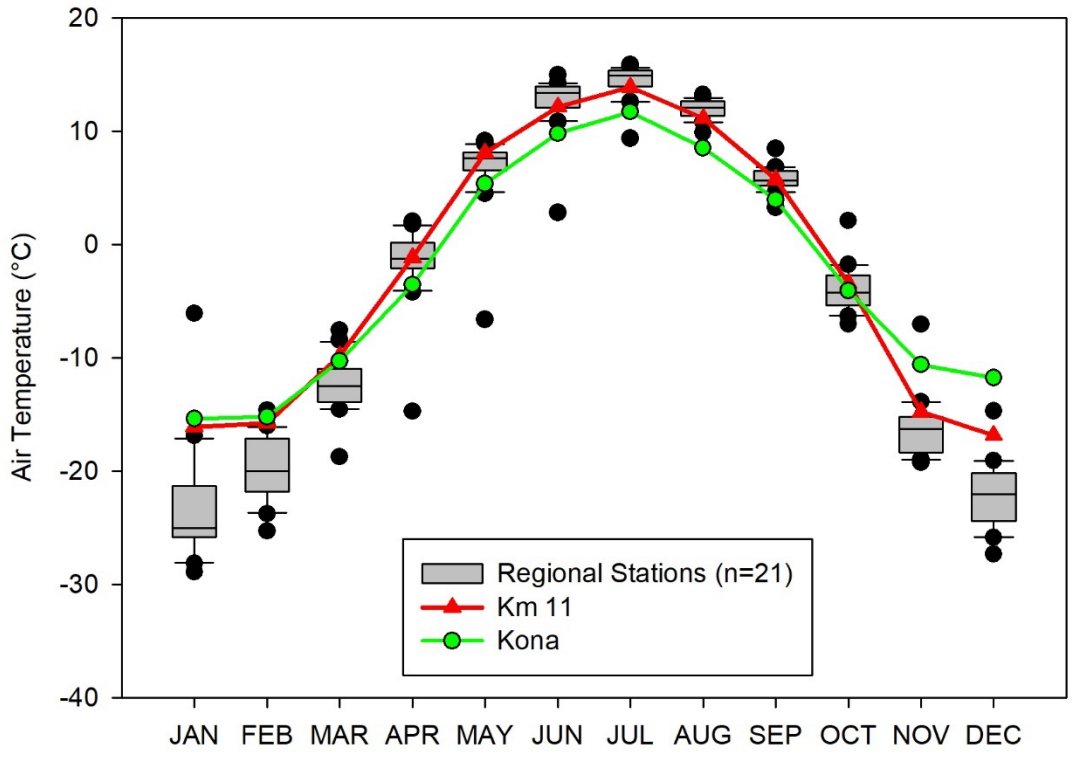

Figure 4-2: Comparison of the monthly average air temperature signature for the Km 11 and Kona climate stations to nearest regional stations (n = 21) with long-term records. The box and whisker plots show the following statistics for the regional stations: median and quartiles (grey box), 5th and 95th percentile values (tails) and outliers (black circles).

4.1.2 Precipitation

4.1.2.1 Regional Setting

The study area is characterized by a cold, continental climate. Large frontal systems generated by the Aleutian Low are blocked by the high topography along the coast, and hence the Project lies in the leeward rain-shadow (Figure 4-3 and Figure 4-4). Cassano and Cassano (2010) analysed sea level pressure patterns for the Yukon River basin and found that the winter circulation patterns are dominated by the strong Aleutian Low. In contrast, summer patterns are characterized by low pressure systems over land and the Beaufort/Chukchi Sea, and weak high-pressure cells to the north, resulting in easterly/north-easterly flows into the Basin.

Cassano and Cassano (2010) report that largest daily precipitation events (*i.e.*, top 10th and 1st percentile daily totals, on an annual basis) were attributable to over-land convective events that occur with increased frequency during the summer months. Evapotranspiration rates are highest during the summer, and therefore additional moisture is recycled and available to precipitate. During the winter, the largest precipitation events result from southerly winds caused by a low-pressure centre located to the southwest of the Yukon Basin and north of the Aleutian Islands. This brings moisture past the higher mountains on the southern edge of the basin and results in appreciable accumulation of precipitation.

The general patterns and trends reported by Cassano and Cassano (2010) are reflected in the mapping results of Brabets *et al.* (2000). Evident in Figure 4-4 are the bands of high precipitation in the southern extent of the Yukon River basin and the drying trend in annual precipitation northward from the southern portion of the basin. Figure 4-4 after Brabets also indicates annual precipitation in the vicinity of the Coffee Gold Project ranges from 250-375 mm for valley bottom location to 375-500 mm for high relief terrain similar to that which characterizes the Project site.

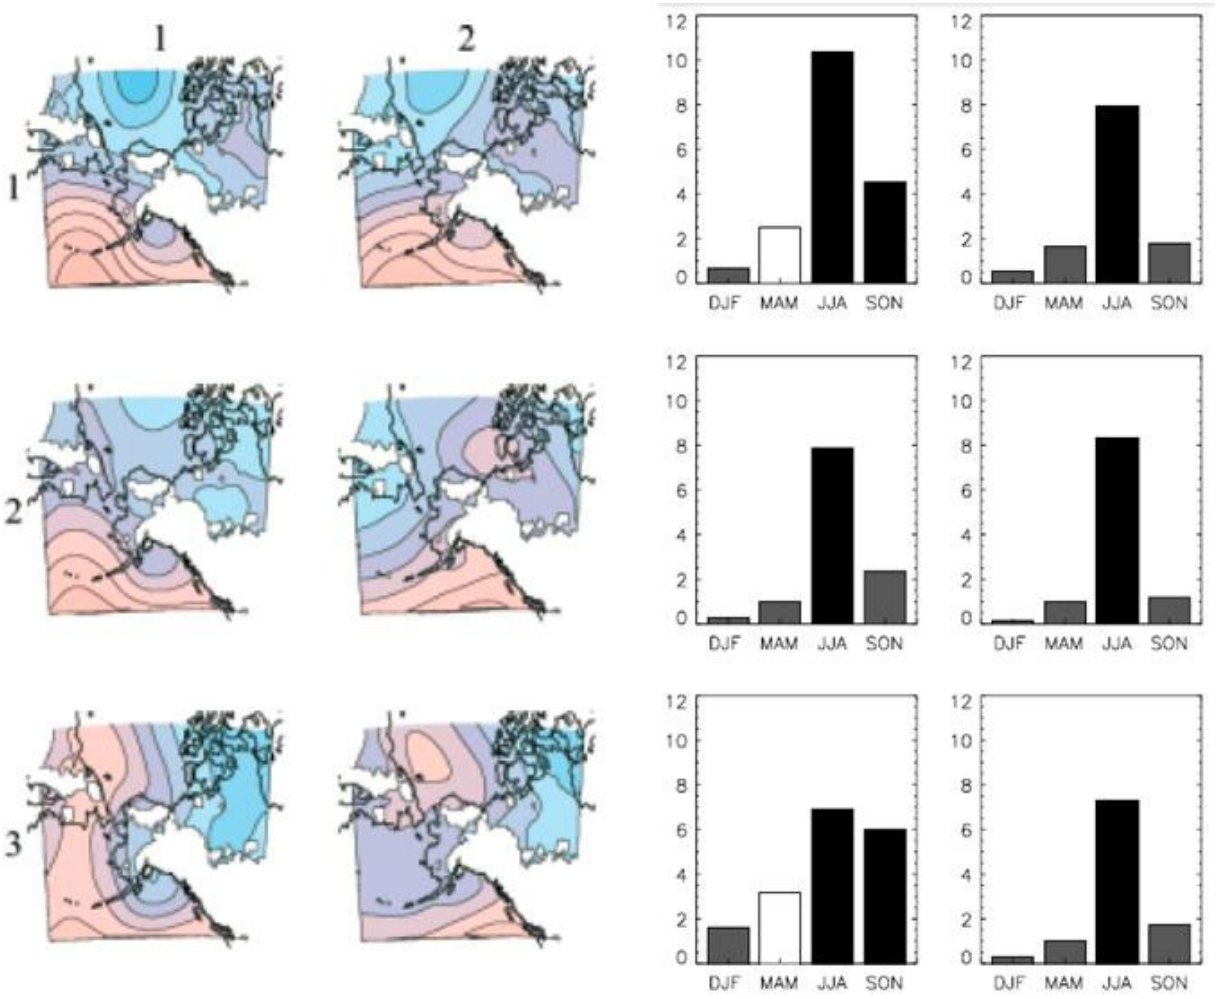

Figure 4-3: **Left: Daily sea level pressure anomaly patterns for the period 1957-2002. Blue shading indicates negative anomalies (low pressure), and red shading represents positive anomalies (high pressure). Right: Corresponding frequency of days that map to each pattern seasonally. Each bar represents the percentage of days that the pattern occurs in a season. Black and grey bars represent positive and negative statistical significance, respectively. Source: Figures 2 and 5 in Cassano and Cassano (2010).**

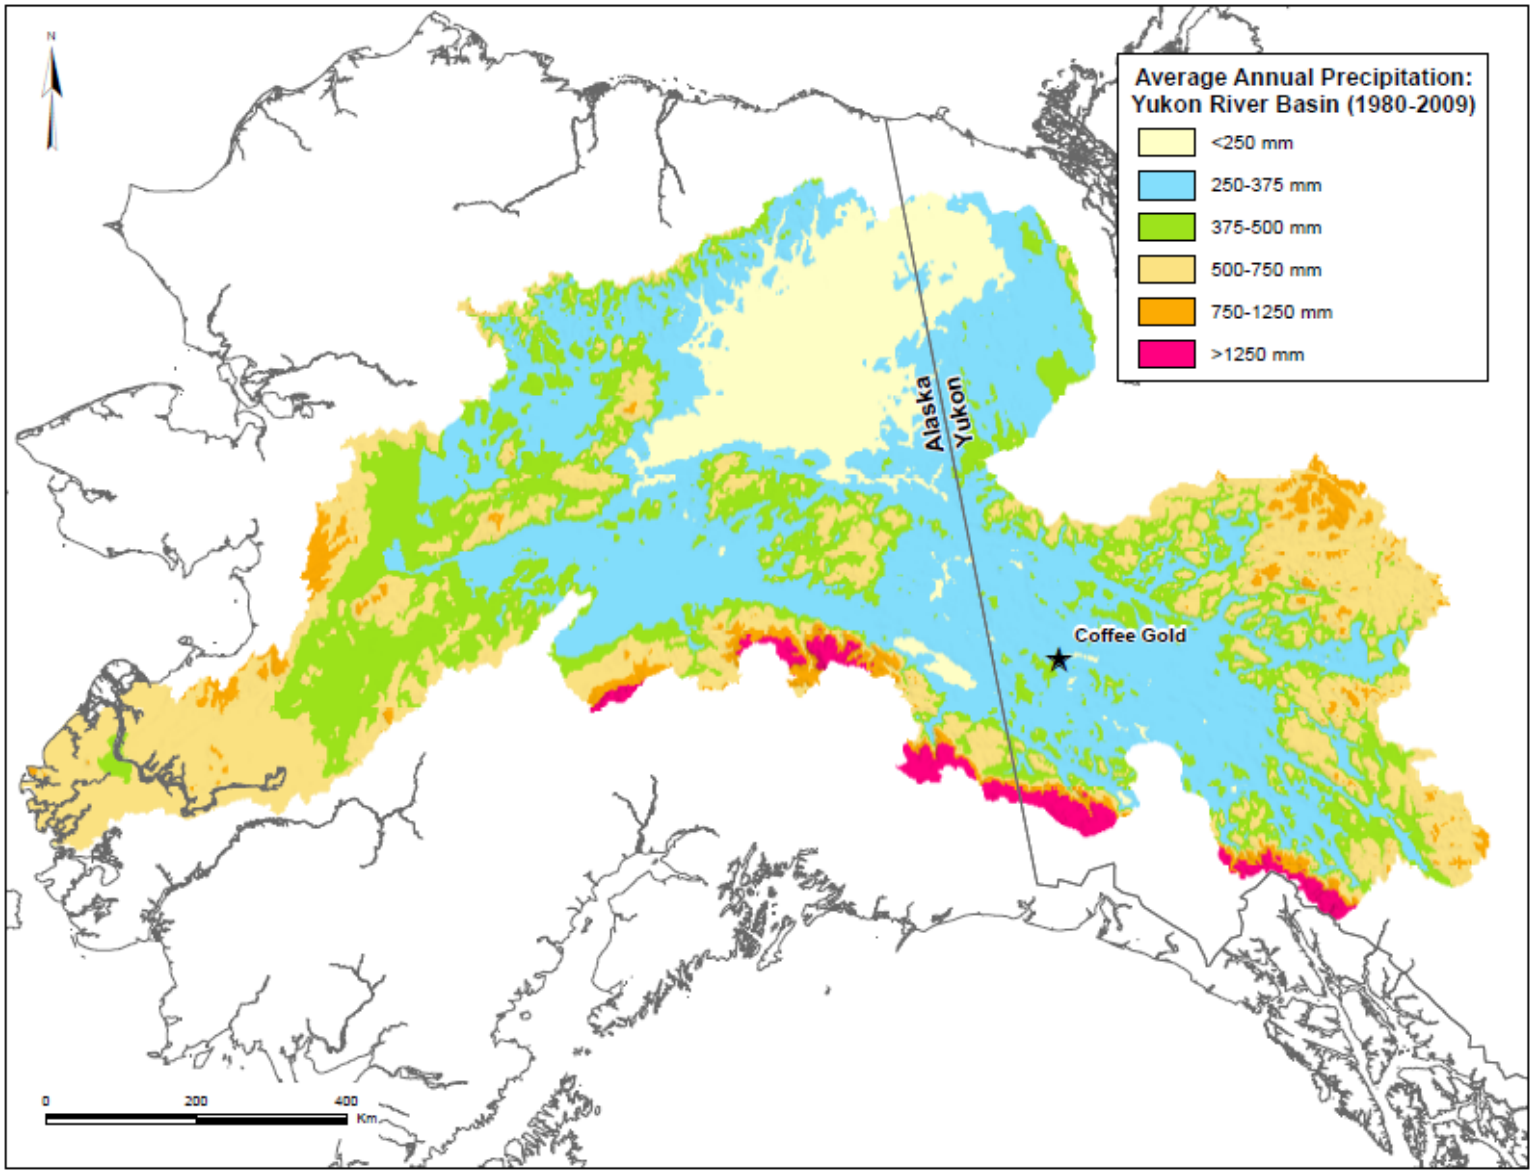

Figure 4-4: Annual precipitation (1980-2009) for the Yukon River Basin (from Brabets *et al.*, 2000).

4.1.2.2 Precipitation – Site Data

Precipitation has been measured on-site since July 2012 at the Km 11 climate station, and at several snow courses located at various elevations around the Project site. Tipping bucket precipitation gauges were also installed at the camp (425 m) and at ridgetop (>1,200 m) in 2015 to refine assumptions related to precipitation accumulation with elevation at the Project site. The Kona climate station was installed at an elevation of 1,340 m in October 2018 to gather data representative of the planned HLF location and has a reliable precipitation record.

Gauge and snow course data gathered during the baseline study indicate mean annual precipitation (MAP) averages 331 mm at 975 m and 398 mm at 1,340 m, with approximately 30% of this amount falling as snow between October and April, and 70% falling as rain from May to September (Table 4-2 and Table 4-3). These measured MAP values for the Project site do not necessarily account for the effects of gauge under-catch or sublimation, which will result in measured precipitation values (winter values in particular) being lower than actual values. These are well-documented issues in northern regions (*e.g.*, Yang *et al*., 2005 and Pomeroy *et al*., 1999) and corrections are required to obtain a true MAP estimate (see Section 2.3.3.3 and Section 4.4.4.2).

Figure 4-5 also shows regional precipitation data from nearby climate stations. Overall, site and regional precipitation measurements show similar magnitudes and monthly patterns. Like air temperature, the local precipitation signature closely approximates the patterns returned by regional climate station. Further, the seasonal precipitation distribution calculated from valley bottom climate records also strongly resembles the proportions measured during the baseline study (*i.e.,* regional data return proportions of snow and rain to be 35% and 65% respectively).

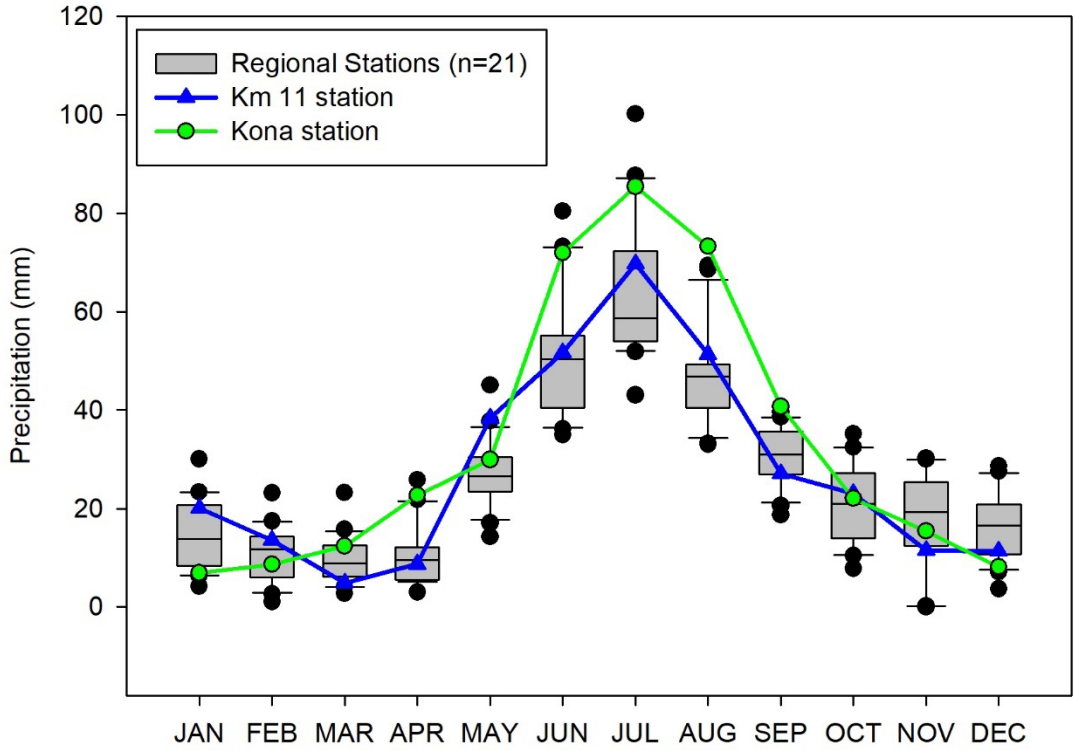

Figure 4-5: Comparison of the monthly precipitation signature for the Coffee Gold Km 11 and Kona climate stations to nearest regional stations (n = 21) with long-term records. The box and whisker plots show the following statistics for the regional stations: median and quartiles (grey box), 5th and 95th percentile values (tails) and outliers (black circles).

4.1.2.3 Snow Depth

The Kona climate station is equipped with an acoustic snow depth sensor which provides a high-resolution interpretation of snow depth in the immediate vicinity of the climate tower.

Data shown in Figure 4-6 confirms snowpack accumulation typically begins in earnest in mid- to late-October each year, and typically melts over a one- to two-week period between late-March and late-April.

The continuous snow course record for Kona differs from the snow course data over the period of record, which is not surprising since the tower measurements are based on a single point of observation. Snow depth measurements from the 10-point snow course are consistently higher than those recorded by the snow depth sensor by 0.1 to 0.3 m, which may reflect localized snow accumulation and ablation patterns, or calibration issues with the snow depth sensor. With respect to snow data, the primary metric of interest from a site water balance perspective is snow water equivalent (SWE), discussed below.

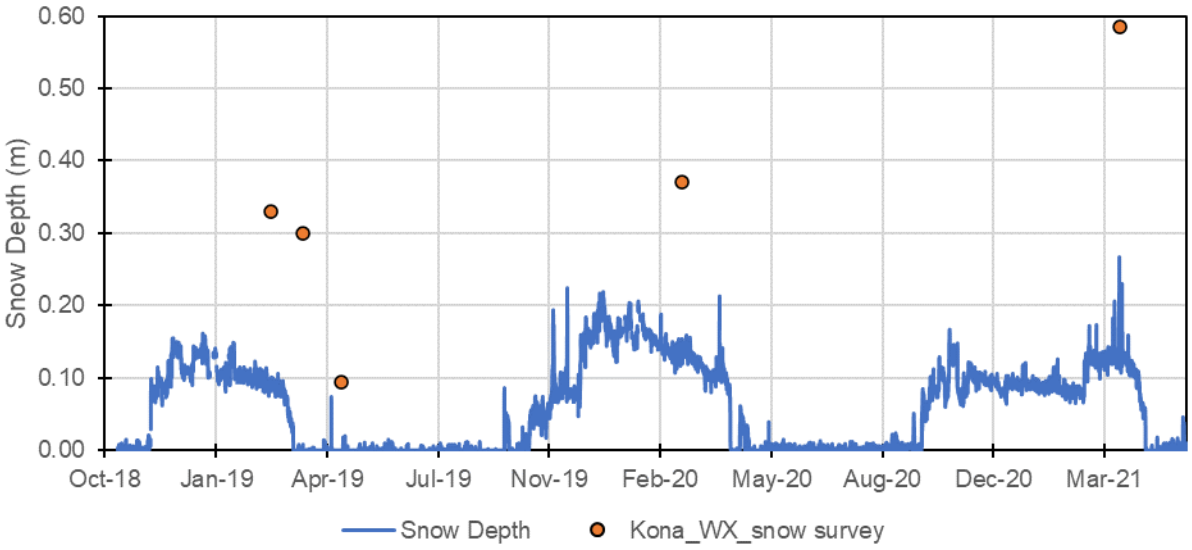

Figure 4-6: Continuous snow depth record measured at the Kona climate station (October 2018 to June 2021).

4.1.2.4 Snow Surveys

Snow surveys are conducted at the Coffee Gold Project along courses established with varying aspects and elevations (Table 2-3; Table 2-4). Period of record measurements are summarized for these monitoring sites in Table 4-4 and Table 4-5.

Snow course measurements are recorded to ground-truth gauge precipitation recorded at automated climate stations as well to understand the spatial variability in snow accumulation at the Project site and elucidate how orographic gradients affect snowfall magnitude. While several stations have been sampled over the years, the following four locations are considered the long-term monitoring stations for site: IC-1.5-SS, CC-east-1, KAM-WX-SS and Mid-Elev-SS. Following installation of the Kona weather station, a snow course was established at KONA-WX-SS, thus increasing the number of long-term snow monitoring stations at Coffee Gold to five locations.

Annual maximum measured SWE values are typically between 60 mm and 120 mm at the upper elevations of the Project site, however, there is substantial variability between sites due to differences in aspect and surrounding vegetation , both of which impact sublimation and melt rates, and wind redistribution patterns.

4.1.3 Relative Humidity

Relative humidity generally varies between 50% and 85% on an average monthly basis, with March to October values showing close correspondence between the two climate stations at site (Figure 4-7). At a monthly time-step and on average, relative humidity values are highest in the winter at the Km 11 station and range from 76-83% between November and February (Table 4-6). The relative humidity signatures at Km 11 display a notable departure at the Kona station, with winter values at Kona tracking lower than the Km 11 values by approximately 10%. This is due in part to the noted temperature inversions at site (see Section 4.1.1.1).

Table 4-6:
Average monthly relative humidity for the KM 11 and Kona climate stations. All values are in %.

Station	Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual

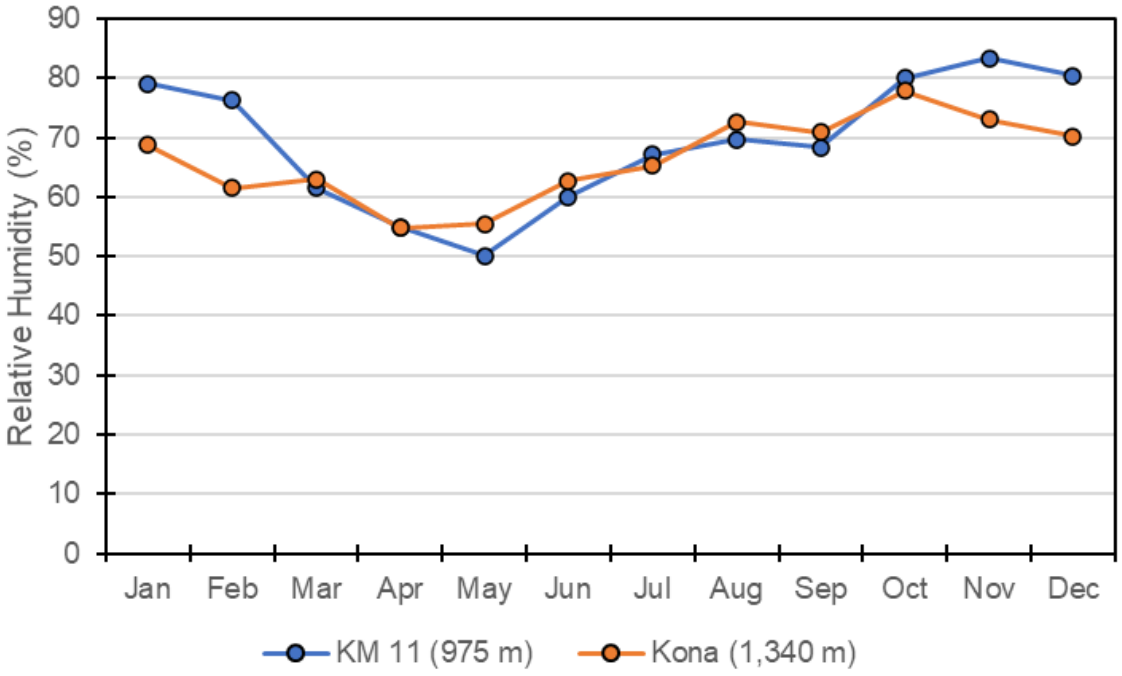

Figure 4-7: Average monthly relative humidity for the Km 11 and Kona climate stations.

4.1.4 Wind Speed and Direction

Monthly average wind speeds range from 0.9 to 2.8 m/s at the Km 11 station, with maximum recorded wind gusts of > 14 m/s occurring in all months. Wind speeds are higher in the months of April through September compared to October through March (Table 4-7, Figure 4-8). By comparison, the higher elevation Kona station experiences monthly average wind speeds of 3.7 to 5.1 m/s, gusting in excess of 20 m/s in all months, with a similar seasonal pattern as noted for the Km 11 record, although maximum wind gust speeds are more often noted in the winter and spring months. The dominant annual wind vector at the Km 11 station is from the south (blowing from), with secondary vectors from the northwest and northeast. At the Kona station, the dominant annual wind vector is from the southwest, with secondary vectors from the southeast through east.

Table 4-7:
Measured wind speed (average and gust) data for the KM 11 and Kona climate stations. All values are in m/s.

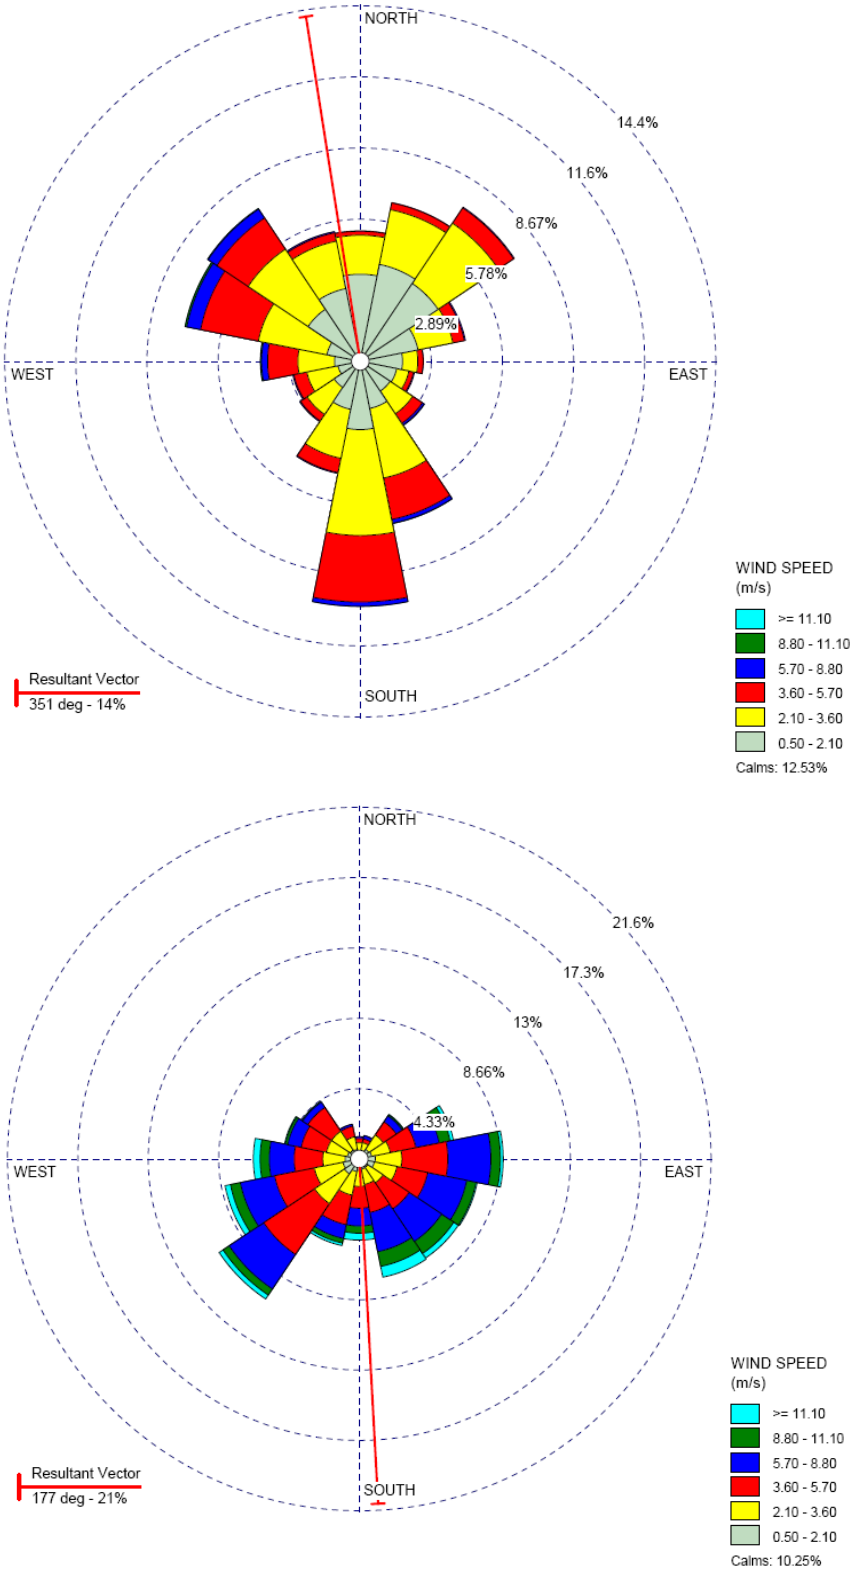

Figure 4-8: Annual wind roses for the KM 11 (top panel) and Kona (bottom panel) climate stations. Wind directions are 'blowing from'.

4.1.5 Atmospheric Pressure

For the baseline study period, monthly average barometric pressure measured at Km 11 climate station ranged from lows of 1003 mb in December to highs of approximately 1015 mb in July (Table 4-8; Figure 4-9). At the Kona climate station, atmospheric pressures track the monthly pattern observed in the Km 11 record, but are approximately 155 mb lower, reflective of this station's higher elevation.

Table 4-8:
Average monthly atmospheric pressure for the KM 11 and Kona climate stations.
All values are in mb.

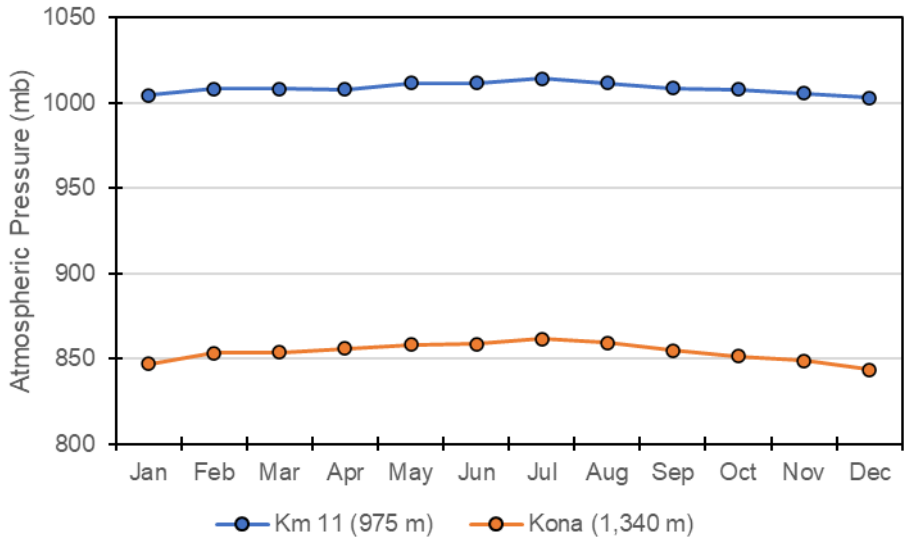

Figure 4-9: Average monthly atmospheric pressure for the Km 11 and Kona climate stations.

4.1.6 Solar Radiation

When data are summarized monthly for the available period of record, solar radiation varies from a monthly average high in June of 0.240 kW/m^2 and 0.256 kW/m^2 to a low of 0.003 kW/m^2 and 0.005 kW/m^2 in December, at the Km 11 and Kona climate stations, respectively (Table 4-9; Figure 4-10). Since July 2012, the highest recorded hourly solar radiation value is 0.991 kW/m^2 at the Km 11 station, and 1.043 kW/m^2 at the Kona station, reflective of the latter stations higher elevation.

Table 4-9:
Average and maximum monthly solar radiation for the Km 11 and Kona climate stations. All values are in kW/m^2.

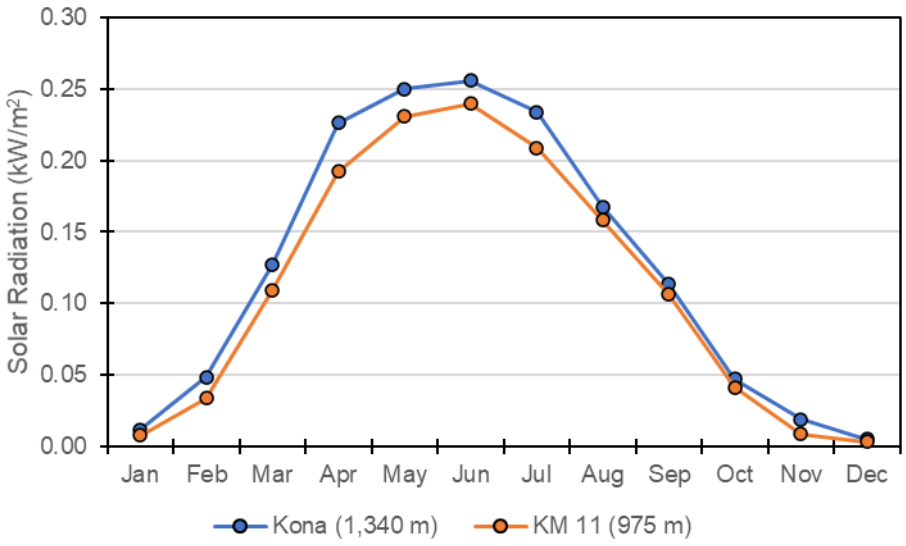

Figure 4-10: Average monthly solar radiation for the Km 11 and Kona climate stations.

4.1.7 Potential Evaporation and Evapotranspiration

Potential evapotranspiration estimates for both the Km 11 and Kona climate stations were derived using the Penman-Monteith and Priestly-Taylor methods and show average April-October totals of 469 mm and 452 mm, respectively (Table 4-10). The estimates are 10% and 20% higher for the Kona station over the common period of record (2019-2021), due to elevated wind speeds and higher solar radiation at the upper station.

As a point of comparison, potential evapotranspiration (PE) estimates for Coffee Gold derived using Km 11 and Kona weather station data and the Hargreaves-Samani method are reported in Table 4-11. Processing of the data returned average PE estimates on the order of 463 mm at 975 m, and 425 mm at 1,340 m, which are slightly higher than those derived from the ClimateWNA software package (Figure 4-13). Like evapotranspiration, monthly PE rates are highest in May, June, and July each year, compared to other months of the year.

As a final comparison, the Km 11 estimates for April to October derived using the three methods are plotted in Figure 4-12 for the 2013-2021 period. Overall, there is close correspondence between the more data intensive formulations (Penman-Monteith and Priestly-Taylor) and the simpler temperature-based method (Hargreaves-Samani).

Actual evapotranspiration estimates are computed using a Campbell Scientific proprietary climate program with Coffee Gold weather station measurements. Average annual evapotranspiration calculated with this methodology was 171 mm for the record period

(2012-2021). At a daily time-step, average evapotranspiration rates are highest in May, June, and July at approximately 3.0 mm/day.

Table 4-10:
Potential evaporation estimates for the Coffee Gold Project based on data collected at the Km 11 and Kona climate stations and the Penman-Monteith and Priestly-Taylor equations.

4.2 ClimateWNA Gridded Data

The ClimateWNA software (Wang *et al*., 2016; v7.10) generates scale-free point estimates of key climatic parameters (*e.g.*, air temperature, precipitation, potential evapotranspiration) at monthly resolution for multiple reference periods, including the standard climate normal periods (30-year duration). Estimates are scaled from regional data, including the climate stations referenced in Section 2.2, and orographic effects on precipitation are incorporated, allowing the orographic gradients noted in the site data to be verified. For grid points corresponding to the Project site, mean annual precipitation varies from 304 mm at 600 m to 472 mm at 1,300 m, with a 60%/40% split between rain and snow, respectively, and monthly precipitation gradients range from 4%/100 m to 8%/100 m (Table 4-12). Peak monthly precipitation and PET are concentrated during the open water season (May to September), ranging from 400 mm/year at 600 m to 344 mm at 1,300 m (Figure 4-13).

Table 4-12:
ClimateWNA estimates of precipitation for representative elevations at the Coffee Gold Project.

Elevation (m)	600	900	1,300	Gradient (%/100 m)
Jan	15	19	24	7%

Snow	120	150	194	7%

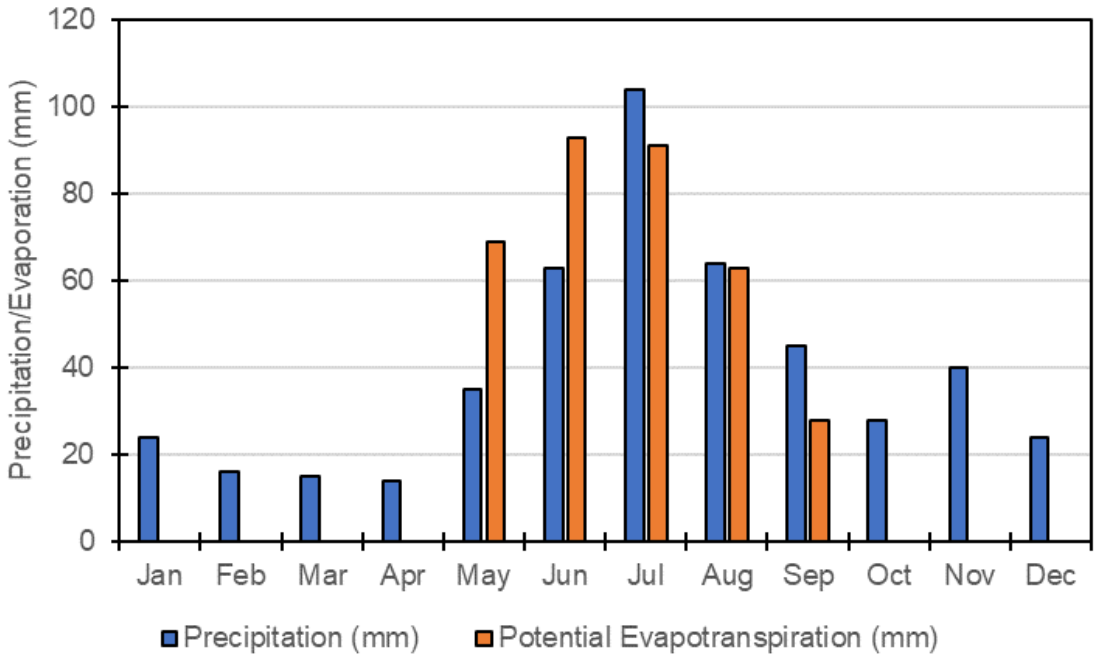

Figure 4-13: Monthly average precipitation and potential evapotranspiration at 1,300 m (Climate WNA).

4.3 Orographic Precipitation Gradients

It is common in areas with high topographic relief for precipitation amounts (annual, low-frequency/high-magnitude events, *etc*.) to increase with elevation due to orographic effects - primarily cooling of the air mass as it is forced upward by topography and subsequent condensation of the entrained water vapour. Most of the available long-term climate records for the Project area are from stations located at lower elevations than the Project site. Therefore, any estimate of precipitation derived from the regional stations must take potential orographic effects into account. The orographic precipitation gradients used to inform all water balance modeling and water management infrastructure design are based on statistical relationships between the climate and SWE data collected at site and the regional climate and snow survey data. These gradients are then applied within the site-wide water balance and water quality model (WBWQM) to adjust the synthetic precipitation series for elevation-related changes within the Project area.

Updated site-specific orographic gradients for rainfall were derived using measured data from the Km 11 climate station, tipping bucket gauges and the Kona climate station through to October 2021 (Table 2-1). These gradients were confirmed with regional climate and snow course data (including the ClimateWNA estimates).

Additional snow course data for the Project site (Table 2-1, Appendix A) through to spring 2021, and the undercatch corrected Km 11 and Kona winter precipitation data (Section 2.3.3.3) were used to refine assumptions related to snowfall gradients. Since 2014, snow course measurements have been recorded consistently at four snow courses designated as long-term monitoring stations.

4.3.1 Winter Precipitation Measurements

The Project site snow courses span a wide range of elevations and provide a useful starting point to identify local gradients. Table 4-13 presents the variation in SWE with elevation for the maximum measured snowpacks of 2013-2021. Precipitation-elevation gradients (% increase with 100 m increase in elevation) are variable, depending on the elevation difference of the stations used in the calculation. As shown in Figure 4-14, the gradients calculated from stations with elevation differences of less then 200 m are confounded by variation in aspect, forest cover and wind redistribution. Therefore, only stations with elevation differences > 200 m were used to calculate an average SWE gradient of 6%/ 100 m for the available period of record at site.

This is comparable to the calculated gradient of 8%/100 m for gauge undercatch corrected winter precipitation measured at the Km 11 and Kona climate stations for the Oct. 2019 to April 2020 period, and the average winter gradient of 7%/100 m evident in the ClimateWNA estimates for site (Table 4-12).

Table 4-13:
Summary of orographic gradient estimates based on Coffee Gold snow course sampling.

Elevation Difference (m)	Measurements (n)	Gradient[a]
<200	11	24.7%
200-300 m	10	7.1%
300-400 m	11	4.0%
400-500 m	10	7.4%
500-600 m	9	4.3%
600-700m	9	7.2%
Total/Avg[b]	**60**	**6.0%**

[a]Orographic gradients are expressed as % increase per 100 m elevation gain.
[b]An average gradient was computed from orographic gradients computed from 2014-21 snow course measurements at four long-term monitoring stations. As shown in Figure 4-9 (lower panel), the average gradient was computed using data based on elevation differences of 200 m or more.

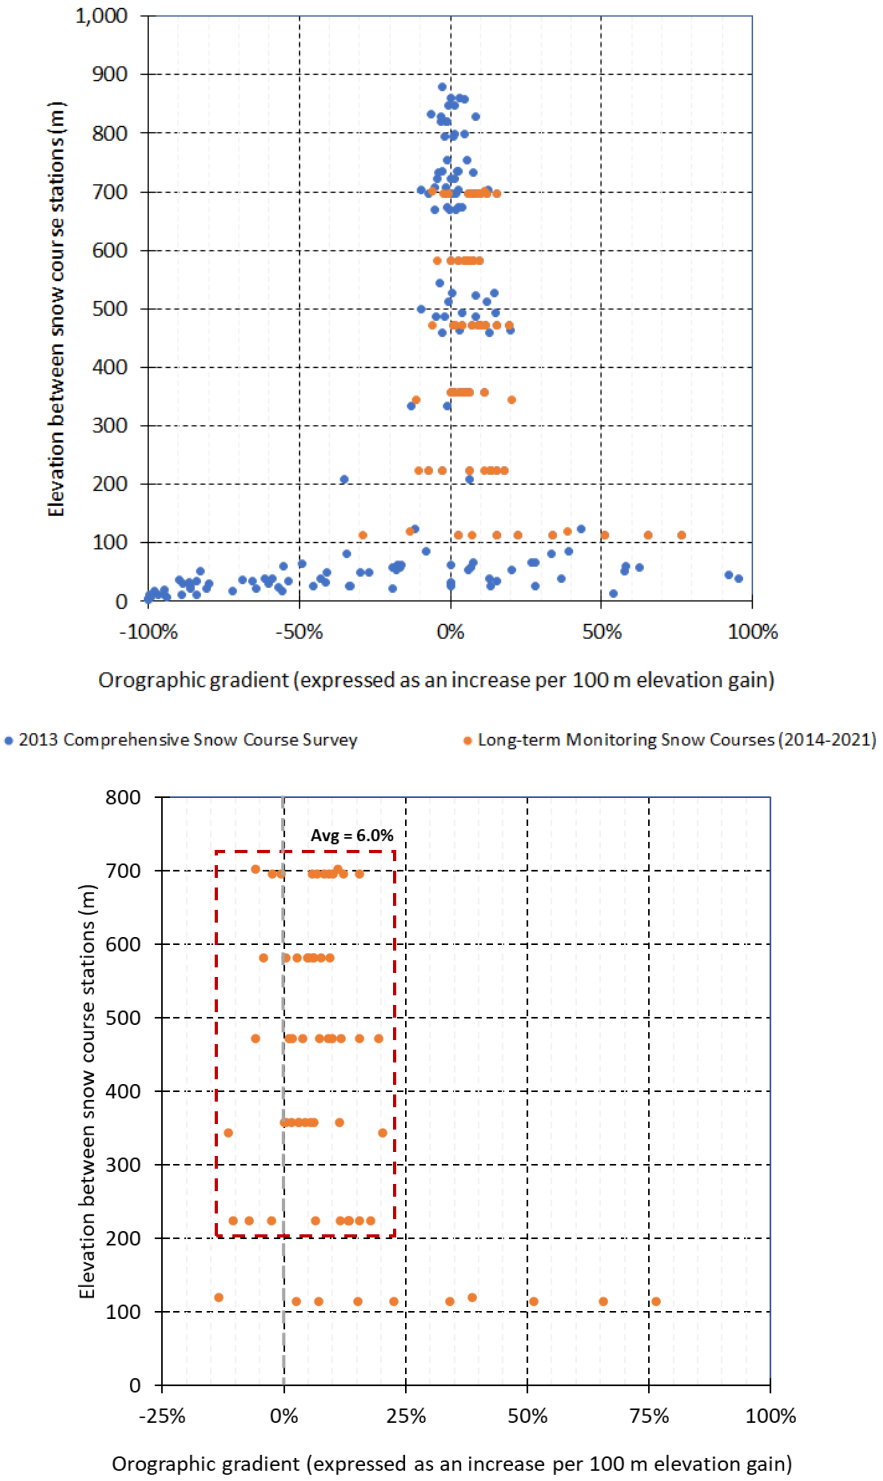

Figure 4-14: The upper plot shows 2013 orographic gradients derived from snow course network (blue dots) alongside gradients for 2014-21 measurements which are based on data collected at four long-term monitoring stations. The lower plot shows data for 2014-21 only and the average gradient computed from a subset of the measurements.

4.3.2 Summer Precipitation Measurements

Two additional tipping bucket rain gauges were installed in 2015 to further resolve the summer precipitation elevation gradient at site. While there is a large degree of variability in the calculated gradients, over the period of May to September (2015-2018), the average gradient from the camp elevation (425 m) to ridge-top (1,300 m) was 4%/100 m (Table 4-14). There is some evidence that this gradient is reduced somewhat at the higher elevations (*i.e.*, does not scale linearly above the hypsometric mid-point of the basin; Loukas and Quick, 1996), but the conservative assumption of a constant gradient was used for all storm event scaling. This assumption is further supported by the overlapping rainfall data collected at the Km 11 and Kona climate stations from May-September 2019 (Table 4-15).

Table 4-14:
Orographic Gradients Computed from Measured Rainfall Data.

Year	Month	Camp (mm)	Met Stn (mm)	High Elev (mm)	Gradient (camp to Met Stn)	Gradient (camp to High Elev)	Gradient (Met Stn to High Elev)
					(%↑/100m)	*(%↑/100m)*	*(%↑/100m)*

4.3.2.1 May and June Rainfall Data

A comparison of corresponding precipitation records for Kona and Km 11 climate stations was undertaken. Overlapping data collected thus far show the Km 11 gauge did not collect snowfall data in winter 2018-19 (Figure A2.3). Accordingly, missing snowfall data at Km 11 were infilled by adjusting Kona measurements downward assuming that an 8%/100 m snow gradient applies between the stations. The limited rainfall data collected thus far also confirms the presence of a local orographic gradient on the order of 6%/100 m elevation gain for the two stations (Table 4-15).

Table 4-15:
Orographic gradients computed for Km 11 and Kona climate stations (2019).

	Rainfall (mm)		
Period	**Kona**	**Km 11**	**Gradient (%, per 100 m gain)**
May[a]	26	19	10%
June	66	56	4%
July	102	97	1%
August	62	56	3%
September	20	31	-1%
Total	276	260	4%

[a]Indicates data are for a partial month.

4.3.3 Regional Stations

To validate the winter precipitation gradient estimate, the two nearest snow survey stations to Coffee Creek were chosen to represent valley bottom (Pelly Farm) and ridge-top (Casino Creek) snowpack regimes. From the available data for these two stations, the elevation gradient calculated from the April 1st SWE data was found to be ~8%/100 m. This gradient is slightly higher than the average value calculated from the available site SWE data (6%/100 m) and the ClimateWNA estimates (7%/100 m), but comparable to that calculated based on the Coffee Gold climate station data, and therefore a median value of 7%/100 m was carried forward to represent the winter precipitation elevation gradient.

4.3.4 Summary of Precipitation Gradient Assessment

Overall, regional findings are consistent with the site data, and therefore the following seasonal orographic gradients were carried forward into subsequent analyses:

- Summer (April to September) gradient is 4%/ 100 m increase in elevation;
- Winter (October to March) gradient is 7%/100 m increase in elevation.

4.4 Design Rainfall and Snowmelt Rates

Estimates of rainfall recurrence intervals (*e.g.,* 1:100 year, 24-hour rainfall) including an estimate of probable maximum precipitation (PMP) for the Project area are required for input to water management infrastructure design. The values presented in Lorax (2017) were updated to include an additional 5-years of data from the regional climate stations.

The daily precipitation records from the regional climate station network (Table 2-5) were screened to remove stations with less than 10-years of complete spring and summer (April to September) rainfall data (Table 4-16). For the PMP estimate, stations with less than 30-years of complete data were excluded, following the WMO guidance (WMO, 2009b). Following this screening process, ten stations had sufficient record lengths to be carried forward for statistical analysis in the rainfall recurrence interval analysis, and nine stations were carried forward for the PMP analysis.

For years of record showing prolonged data gaps (*e.g.*, >10 days of missing data; <80% complete) during May – September – the year of record was considered incomplete and excluded from the frequency analysis. This screening reduced available data entered into the frequency analysis by a small amount (*e.g.,* a year or two of annual maxima data excluded for a 50-year long climate record).

Table 4-16:
Regional climate stations included in rainfall recurrence interval and PMP estimates. Shaded grey stations were excluded from the PMP analysis.

Station	Elevation (m)	Latitude (°)	Longitude (°)	Record Period	Record Length (years)
BEAVER CREEK A	649	62.41	-140.87	1968 - 2015	38
SNAG A	587	62.37	-140.40	1943 - 1966	24
STEWART RIVER	358	63.32	-139.43	1976 - 1993	17

DAWSON A	350	64.04	-139.13	1897 - 2021	121
KLONDIKE	973	64.45	-138.22	1966 -2010	40
MAYO A	504	63.62	-135.87	1925 - 2021	97
MCQUESTEN	458	63.59	-137.52	1986 - 2014	28
PELLY RANCH	445	62.82	-137.37	1952 - 2017	64

Cassano and Cassano (2010) analyzed sea level pressure patterns for the Yukon River basin and found that the winter circulation patterns are dominated by the strong Aleutian Low.

The authors found that in the summer, largest daily precipitation events (*i.e.*, top 10th and 1st percentile daily totals, on an annual basis) were associated with an increased frequency of cyclones and over-land convective events. Evapotranspiration rates are highest during the summer, and therefore additional moisture is recycled and available to precipitate. Synoptic patterns and mechanisms governing summer and winter precipitation near the Coffee Creek property are discussed further in Section 4.1.2.1. The highest magnitude rainfall events in the Project site vicinity are likely to be realized in June, July, and August, and often are associated with convective summer storms (Figure 4-15). Regardless of month, climate station or record length, no 1-day rainfall events have been recorded in the Project area that exceed 53 mm.

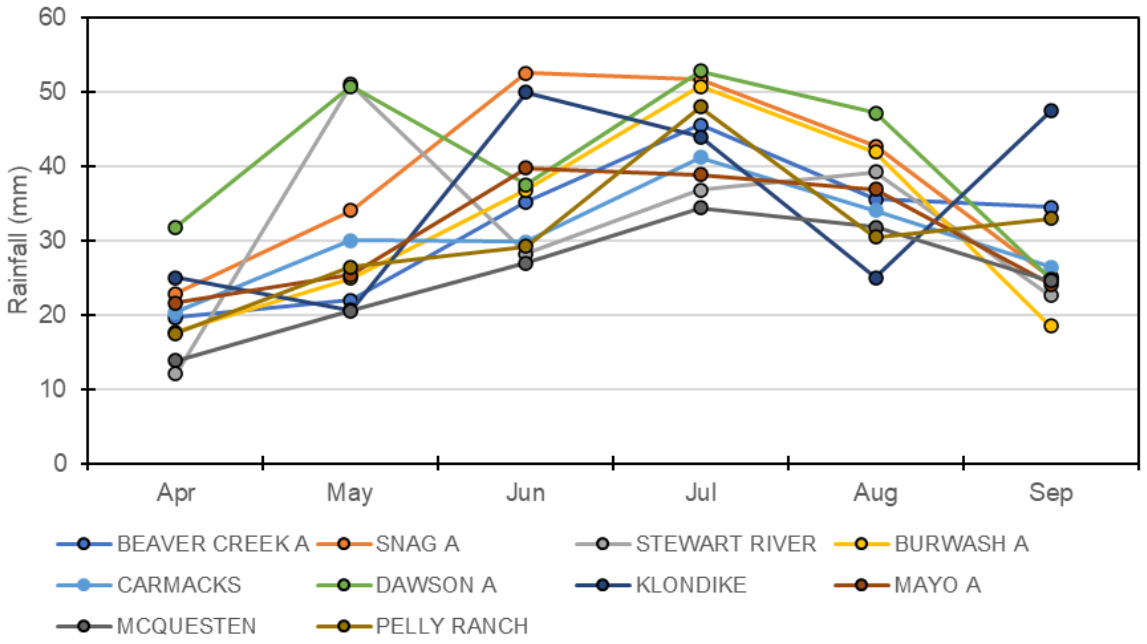

Figure 4-15: Monthly distribution of period of record maximum 1-day precipitation at climate stations near Coffee Gold.

The tabulated 1-day annual maximum precipitation amounts from the climate stations in Table 4-16 were adjusted upward by a factor of 1.13, as recommended by Hershfield (1961), and consistent with NOAA (2012). This scalar accounts for the fact that daily precipitation amounts calculated based on a fixed start and end of a 24-hour period (*i.e.*, midnight) will be lower than a rolling 24-hour total of the same event.

Prior to conducting the rainfall recurrence interval and PMP analyses on the available datasets, raw climate data files were inspected and explored to identify spatial, temporal, and orographic patterns within. Figure 4-16 shows the 24-hour annual maxima series for

the Dawson A, Eagle, Mayo A and Northway AP stations. These data show evidence for inter-decadal variability in annual maxima. There are two periods with generally larger precipitation events: 1) 1930 to 1960; and 2) 1990 to the present. Currently, the timing and phase of long-term climate cycles (*e.g.*, Pacific Decadal Oscillation [PDO], Arctic Oscillation [AO], and El Niño Southern Oscillation [ENSO]) are thought to influence the magnitude and frequency of extreme precipitation events in this region (*e.g.*, Papineau, 2015).

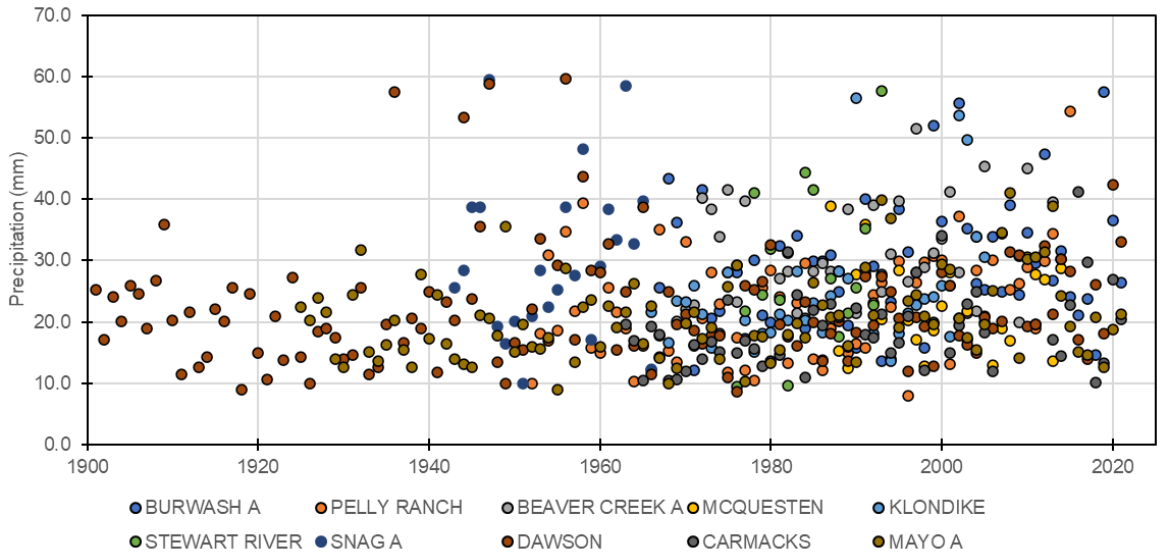

Figure 4-16: Time-series of annual maximum rainfall for regional stations screened into the recurrence interval analysis.

As noted in Lorax (2017), a strong latitudinal gradient in high-magnitude rainfall is evident from eastern Alaska across the Yukon Territory. To confirm that this longitudinal gradient remained when considering the updated data, the maximum recorded 24-hr rainfall value for each station was scaled to the reference elevation of 1,300 m by the 4%/100 m summer precipitation gradient (Section 4.3.2), and plotted against station longitude (Figure 4-17). The gradient is unaltered, and therefore the subsequent analyses placed greater weight on the Stewart River, Burwash A and Dawson A precipitation records.

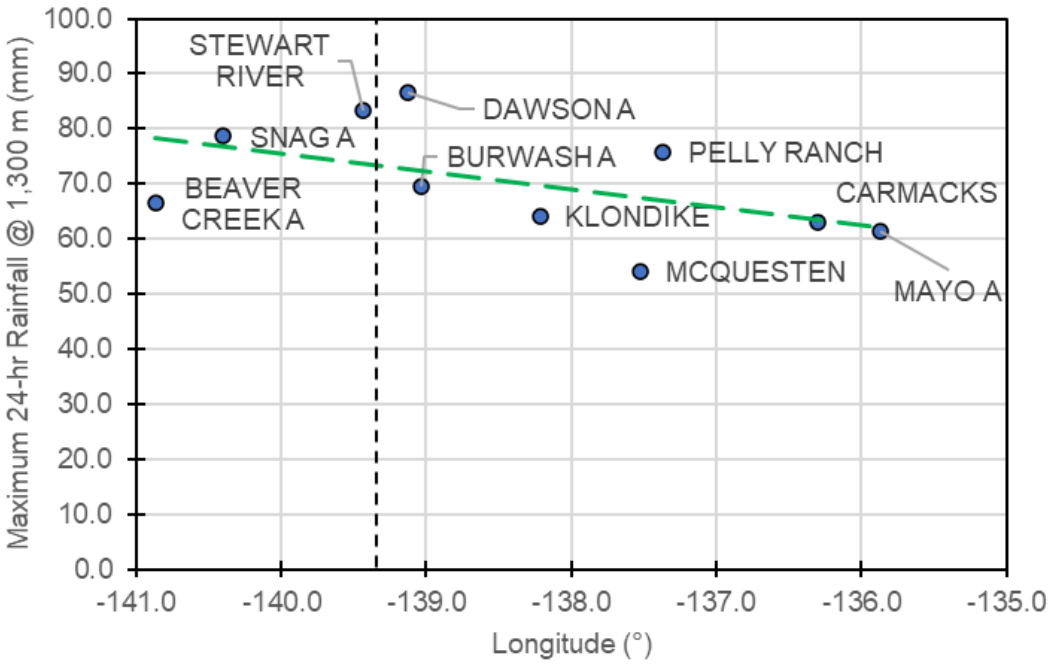

Figure 4-17: Maximum recorded 24-hr rainfall, scaled to 1,300 m elevation, and plotted by longitude. The longitude of the Coffee Gold Project is shown by the dashed black line.

4.4.1 Rainfall Recurrence Interval Estimates

Annual maximum 24-hour rainfall series per station were imported to EasyFit Statistical Software and continuous probability distributions were fitted to the data. Similar to NOAA (2012) and through an inspection of the statistics and ranking data outputted by EasyFit - several distributions were found to fit the input data well. For purposes of consistency with the NOAA (2012) assessment, the GEV distribution was adopted as the *de facto* distribution for the Yukon assessment. The following return periods were estimated for the climate stations and events of interest: 1:2-year (median), 1:5-year, 1:10-year, 1:25-year, 1:50-year, 1:100-year and 1:200-year. Maximum recorded 1-day, 24-hour and 24-hour scaled to 1,300 m are reported for the regional stations screened into the analysis (Table 4-17). The Stewart River and Dawson A records contain the highest recorded rainfall values when controlled for elevation, and therefore, the representative rainfall recurrence interval estimates are based on these stations. Recommended 24-hr rainfall event values for representative elevations (scaled by 4%/100 m) at the Project site are reported in (Table 4-18), noting that the maximum recorded values in Table 4-17 fall between the 1:25- and 1:50-year recurrence interval estimates (Table 4-18).

Table 4-17:
Period of record 1-day and 24-hour maximum estimates for near-Project stations

Station	Elevation (m)	Record Length (years)	Maximum Recorded 1-day Rainfall (mm)	Maximum Recorded 24-hr Rainfall (mm)[1]	24-hr Maximum Scaled to 1,300 m[2]

1,300	38	56	67	80	89	98	106

4.4.2 Probable Maximum Precipitation Estimate

The probable maximum precipitation is defined as the greatest depth of precipitation for a given duration meteorologically possible for a design watershed or a given storm area at a particular location at a particular time of year, with no allowance made for long-term climatic trends (WMO, 2009b). Estimation methods are categorized as either statistical, or

hydrometeorological (moisture maximization and storm transposition). The statistical method is much simpler than the hydrometeorological method and does not have the same data requirements (*e.g.*, dewpoints and wind vectors). It is based on extensive analyses of thousands of station records, which provide the enveloping value (K_m) on which the method is based. It should be noted that the procedure will only provide a point estimate (as opposed to a basin-wide average), and so must be scaled using an area-reduction curve for application to basins larger than 1,000 km^2 (WMO, 2009b). Given that the contributing areas for Project infrastructure are much lower than this, the application of area-reduction curves is not necessary.

The statistical procedure follows the methodology presented in Hershfield (1961), and as summarized by the WMO (2009b). It is based on the general frequency equation:

$$X_t = \bar{X}_n + K\sigma_n \quad [1]$$

Where X_t is the rainfall for return period t, $\bar{X}_n$ and σ_n are the mean and standard deviation (respectively) of the series (n) of annual daily precipitation maxima, and K is a variable that varies with the frequency distribution fit to the annual maxima series.

K_m represents the empirical factor that substitutes for K in Equation 1 to estimate the point PMP. Originally, it was thought that $K_m = 15$, but was later found to be a function of event duration and the mean annual maximum rainfall (Hershfield, 1997). The function to derive K_m for a 24-hour storm duration is presented in Hogg and Carr (1985):

$$K_{m24} = 19(10)^{-0.000965\bar{X}} \quad [2]$$

K_{m24} was calculated for all regional stations (range of 17.3 to 18.2), and then inserted into Equation 1 to calculate the PMP value for each station. For reference, the K_{m24} value calculated from the isoline map in Hogg and Carr (1985) is 18.2. Finally, all estimates of the 24-hour PMP derived from the regional climate records were scaled from the station elevation to the reference elevation of 1,300 m by 4%/100 m (Table 4-19).

The average estimate for the eight stations considered is 243 ± 49 mm, which is slightly higher than the estimate derived from Hogg and Carr (1985), and comparable to the value derived from the NOAA No. 47 guidance document.

Table 4-19:
24-hour PMP estimates for near-Project stations (scaled to 1,300 m).

Station	24-hour PMP (mm)
SNAG A	346
DAWSON A	283
PELLY RANCH	254
BURWASH A	251
BEAVER CREEK A	236
KLONDIKE	224
MCQUESTEN	218
MAYO A	197
CARMACKS	182
AVERAGE	243
σ	49
Hogg and Carr (1985)	221*
NOAA No.47 (1963)	254

*The value derived from the isolines was adjusted by a factor of 1.5 to account for orographic enhancement in mountainous terrain (in non-coastal mountains above 800 m and for events >12 hours), as recommended.

The value for the Snag A station (346 mm) is notably higher than that for the others. This is due to the relatively short record (24 years), and the fact that this record represents an unusually wet period (1943-1966). When plotted alongside the Dawson A record, it's clear that the two stations display similar variability in rainfall magnitude (Figure 4-18). Given the very low frequency of the PMP event, a longer record is preferable when developing the estimate, and therefore the estimate from the Dawson A climate station is recommended for use in water management infrastructure design (283 mm). The Dawson A estimate is based on 121 years of data and is notably higher than all other estimates derived from the nearby station records.

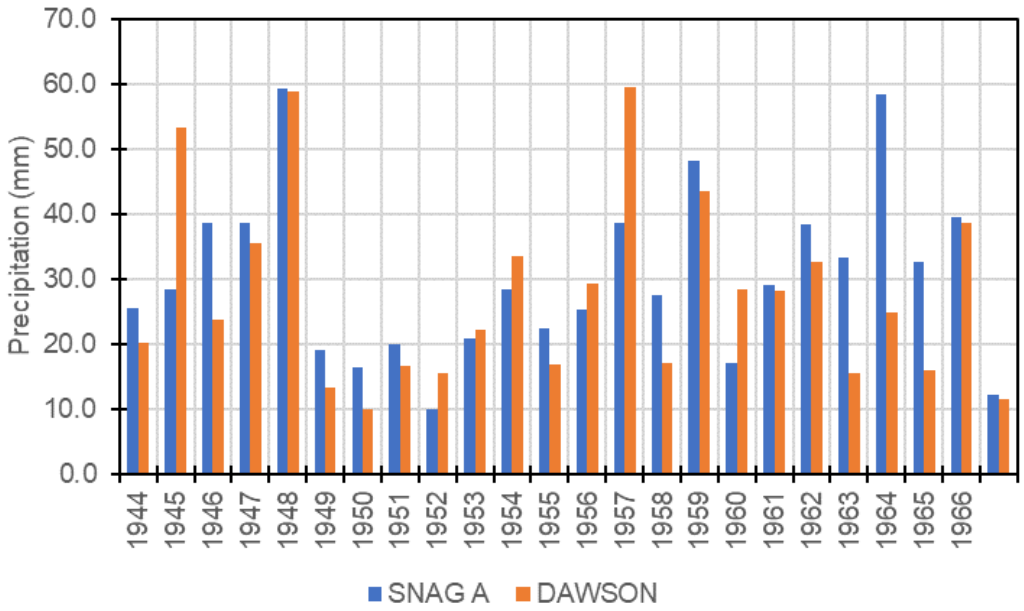

Figure 4-18: Overlapping records of maximum recorded 24-hr rainfall for the Snag A and Dawson A climate stations

4.4.2.1 Monthly Probable Maximum Precipitation Estimates

Large volumes of water are expected to report to the HLF water management system during the months of May and June in response to snowmelt, and thus the potential for a similar magnitude PMP event to the annual event could occur in the months of May of June, which were identified by the heap leach water balance model as being potentially problematic from the standpoint of encroaching on emergency storage capacity in the event ponds.

To address this question, the annual maximum precipitation data were updated to the end of 2021, and the maximum values were tabulated for the months of May through September. The annual value of 283 mm remains higher than any of the month specific PMP estimates (Table 3-3), and notably, the annual value is higher than the July value by 13 mm. This is due to the fact that the annual maximum precipitation in any year does not always occur in the same month, and thus the K_m scalar is slightly different. In fact, 30% of the annual maxima occur in July, 28% in August, 21% in June, and only 5% in May.

The results of this updated analysis confirm that the estimated 24-hour PMP for the freshet months, when event pond volumes are expected to be highest, are lower than the design estimate.

Table 3-3:
Updated Monthly PMP estimates for the Coffee Gold Project at elevation 1,300 m.

Month	24-hr PMP (mm)	% Total Maximum Annual Events
May	185	5%
June	198	21%
July	270	30%
August	252	28%
September	166	17%
Annual Maximum	**283**	**100%**

4.4.3 Maximum Snowmelt Estimates

Representative snowmelt rates (*i.e.*, daily minimum, average and maximum rates) were derived from the series of annual maximum melt rates for nearest snow pillow stations in Alaska and the Yukon (Table 4-20). The analysis found that in a typical year, peak melt rates of an accumulated snowpack are likely to proceed at rates on the order of 10-20 mm/day (Table 4-20). However, the highest rates calculated from regional data are much larger and range from 30 to >50 mm/day, noting that the highest values are associated with snowpacks that persist later in the melt season, and thus are subjected to higher solar radiation inputs.

Table 4-20:
Summary of snow melt rates from snow pillow stations near Coffee Creek

	Parameter	American Creek	Chisana	Granite Creek	May Creek	Teuchet Creek	Upper Chena
Station Information	*Latitude*	64.79	62.07	63.94	61.35	64.95	65.1

* Measurements reflect late May melting of a deep snowpack (year 1993).
[A] Statistics computed on the annual series of maximum melt rates (per station and for period of record).

Recurrence interval estimates of maximum annual SWE accumulation are presented in Table 4-21. Maximum annual SWE values were determined based on snow survey data from the March 1st, April 1st and May 1st snow survey conducted at nearby snow courses. The three best fitting statistical distributions were applied, and the recurrence interval estimates presented in Table 4-21 are an average of the three estimates for each interval.

Table 4-21:
Recurrence Interval Estimates for Maximum Annual SWE

			Maximum Annual SWE (mm)

4.4.4 Synthetic Climate Dataset

Following the adjustments to site data and the revised selection of a regional analogues described in Section 2.3.3, the air temperature lapse rates and orographic precipitation gradients derived from both site and regional data were applied to the Dawson A climate record to develop a multi-decadal synthetic climate dataset for the Project site.

4.4.4.1 Synthetic Temperature Record

To generate a synthetic daily temperature record for the Project site, the Dawson A station temperature record (minimum, mean and maximum daily air temperatures) were compared to the Km 11 climate station data for the overlapping period of record (2012-2021). A total of 36 monthly lapse rates were calculated based on this comparison, based on an elevational difference of 605 m (Table 4-22). Over the comparison period, the average summer (April to September) lapse rate is -2.6°C/1000 m, and the average winter (October to March) lapse

rate is 6.6°C/1000 m. These lapse rates were then used to adjust the Dawson A temperature record to the 975 m and 1,300 m elevations. A comparison of the measured and synthetic monthly records shows close correspondence for all months, including the period where inversions are commonplace (December through February; Figure 4-19).

Table 4-22:
Calculated monthly lapse rates between Dawson A and Km 11 climate stations for the period 2012-2018.

Month	Lapse Rate (°C/1,000 m)		
	MinT	MeanT	MaxT
January	11.8	10.2	8.6
February	14.8	10.4	6.7
March	12.5	3.3	-5.0
April	5.0	-1.4	-7.1
May	3.0	-2.8	-7.8
June	1.8	-3.6	-7.9
July	1.6	-3.8	-7.8
August	2.5	-2.2	-5.8
September	2.7	-1.9	-5.2
October	3.2	0.2	-2.0

Winter	**10.3**	**6.6**	**3.2**

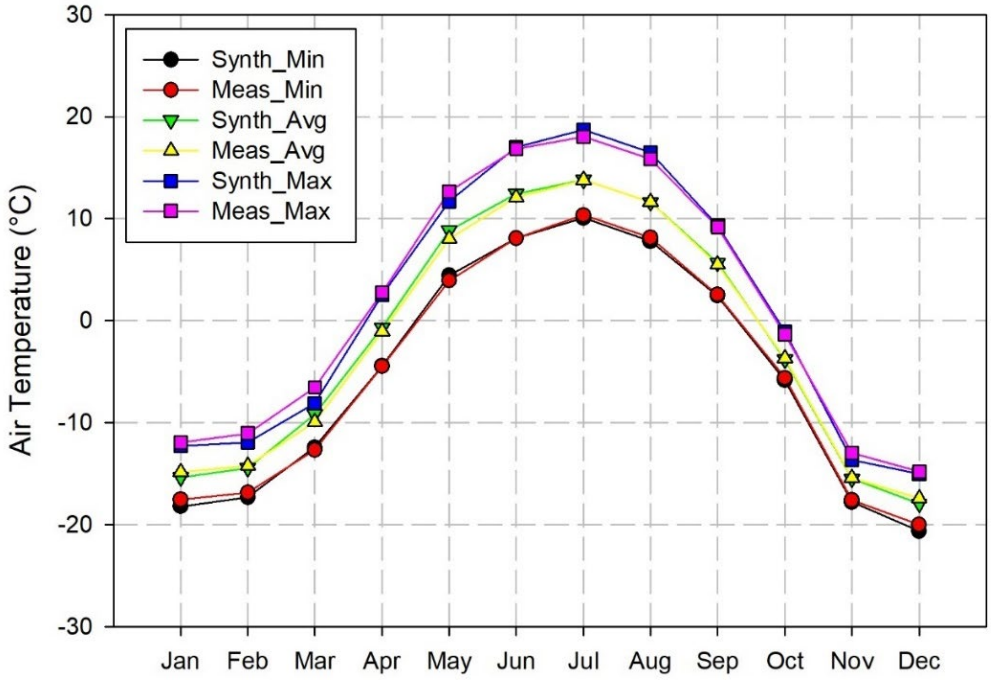

Figure 4-19: Measured and synthetic monthly average minimum, mean and maximum air temperatures for the Coffee Gold Project site.

4.4.4.2 Synthetic Precipitation Record

Consistent with the development of the synthetic temperature record, the Dawson A precipitation record was used as the basis for generating the synthetic precipitation record for the Project site. In this instance, the seasonal orographic gradients described in Section 4.3 were used to scale the Dawson A climate station precipitation record to the site elevation of interest (*i.e.*, Km 11 – 975 m; Kona – 1,300 m). The average monthly measured and synthetic precipitation values were compared over their corresponding periods of record to assess the ability of the seasonal and annual synthetic precipitation estimates to replicate the precipitation regime at the Project site (Table 4-23; Figure 4-20).

Noting that the monitoring record periods are relatively short (10 years and 3 years, respectively), the synthetic April to September rainfall totals generally align with the measured data at both climate stations, both in terms of magnitude and the monthly pattern. Summer precipitation is slightly overestimated relative to measured values at Km 11 and underestimated at Kona. The synthetic estimate for July is notably lower than the measured data at the Kona station, but the 1991-2020 average is much closer to both the measured values, and the estimated values derived from ClimateWNA (Figure 4-20), providing further confidence in the synthetic series ability to replicate the long-term pattern of rainfall variability at the Project site.

Table 4-23:
Comparison of average monthly measured and synthetic precipitation for the Km 11 and Kona climate stations.

Elevation. (m)	975	975	975	1,300	1,300	1,300	1,300

[2]1991-2020 climate normal not available from ClimateWNA at time of writing
[3]April 1st SWE value measured at co-located snow course for the 'Measured' columns, and calculated using a simple temperature based algorithm based on the synthetic climate data for the 'Synthetic' columns.

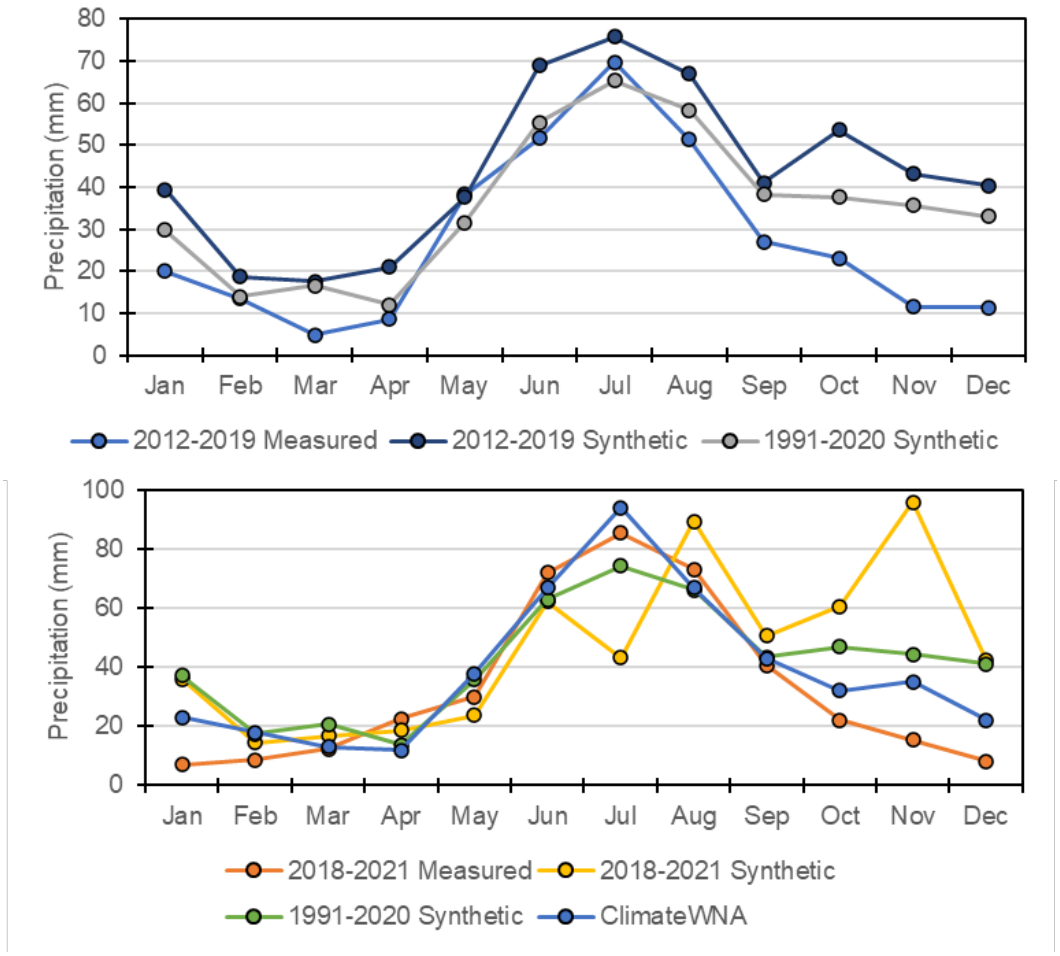

Figure 4-20: Measured and synthetic monthly average precipitation for the overlapping periods of record for the Km 11 (top) and Kona (bottom) climate stations

Deviations between the measured and synthetic series are more pronounced for the early winter months (*i.e.*, October through December), with the synthetic series consistently producing higher precipitation totals than the measured data, but generally aligning for the months of January through March at both stations. This is likely due to gauge undercatch, which the measured data has been corrected for (Section 2.3.3.3), however this correction process is not able to completely remove the influence of local turbulence on undercatch. Comparison with SWE measurements made at co-located snow courses is complicated by wind redistribution due to the limited vegetation at elevation, and sublimation, both of which serve to reduce the total end-of-winter SWE values relative to the total snowfall.

Sublimation is the process whereby water changes phase from solid to vapour, without first passing through the liquid phase. Sublimation typically occurs directly from the snow surface (Cline, 1997), and can be accelerated during blowing snow events, where the time and surface area exposure of a snow particle is greatly increased (Pomeroy and Gray,

1995). The Wolf Creek Research Basin provides the nearest and most representative detailed information on the expected sublimation losses at the Project site, where sublimation loss rates of 0.15 to 0.25 mm/day were reported for the winter accumulation season by Pomeroy *et al.* (1999b) and 0.35 to 1.08 mm/day for the snowmelt period by Pomeroy *et al*. (2006) and Janowicz *et al.* (1995).

Assuming winter accumulation and snowmelt season durations of approximately 160 and 30 days, respectively, these sublimation rates translate to average potential SWE losses of:

- Winter season – 42 mm
- Snowmelt period – 20 mm

The total estimated sublimation loss of approximately 60 mm is comparable to the 58 mm difference between the measured and synthetic SWE values at the Km 11 station (Table 4-23), and slightly lower than the 98 mm difference at Kona, noting again the very short record period and the average higher winter wind speeds (2.7 m/s; Table 4-7) for the latter climate station. Higher windspeeds are understood to increase sublimation rates, with multiple studies concluding that orographic effects play an important role, as wind speed and solar radiation vary with slope angle, elevation, and aspect, leading to relatively higher sublimation and melt rates on steep south facing slopes, and at higher elevations (*e.g.*, Pomeroy *et al*., 2003; Zhang *et al*., 2004). Therefore, there is support for assuming that sublimation losses are higher at the Kona station relative to the Km 11 station.

As a final check on the synthetic winter precipitation estimates, the maximum annual SWE values from the nearby Casino Creek snow course (09CD-SC01; 1,065 m) were scaled to the reference elevation of 1,300 m, and compared to the synthetic winter SWE totals, for the overlapping period of record (1977-2019; Figure 4-21). Regional snow courses are typically situated in protected areas, where wind redistribution and wind-induced sublimation effects on maximum winter SWE values are minimal. Therefore, both the scaled Casino Creek and synthetic SWE data can be considered comparable, assuming that sublimation has not substantially impacted the annual maximum SWE values in either series. While there is substantial inter-annual variability between the two series on an annual basis, the long-term averages are closely aligned (*i.e.*, within 3%), providing further confirmation that the synthetic precipitation dataset adequately represents the long-term snowfall accumulation signal.

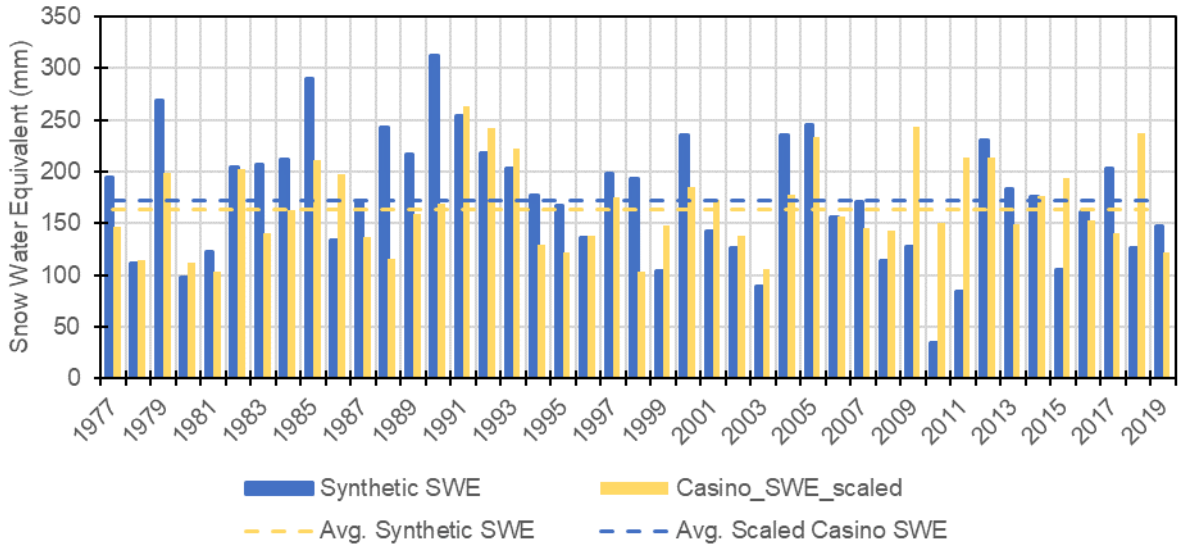

Figure 4-21: Maximum annual snow water equivalent for the synthetic climate data and Casino snow course, scaled to 1,300 m.

In summary, mean annual precipitation (MAP) is estimated to be 504 mm at the reference elevation of 1,300 m over the 1991-2020 period. This synthetic precipitation record will be used as a driving input to the site wide WBQM and is adjusted within the WBQM by the orographic gradients presented in Section 4.3 to represent the influence of elevation on precipitation depths at the Project site.

4.5 Climate Change

The influence of a changing climate on the hydrologic regime of the discontinuous permafrost zone is well documented (see Appendix B for a detailed summary of historical climatic trends and projected changes in temperature and precipitation). Average annual temperatures are projected to rise significantly in the region over the next century. Present day annual average temperature is approximately -2°C at the Project site, and the annual average is forecasted to rise by 2.5 to 5°C by the end of the century (Table 4-24). Net precipitation in the vicinity of the Coffee Gold Mine is projected to increase by 20% to 35% over the course of this century (Table 4-24), where summer and winter can be expected to be slightly wetter in the future, and spring and fall seasons are projected to see little net change in precipitation abundance.

A trend analysis conducted on the regional historic climate records (Appendix B1) indicates that recent climate trends are in line with future projections. Average winter temperatures are increasing by 1°C/decade, while the trend in summer temperatures is of lower magnitude at 0.3°C/decade. Seasonal precipitation trends show a mixed signal in summer, and a strong regional trend towards increased autumn precipitation

(4-6 mm/decade). Streamflow metrics are consistently increasing in the Yukon, with significant trends noted for winter low flows (increasing), and the timing of freshet onset (moving earlier).

4.5.1 Climate Change Scenario Data for State of Alaska and the Canadian North

The Scenarios Network for Alaska and Arctic Planning (SNAP) is a collaborative network of the University of Alaska, state, federal, and local agencies, NGOs, and industry partners. SNAPs mission is to provide timely access to scenarios of future conditions in Alaska and the Arctic for more effective planning by decision- makers, communities, and industry.

Climate change scenario data from this network was used as the basis of the climate change assessment presented in this section (see https://www.snap.uaf.edu/). SNAP provides several platforms for looking at historic climate trends and climate projections in Alaska and western Canada:

- Downloadable datasets for historic climate data and projected climate data (temperature and precipitation).
- Options to use an interactive mapping interface that provides climate projections for Alaska and western Canada for each decade through 2100. Within the mapping interface there are user options to select variables, time periods, seasonal averages, and emissions scenarios of interest.
- The option to view Community Charts which are already completed air temperature and precipitation analyses for cities, towns and hamlets across Alaska and Western Canada, including Yukon and British Columbia.

4.5.1.1 Available Scenarios

Climate change scenario data are available at SNAP for three of the 4 Representative Concentration Pathways (RCPs) (*i.e.*, RCP4.5, RCP6.0 and RCP8.5, noting each RCP is resolved out to the year 2100 (Figure 4-22). For context, the RCP4.5 pathway assumes global emissions peak around 2040, and that radiative forcing is stabilized shortly after 2100. RCP4.5 is likely optimistic, and as such SNAP refers to it as a "low" scenario (*i.e.*, typically associated with smaller incremental changes in air temperature compared to other RCPs.

The RCP6.0 (middle or SNAP "medium" scenario) assumes that a range of technologies and strategies for reducing greenhouse gas emissions are developed, allowing emissions to peak around 2080, then decline, with total radiative forcing stabilized shortly after 2100. Finally, the RCP8.5 ("high" scenario) is a potential future characterized by continuous increases in greenhouse gas emissions throughout the 21st century.

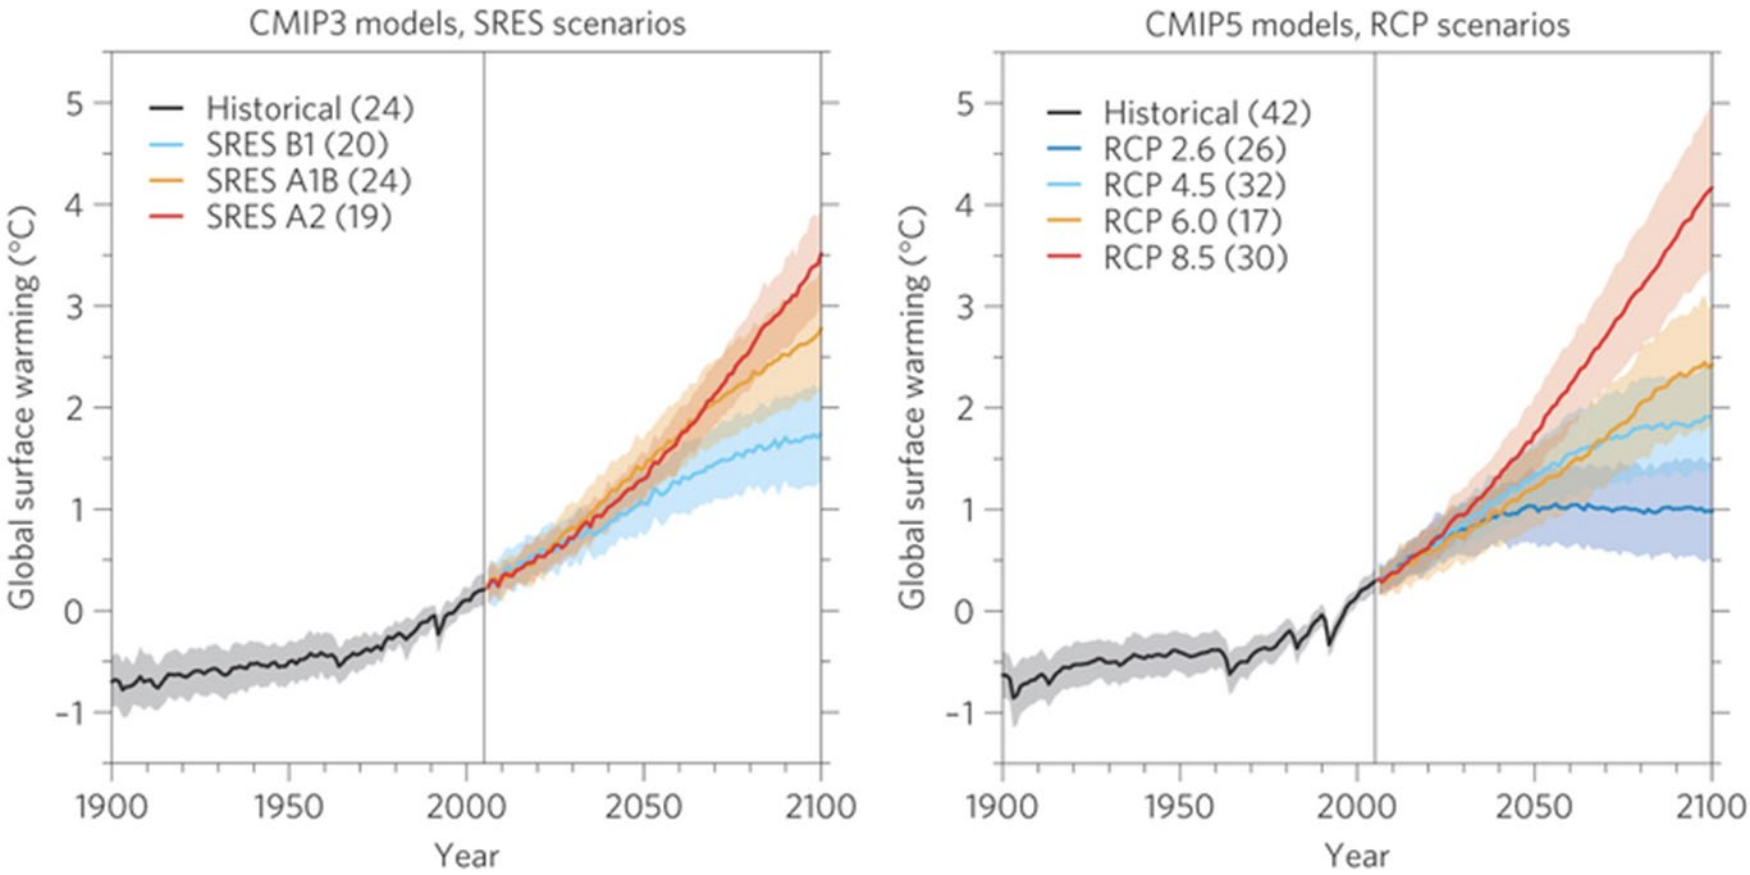

Figure 4-22: Global temperature change projections for SRES scenarios run by CMIP3 (left) and the RCP scenarios run by CMIP5 (right). Mean global temperature change relative to 1986–2005 is shown as a colored line and one standard deviation shown with colored shading. The number of models run is given in parentheses. Figure reprinted from Knutti and Sedláček (2013).

As described at SNAP (refer to https://www.snap.uaf.edu/methods/data), available data summaries and/or downloadable datasets for high latitude stations in North America, including the entire Yukon Territory, are based on CMIP5 model outputs for the first ensemble model run.

4.5.1.2 SNAP Downscaling Method

Referencing the website (see https://www.snap.uaf.edu/methods/downscaling), GCM output variables of surface temperature and precipitation were downscaled for Yukon Territory via the delta method (Hayhoe 2010, Hay *et al*. 2000) using PRISM 2 km resolution climate normals as baseline climate across three future climate scenarios (*i.e.*, RCP4.5, RCP6.0, RCP8.5). The delta method of downscaling was implemented by calculating climate anomalies applied as differences for temperature or quotients for precipitation between monthly future GCM data and calculated GCM climate normals (*i.e.*, the delta) at a monthly time step. These coarse resolution anomalies were then interpolated to PRISM spatial resolution (*i.e.*, 2 km) via a spline technique, and then added to (temperature) or multiplied by (precipitation) the PRISM climate normals.

The representative downscaled projections for each of the three RCP scenarios were downloaded from the SNAP website, for the four grid points that overlap the Coffee Gold Project site. Average values were then calculated from these four-grid point time-series, and trend lines fitted to the monthly projections (Figure 4-23). The slope of the trend line for each parameter (*i.e.*, minimum, mean and maximum air temperature and precipitation) was then used to determine the delta from the baseline reference period (2006-2020) on a monthly basis over the full prediction period out to the year 2100. These parameter specific scalars are intended for input to the site-wide water balance and water quality model to generate climate inputs that can be scaled to account for the projected effects of climate change on the Project site climate series.

Table 4-24:
Decadal statistics for the Coffee Gold Project (mean annual air temperature and precipitation) for the RCP4.5, RCP6.0 and RCP8.5 climate change scenarios.

Decade	Mean Air Temperature (°C)			Precipitation (mm)		
	RCP4.5	RCP6.0	RCP8.5	RCP4.5	RCP6.0	RCP8.5
2010-2019	-2.9	-2.8	-2.7	603	592	615
2020-2029	-2.4	-2.3	-2.0	617	626	640

5. Streamflow Regime Characterization

Newmont™
COFFEE

5. Streamflow Regime Characterization

5.1 Coffee Creek Hydrometric Data

From the extensive hydrometric network at Coffee Creek, combined with the monthly sampling trips conducted since autumn 2010, a high-quality and high-resolution streamflow dataset has been assembled. These data are presented in full in Appendix C and have been used to: inform project feasibility studies; complete design and engineering studies related to the Project; and they have also been used to build and calibrate a site-wide water balance and water quality model for the proposed undertaking. As a complement to the information presented in Appendix C, this section presents examples of the available hydrometric data to illustrate overall quality, and also presents roll up tables (*e.g.,* for unit yields, peak flows, low flows) and discussion in an effort to synthesize the data.

5.1.1 Drainage Basin Characteristics, Rating Curves and Discharge Records

Hydrometric data and outputs are presented in Appendix C for 2010 to 2020. Appendix C is separated into fourteen sub-sections or data reports, each sub-section reporting out baseline hydrometric data for monitoring locations at Coffee Creek. For each monitoring station, an assortment of information is presented in Appendix C, including:

Drainage Basin Information

Mean elevation, basin area, a detailed basin map, aspect and hypsometry information are presented per hydrometric station in Appendix C. Figure 5-1 shows an example of a drainage area map included in Appendix C (for hydrometric station LC-0.1 (Latte Creek), upper plot), as well as a summary of available hypsometric data for the Coffee Creek monitoring station (lower plot).

Station Information

Summary reports list all pertinent station information for the various monitoring station. Included in Appendix C are the following: (new) Station ID, previous Station ID, period of record, instrumentation (type of water level logger) and sampling frequency, and benchmark survey results.

Photos of the stations and watercourses, under various flow conditions, are also included in Appendix C.

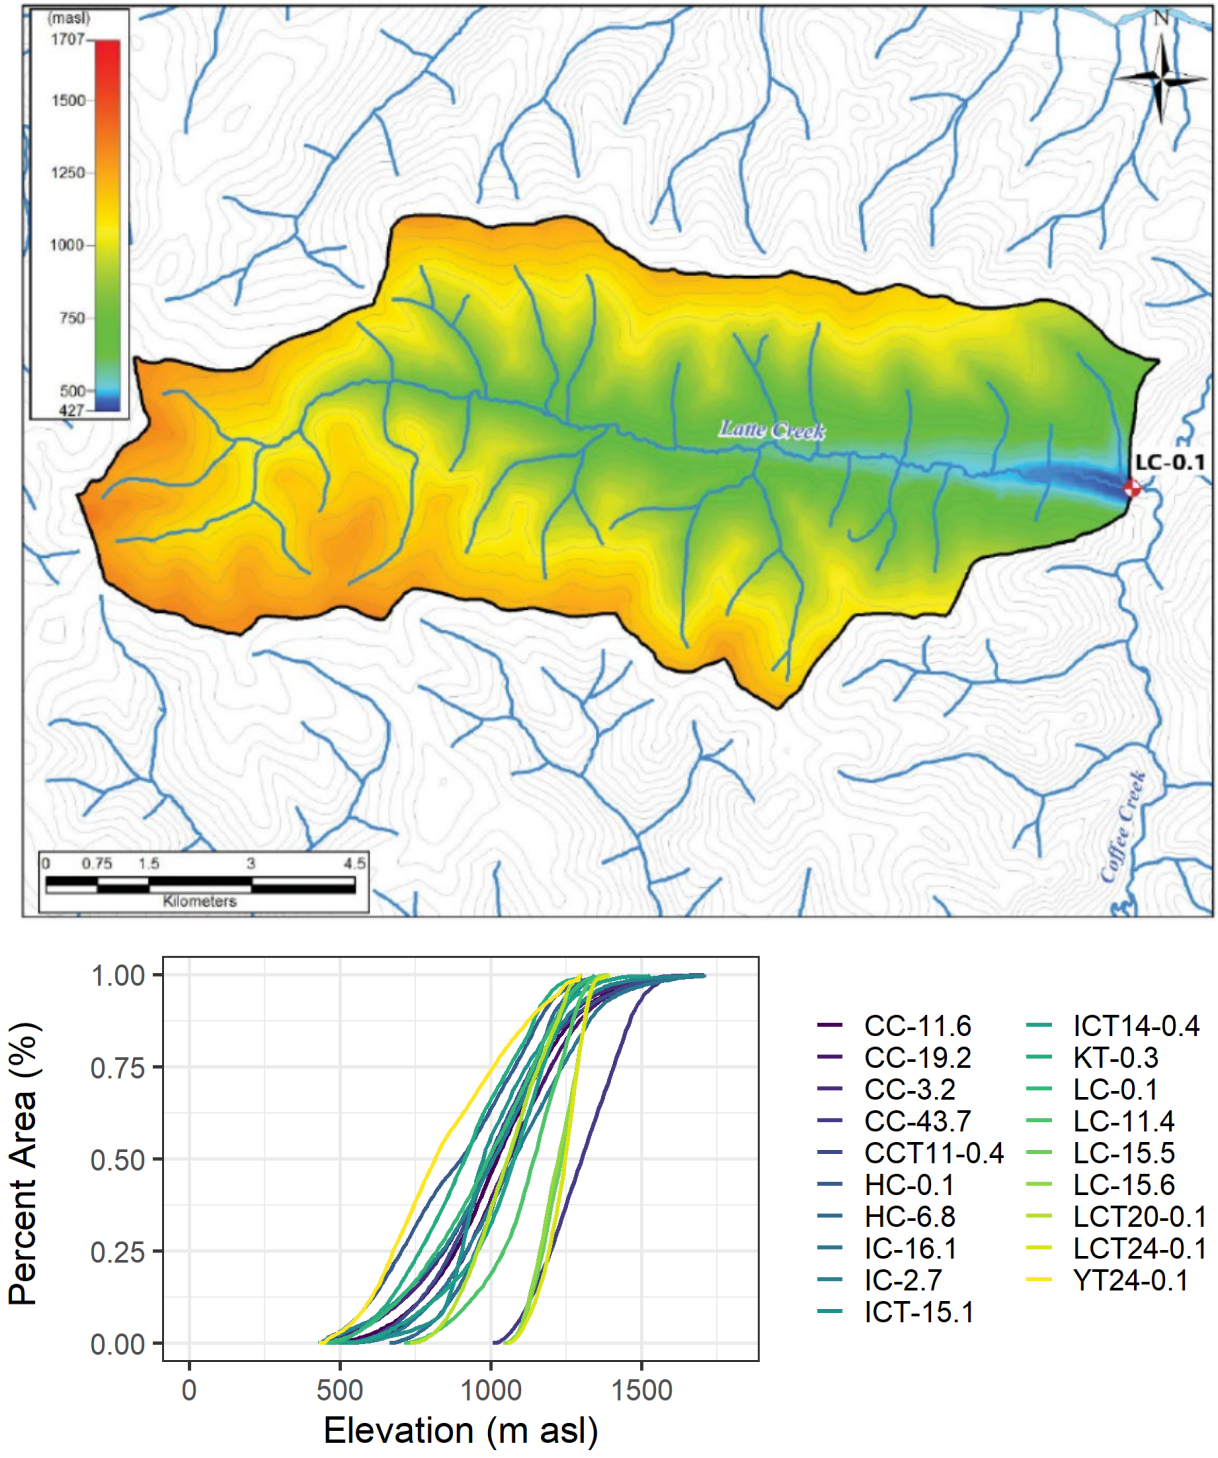

Figure 5-1: Drainage basin map for hydrometric station LC-0.1 (upper plot) and plot showing hypsometric curves (basin area vs. elevation) for all hydrometric stations (lower plot).

Rating Curves

Appendix C shows active rating curves for the Coffee Creek hydrometric stations, which have been adjusted and validated annually from 2011 to 2020. An example is shown for the LC-11.4 hydrometric station in Figure 5-2, where the highest 15-minute discharge calculated from the rating curve is represented by a vertical dashed blue line, and the green highlighted area indicating the 90th percentile of all calculated discharge values for that station. Appendix C also summarizes, by station, all spot measurements of discharge recorded at the property since 2010, the calculated discharge based on the current rating curve and staff gauge reading, and the relative error of the rating curve with respect to the measured discharges.

Measured Time Series Data

Period of record discharge data are shown for hydrometric stations in time series format. Discharge data are also presented in summary table format (by month, as yields, discharges, and runoff depths) per station for the period of record. Included on time series plots are continuous discharge data estimated from rating curves, and spot measurements of discharge. Discharge data for Halfway Creek stations HC-6.8 and HC-0.1 are shown below (Figure 5-3) as representative examples.

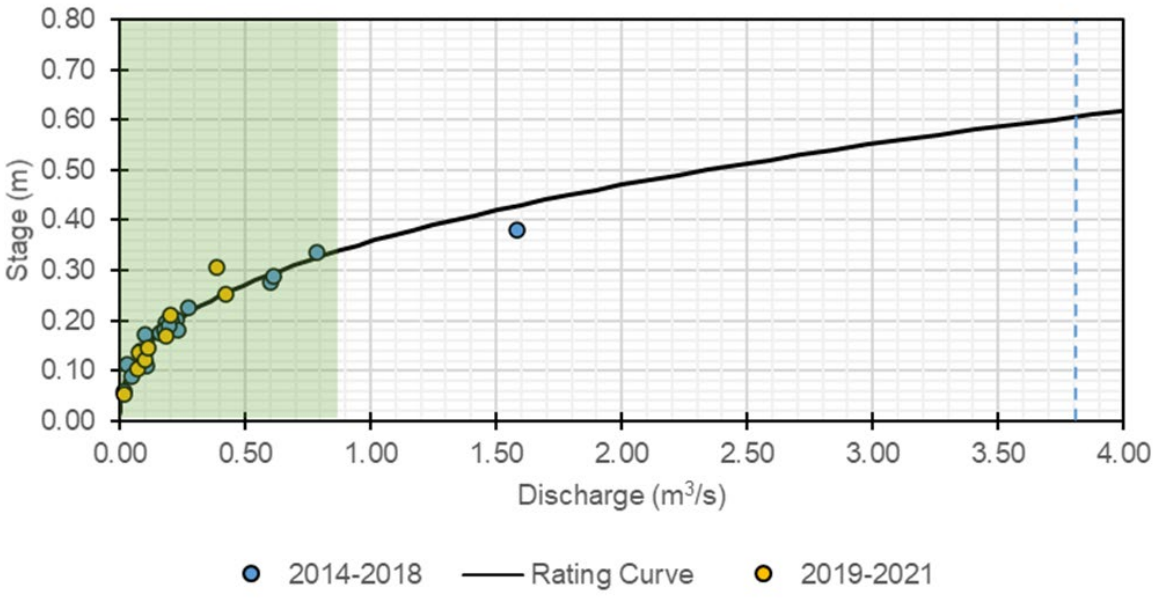

Figure 5-2: Rating curve for LC-11.4 hydrometric station. Dashed blue line represents highest estimated discharge using rating curve. Green shaded area represents 90% of all estimated discharges using rating curve.

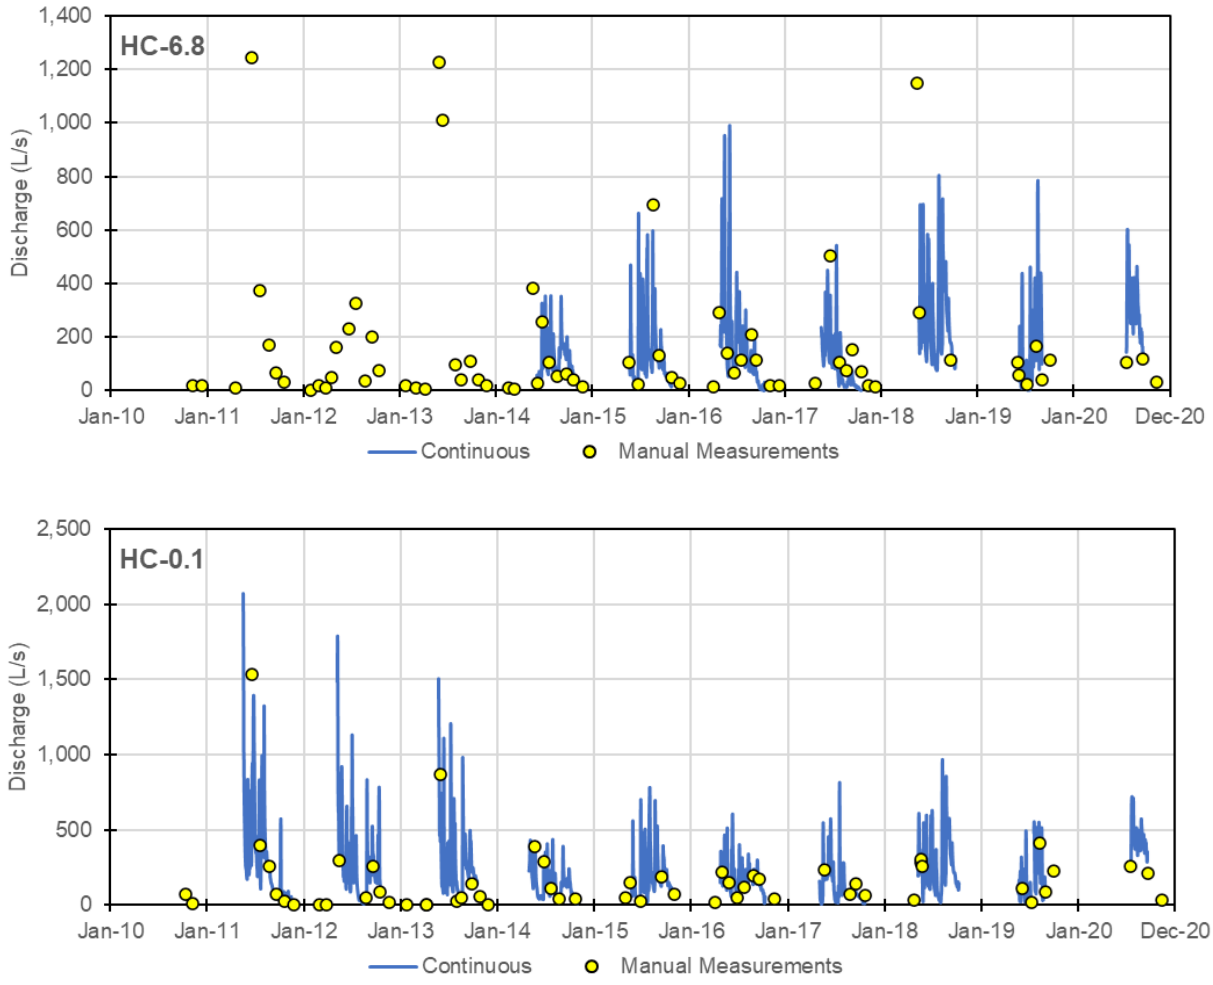

Figure 5-3: Time series discharge data for hydrometric stations on Halfway Creek. The upper panel shows discharge data (blue line) and spot measurements of discharge (green circles) for HC-6.8. The lower panel shows the same information for HC-0.1.

5.1.1.1 Unit Yields

Local patterns of streamflow are dominated by a snowmelt freshet that typically occurs late-April to mid-June and punctuated by multiple rainfall-induced high flow events that occur throughout the summer and autumn. In general, these high flow events are short lived, often persisting for a duration of 1 or 2 days. A plot showing the unit yields for all Project drainages, for their periods of record, is presented as Figure 5-4.

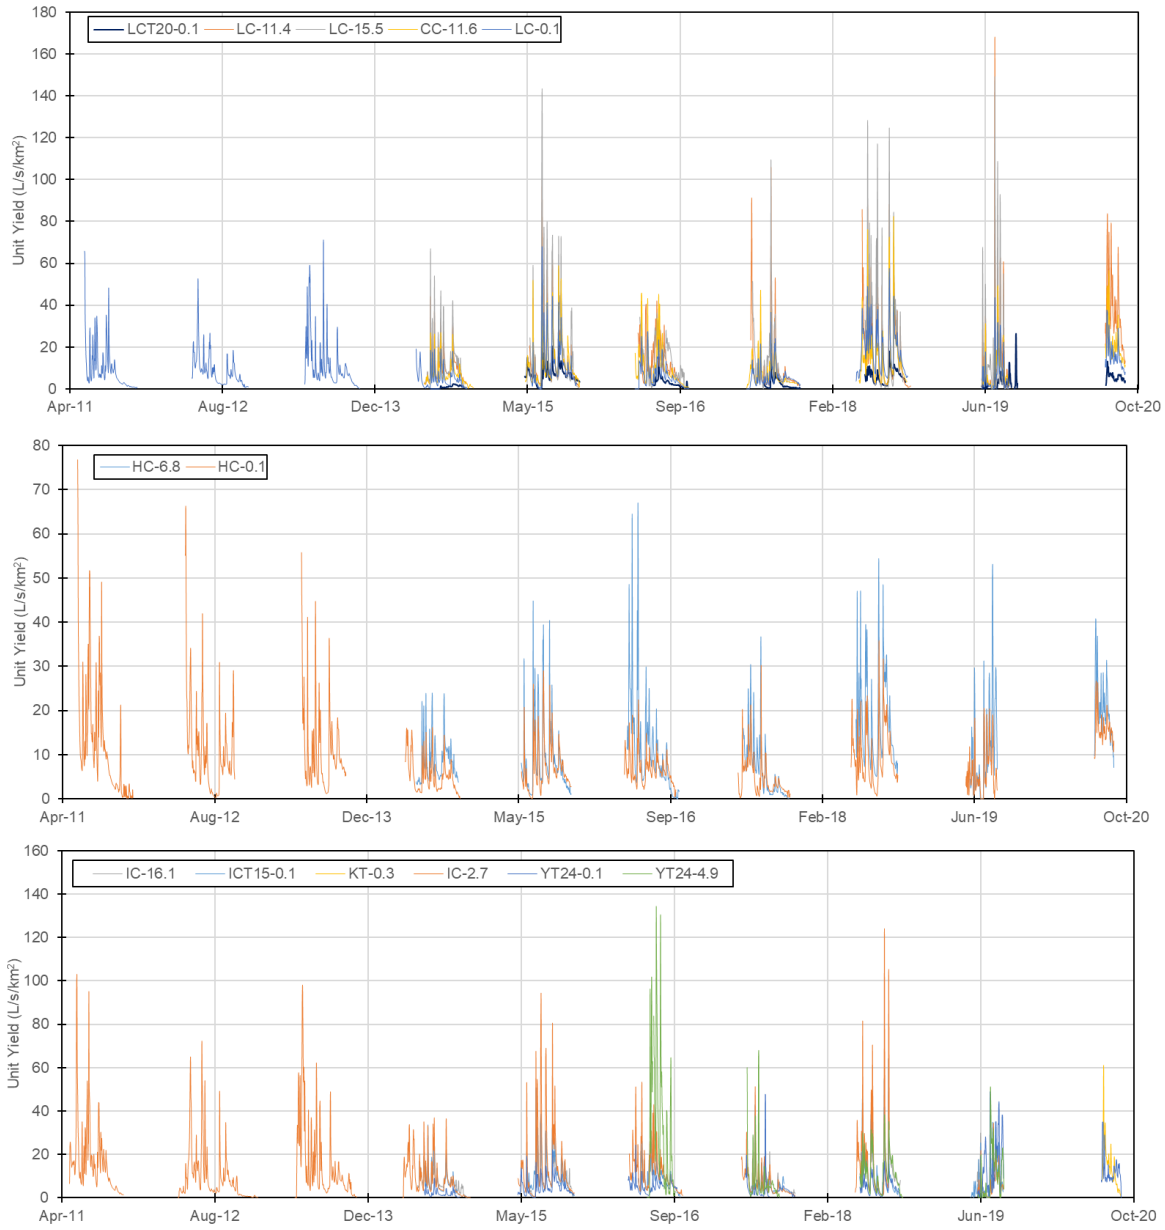

Figure 5-4: Unit yield hydrographs for gauged Project basins.

In general, average unit yields across the Project site are 10.6 L/s/km^2 for the open water season (May to October) and range from 4 to 16 L/s/km^2, depending on the drainage and noting the variation in record lengths between stations. The YT-24 (YT24-0.1) and LCT20-0.1 tributaries that drain the Supremo North and Upper Latte Creek development (respectively) have the lowest yields, while Upper Latte Creek (LC-15.5 and LC-11.4) and Halfway Creek (HC-6.8) have the highest yields (Table 5-1). Note that the YT24-4.9 station shows much higher yields than the YT24-0.1 station. This is due to several factors, including the preliminary rating curve used to generate the YT24-4.9 continuous discharge series, and the known losing reach that YT24-0.1 is located in.

Table 5-1:
Average unit yields by month (L/s/km^2)

Station	Area (km^2)	Record	May	June	July	Aug	Sept	Oct	May-Oct Average
CC-11.6	385.6	2014-2020	12.3	9.5	12.1	13.3	8.9	3.5	9.9
LCT20-0.1	3.4	2014-2020	7.6	3.2	4.1	4.9	3.9	2.0	4.3
LC-11.4	23.1	2014-2020	21.3	12.3	20.4	19.0	10.5	3.3	14.5
LC-0.1	69.8	2011-2020	13.2	9.7	12.4	11.0	7.6	2.7	9.4
LC-15.5	9.6	2014-2019	23.8	15.6	22.8	18.1	11.7	5.1	16.2
HC-6.8	14.8	2014-2020	18.6	13.5	13.7	13.9	9.8	3.9	12.2

Note: Unit yield estimates for station YT24-4.9 are considered preliminary, due to the incomplete rating curves for this station.

5.1.1.2 Peak Flows

Peak flows are driven primarily by the intense convective rainfall events that are common in the summer months, with secondary peaks occurring in late-May, as a result of melting snowpacks. Measured peak flows are summarized in Table 5-2 for Coffee Creek stations.

Instantaneous peak flow unit yields are typically between 120 and 200 L/s/km^2, although the ICT15-0.1 station has only recorded an instantaneous peak flow of 60 L/s/km^2 range (Table 5-2). Upper Latte Creek experiences relatively larger instantaneous peak flow yields, on the order of 200 to 270 L/s/km^2.

Table 5-2:
Instantaneous peak yields by month from 15-min measurements (L/s/km^2)

Station	Area (km^2)	Record	May	June	July	Aug	Sept	Oct	Annual Maximum
CC-11.6	385.6	2014-2018	100.1	65.3	59.7	135.5	29.13	13.9	136

YT24-0.1	11.8	2014-2018	39.9	26.8	400.0	29.8	14.4	15.7	400

Note: Peak flows for station YT24-4.9 are not reported due to the preliminary nature of the rating curve, and associated higher error in peak flow estimates.

5.1.1.3 Low Flows

During the open water season, the recession limbs of local hydrographs are often steep following the passage of a large rain event and the associated peak flows. Low flow conditions can occur intermittently during the summer and early autumn across the Project site, with unit yields during early summer often approaching those measured during the winter months. Measured low flows are summarized in Table 5-3.

Low flows measured in June 2015 at valley bottom stations (~1 L/s/km^2) formed a critical input to the site-wide groundwater model calibration. As the summer progresses, baseflows in the lower reaches of the Project site creeks are enhanced by active layer melt and soil moisture recharge. At the upper elevation stations (*e.g.*, LC-15.5) and those situated in alluvial deposits (*e.g.*, LCT20-0.1) effective yields can drop to near zero flow conditions (Table 5-3). By November, unit yields were observed to drop to 0.5 to 1.5 L/s/km^2 in all Project drainages, and zero flow conditions become widespread by late January and are accompanied by extensive aufeis formation. Aufeis (*i.e.*, frozen groundwater seepage that accumulates within- and adjacent to local watercourses) is pervasive in creeks and streams at the Project site. Aufeis melts during the freshet but may persist into the early summer (mid- to late-June). It is discussed in more detail below.

Table 5-3:
Minimum recorded low flow yields by month from daily averages (L/s/km^2)

Station	Area (km^2)	Record	May	June	July	Aug	Sept	Oct	Open Water Minimum

YT24-0.1	11.8	2014-2018	0.58	0.03	0.33	0.40	0.40	0.00	0.00

Note: Low flows for station YT24-4.9 are not reported due to the preliminary nature of the rating curve, and associated higher error in low flow estimates.

Annual Low Flow Regime and Aufeis

Over the course of the 8+ years of baseline study, all available winter spot flow measurements (October through April) were averaged by month then presented in Table 5-4 below. Low flow plots (*i.e.,* spot flow measurements and synthetic discharge estimates) are also presented for the hydrometric stations in Appendix A.

Site data show that yields range from 0.6 – 3.4 L/s/km^2 in October and decrease steadily to their annual minima by March (0 – 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rainfall. Based on the site data alone, winter low flows are expected to range from 0 to 0.7 L/s/km^2.

An important component of the winter flow regime at the Project site is the extensive icing of the local channels. This ice growth, or aufeis, is the result of shallow groundwater discharge and/or baseflow in the stream channel freezing. This ice impedes subsequent flow, which is forced on top of the existing ice sheet, where it freezes (see Figure 5-5). This process repeats continuously throughout the winter, and results in laminated ice sheets that have been measured close to 1.5 m in thickness and 50+ m in width in the Project channels (Figure 5-6). Liquid flow is thus either not present, or it can still occur between these laminae, and at the edges of the stream channel. It is these flows that the water quality samples are taken from during the winter. The aufeis process also acts as a storage reservoir for winter baseflows and can store up to a third of the cumulative annual baseflow in sub-Arctic watersheds (Yoshikawa *et al*., 2007).

Table 5-4:
Winter spot flow measurements presented as monthly averages for Project area hydrometric stations. Values are unit yields (L/s/km^2).

Notes:
*Value is based on a single measurement.
No winter flow measurements are available for YT24-4.9

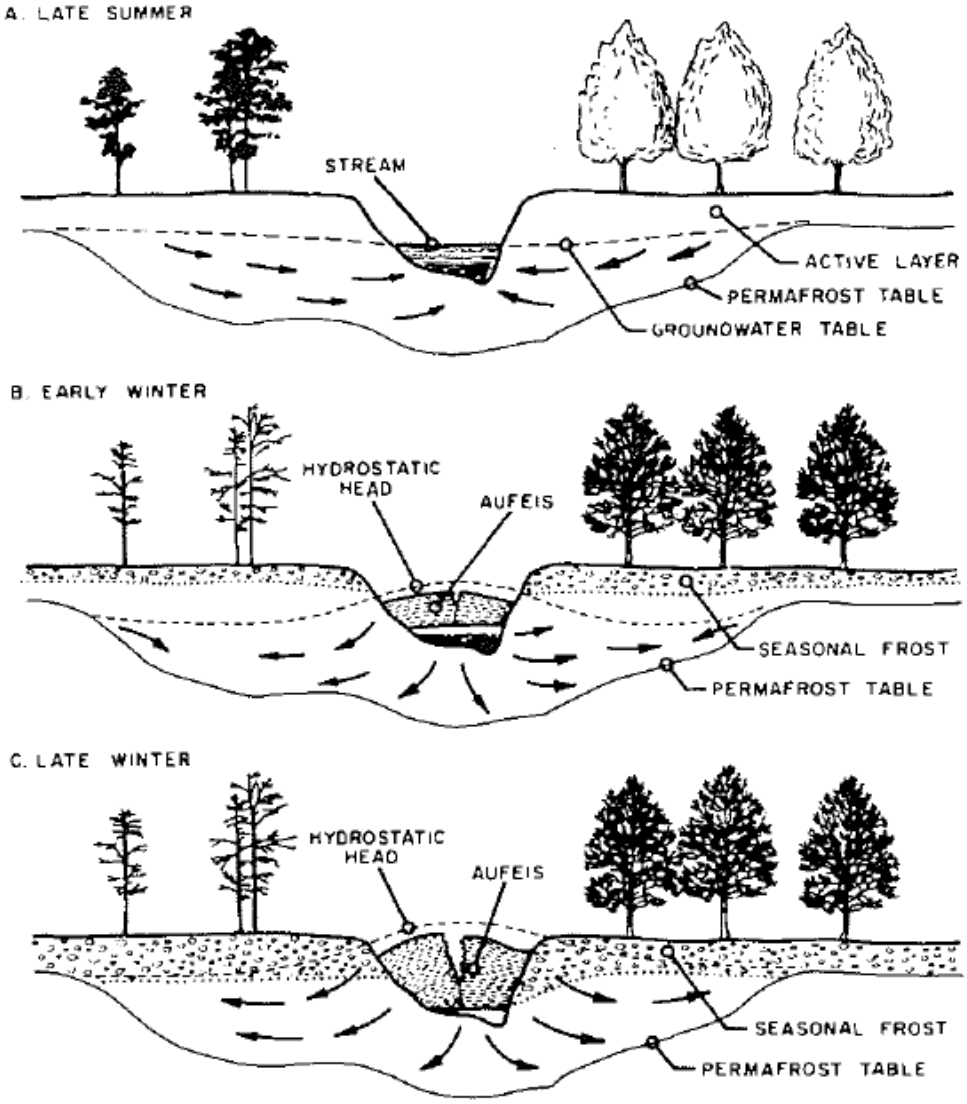

Figure 5-5: Groundwater flow patterns and aufeis formation (from Kane, 1981).

Figure 5-6: Extensive aufeis (~50 m wide) at HC-6.8. For reference, the stream channel is typically 2 m wide at this point.

Aufeis often far exceeds the natural stream channel width in the smaller tributaries, and as ice melts much more slowly than the snowpack, much of the freshet occurs while extensive aufeis is still present. This makes accurate measurement of streamflows (where they exist) challenging or impossible during the winter season at most hydrometric stations, and dangerous during the initiation of freshet. This process also influences the distribution of annual streamflow, as the baseflow stored in aufeis during the winter months is released during the freshet and early summer periods. This means that proportionately even more of the total annual runoff is expressed during the months of May through October.

A map of the Project site drainages with measured and inferred aufeis extents and thicknesses is presented in Figure 5-7.

5.1.1.4 Mean Annual Runoff (MAR) and Elevation

Hydrometric data tabled in Appendix C is presented in runoff depth format. Estimates for each station are presented monthly, annually and as an average (mean annual runoff, MAR) per station, for the available period of record. MAR estimates for the Project area creeks vary from basin to basin. For example, the runoff generated by YT-24 is low and approximately 50 mm based on the 2014-2018 open water season average (Appendix C). Measured runoff data for 2019-2020 were not included in this analysis due to the more limited coverage, including the lack of freshet discharge data. In contrast, runoff generated in the headwaters of Latte Creek are comparatively high and estimated to be 180 mm based on the same period. MAR for LC-15.5, a high-elevation headwater station within the Latte Creek drainage shows an even higher MAR value 205 mm). Note that these estimates are based on the measured data for the open water season only, and thus do not include additional runoff generated during early freshet and the winter months, where present. The MAR values presented in Section 5.1.2.1 are based on the synthetic streamflow time-series, and explicitly include estimates of runoff for these periods.

To explore relationships between runoff generation and basin characteristics, MAR estimates were regressed against mean basin elevation (m), basin area (km^2) and dominant aspect within the drainage. While resulting relationships were weak or poor for the basin area and aspect assessments, a robust relationship between runoff and elevation was ascertained. This relationship is shown for Project site drainages in Figure 5-8.

With the exception of the LCT20-0.1 basin, a small (3.4 km^2) catchment in the headwaters of Latte Creek, MAR increases linearly with increase in median basin elevation at the Project site. Compared to other basins, the uniqueness of the LCT20-0.1 flow regime is assumed attributable to its basin outlet configuration (*i.e.*, small, wide, permeable surficial geology) that returns lower than expected surface water flow (especially in 2014) and presumably higher groundwater discharge than other gauged basins.

The line of best fit through the MAR:median elevation points [MAR (mm) = 0.314*elevation (m) - 195.77] returns an annual runoff elevation gradient of 7%/100 m, which is equal to the annual average orographic precipitation gradient of 7%/100 m. The strong correlation between median basin elevation and runoff is likely influenced in part by more extensive permafrost coverage at higher elevations but is also driven by higher precipitation at the upper elevations of the Project area, further supporting the conceptual model of orographic precipitation gradients at site (Section 4.3).

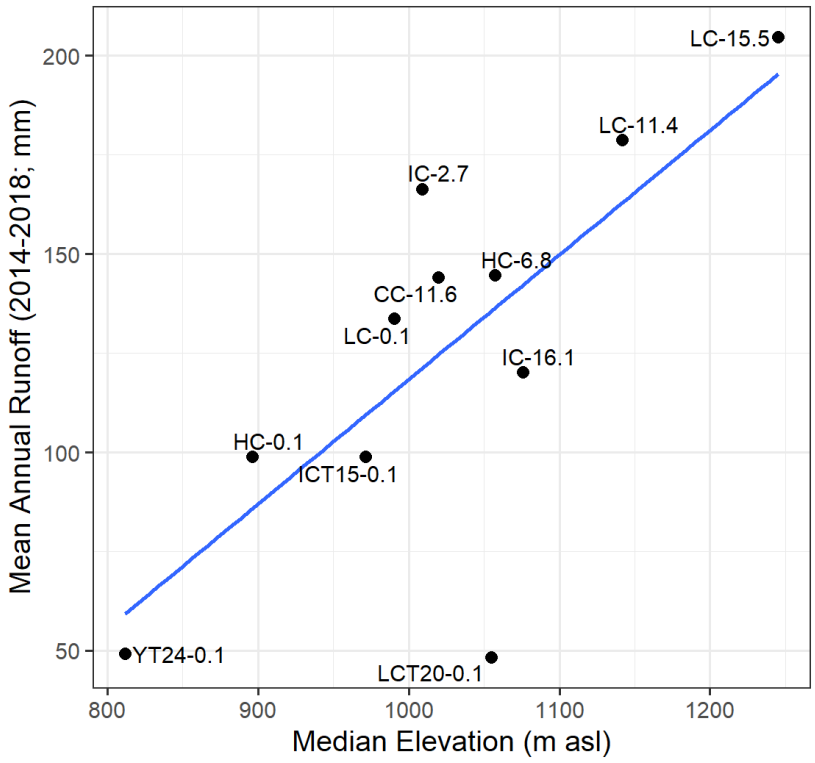

Figure 5-8: Mean annual runoff for the open water season plotted against median basin elevation (2014-2018).

5.1.2 Synthetic Discharge Data and Streamflow Metrics

The creation of synthetic hydrographs for all Project stations resulted in a 44-year record (1975-2018) of daily discharge being created for the Project site drainage basins. Extension of the synthetic record beyond 2018 was not possible due to the lack of QA/QC'd hydrometric data from regional WSC stations beyond this date. Ultimately, these records allow the short-term site data to be placed in a broader historical context. An example synthetic record is shown in Figure 5-9 for Latte Creek hydrometric station LC-11.4. The upper plot of this figure shows the synthetically estimated discharge data for this station. The lower plot compares measured and synthetic discharge data for LC-11.4 (for the overlapping record of 2014-2018) in flow duration curve format. The strong similarity of these flow duration curves gives an indication that the magnitude of the discharges and the range of variability for discharge in the measured record is appropriately replicated in the synthetic series.

Figure 5-10 depicts the long-term annual runoff time-series for stations LC-11.4, HC-6.8 and YT24-0.1. Given the general arrangement for the proposed mine (refer to Figure 1-2), these three basins may see modification and/or alteration to surface flow, surface water quality and/or groundwater condition (quantity, quality) as Project footprints advance.

Runoff data in this figure show that overall, range in inter-annual variability for each station is substantial, and the relative magnitude of variation differs between basins. The differences in magnitude are assumed attributable to site-specific differences in mean basin elevation (Figure 5-8), that have been correctly embedded into the respective synthetic discharge series.

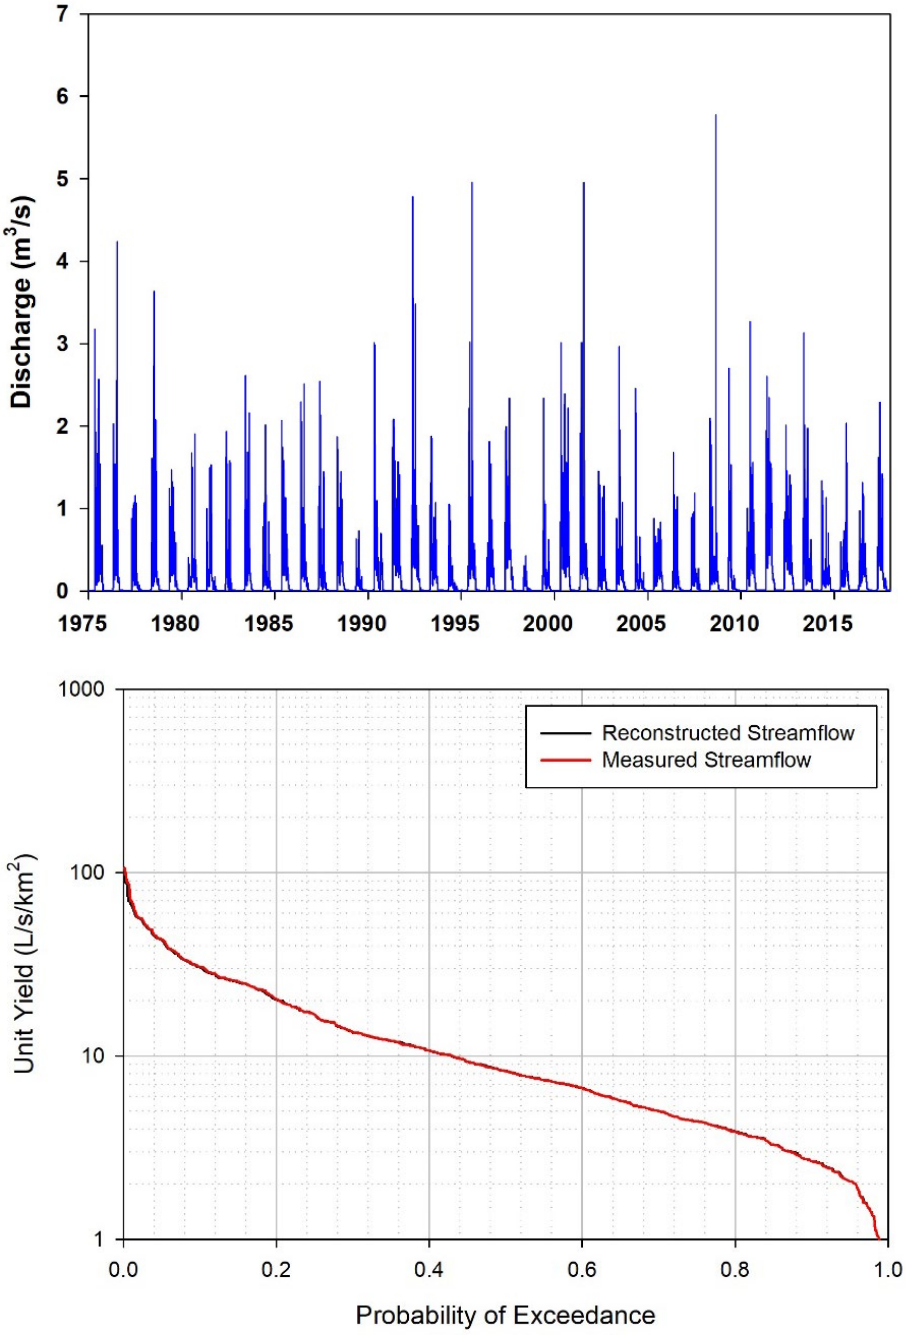

Figure 5-9: Time-series of daily discharge for the LC-11.4 synthetic discharge record (upper panel). The lower panel shows LC-11.4 discharge data (measured and synthetic) in flow duration curve format.

The long-term variability in natural runoff contained within each synthetic dataset can be shown in standardized anomaly plot format. An example anomaly plot is shown for LC-11.4 in Figure 5-11, where positive Y-axis and negative Y-axis scaling indicate progressively higher and lower deviations from long-term average runoff respectively. From Figure 5-11, it is apparent that the baseline study period (*i.e.*, autumn 2010 to end 2018) captured five years that were wetter than average (2010 through 2013 and 2018), and four years that were average or slightly drier than average (2014 through 2017). This is critical information, as a series of wet- or dry-years occurring during a short baseline data collection period can heavily bias estimates of streamflow metrics.

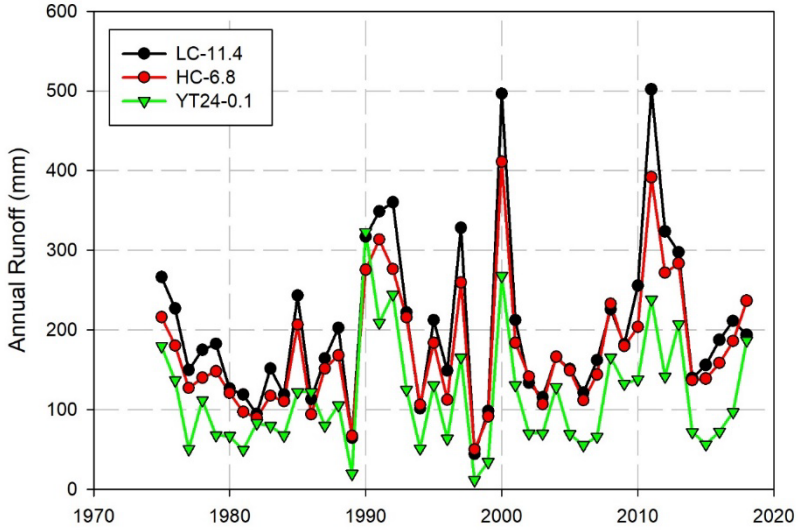

Figure 5-10: Annual runoff time-series for stations LC-11.4, HC-6.8 and YT24-0.1.

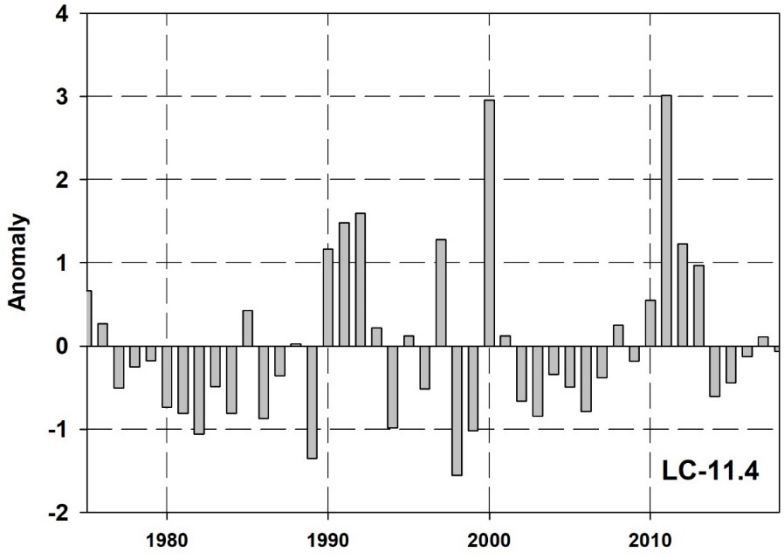

Figure 5-11: Standardized anomaly plot for annual runoff at LC-11.4.

5.1.2.1 Annual Runoff: Wet- and Dry-year Recurrence Intervals

Results of the annual runoff recurrence interval analysis are presented in Table 5-5, along with the average runoff ascertained from the measured site data. Agreement is generally good for all basins, although the average runoff calculated from site data are biased toward the 2014-2018 period of common record, and by the lack of continuous data throughout the winter low-flow season. The spread between the 1:200 dry- and wet-years is confirmed to be substantial at Coffee Creek, and generally, wet-years are expected to produce an order of magnitude higher runoff than an extreme dry-year. As a point of reference for the wet- and dry recurrence interval data presented in Table 5-5, the synthetic discharge records vary by factors of 8-9 over the 44 years of record, with much higher variability at LCT20-0.1 and YT24-0.1, where the wettest year has 16 and 84 times the runoff of the driest year, respectively.

The average runoff for all site stations is presented alongside the corresponding annual precipitation estimate for each recurrence interval in Table 5-6. Average runoff coefficients for each interval are presented in this table as well. These data show that the proportion of annual precipitation converted to runoff increases in proportion to the total annual precipitation estimated, which is consistent with the expected basin response. For a wet year, soil moisture storage would likely be fully recharged, and would have limited additional capacity to store infiltrated precipitation. Conversely and for a dry-year, a below average snowpack or prolonged summer drought combined with evaporation, may require appreciable precipitation to replenish basin storage and soil moisture deficit, and only then will surface runoff be produced.

Table 5-5:
Annual runoff recurrence interval estimates for Project site basins (all values in mm/year).

5.1.2.2 Peak Flows

As an extension to the peak flow analysis presented using measured data from site, a regional peak flow analysis was conducted using the stations listed in Table 3-7. Recurrence interval estimates of annual instantaneous peak flows were plotted against drainage area, and an enveloping power law function was then fit to the data. For reference, the measured peak flows from the site data were also plotted, with a separate function fit to these data. The enveloping power law functions derived from the regional data for each recurrence interval (*e.g.*, 1:100-year peak flow) were used to estimate the corresponding peak flow for all Project drainages. The results of this analysis are presented as unit yields in Table 5-7 and plot of the regional- and site- peak flow data is provided in Figure 5-12.

Table 5-7:
Instantaneous peak yield recurrence interval estimates for Project basins derived from regional analysis (L/s/km^2)

Station	Drainage Area (km^2)	1:2 year	1:5 year	1:10 year	1:25 year	1:50 year	1:100 year	1:200 year	Measured Peak Yield

IC-2.7	222.3	106	143	166	198	245	288	339	207
YT24-0.1	11.8	128	189	231	292	377	459	563	400*

Note:
*Estimated discharge value, hydrometric station was destroyed during July 15, 2017 flood event. Highest recorded water level prior to record interruption returned a unit yield value of 400 L/s/km^2, albeit with a high degree of uncertainty.

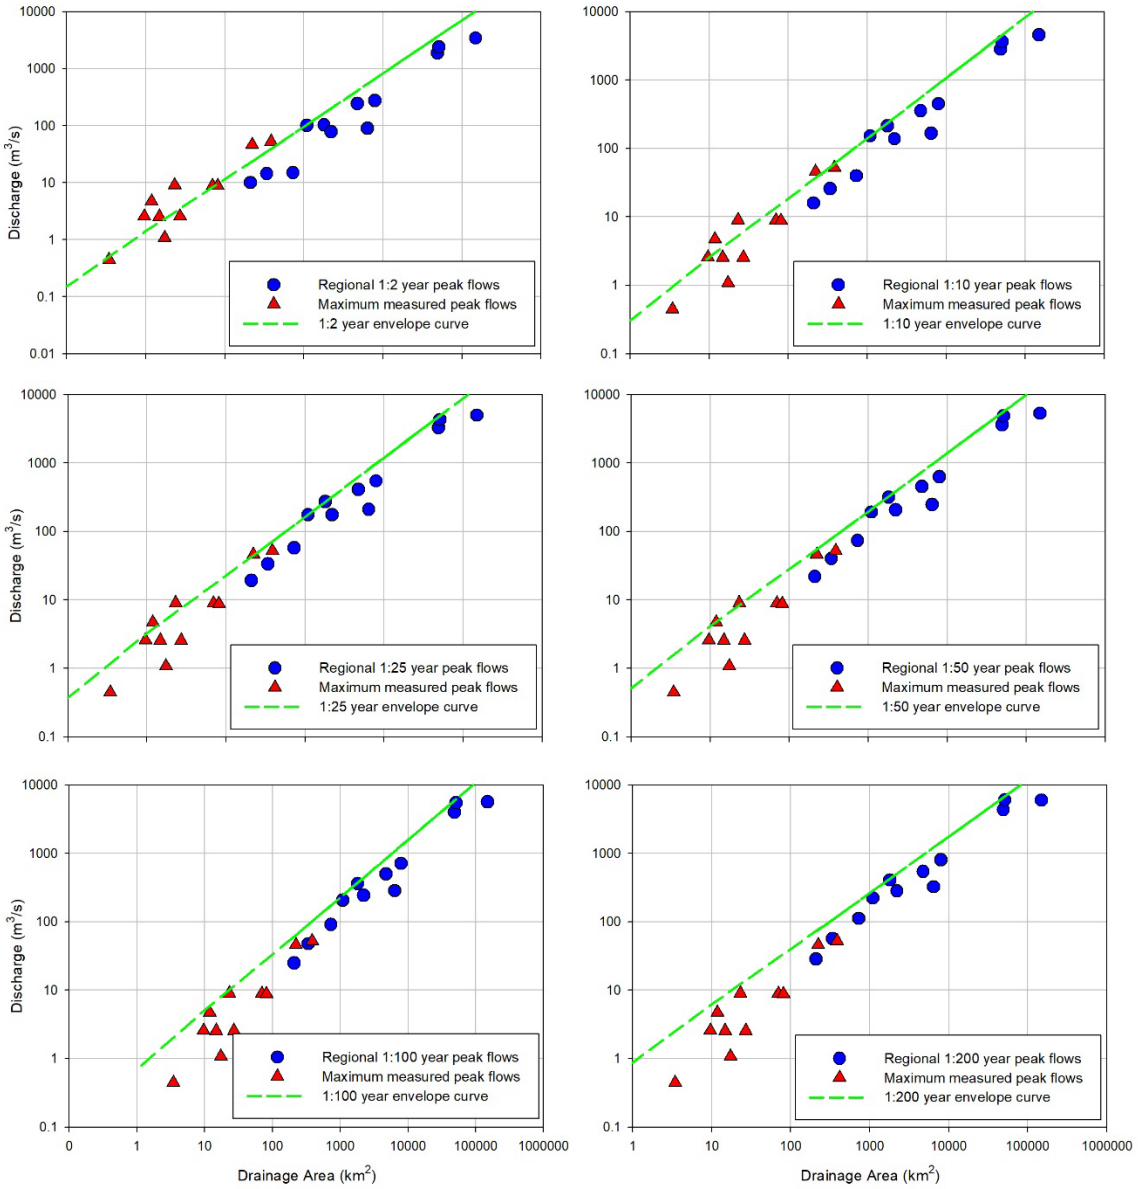

Figure 5-12: Peak flow estimates for regional stations (blue) and maximum recorded instantaneous site discharges (red).

For basins under 1,000 km^2, there is overlap between the regional- and site data for the 1:5 year and 1:10 year envelope curves shown in Figure 5-12, and this is not unexpected given that period of record for Coffee Creek is approximately ten years. By comparison, peak flows returned from the regional analysis are higher in magnitude and therefore more conservative that an estimate returned from site- measurements alone for the most extreme peak flow events (*i.e.*, 1:50 year, 1:100 year and 1:100 year). To validate the reasonableness of the peak flows returned from the envelope curves, regional guidance documents published by state and territorial governments on the estimation of peak streamflows in ungauged basins were consulted (Curran *et al.*, 2003; Janowicz, 1989). Table 5-8 list the

proposed peak flow equations for Project area basins and reports peak flow estimates for a 100 km^2 drainage using envelope curves and the data models proposed by Curran *et al.,* 2003. It is notable that the peak flow estimates for the site drainages are comparable to those developed using the Curran *et al.* method for high frequency peak flow events but are substantially lower for lower frequency events (*i.e.*, > 1:10 year recurrence intervals). This is due to the pronounced west-east precipitation gradient noted in Section 4.4.1.

Table 5-8:
Summary of predictive equations for select peak flow events

Event	Envelope Curve Equation	Peak Flow Comparison (Envelope Curve, Curran *et al.,* 2003)
1:2 year	$y = 150A^{-0.065}$	11, 8
1:5 year	$y = 240A^{-0.096}$	15, 18
1:10 year	$y = 305A^{-0.113}$	18, 28

Notes: The Envelope Curve Equations in the table above are shown graphically in Figure 3-26. In the right most column above, peak flows (in m^3/s) from the Envelope Curve Equations are compared to estimates after Curran *et al.,* 2003. The values reported are for a hypothetical drainage basin with area 100 km^2. The Envelope Curve Equation uses *A* (basin area in km^2) as the predictor variable for the peak flow value and the equation returns a value in units of L/s/km^2. For the Curran *et al.* peak flows the following was assumed: 1) peak flow equations for Region 5 were applied; 2) mean basin elevation (E) was assumed to be 1,067 m asl (3,500 ft); 3) forest cover (F) was set to 75% in the data model; and 4) storage (S) was conservatively set to a value of 1%.

July 15, 2017 Flood Event

A high magnitude rainfall event occurred on July 15th, 2017 at the Project site, resulting in highly localized and short duration peak flows in the YT-24 basin. The rainfall totals were highly variable across the Project site and increased strongly with elevation, with the high elevation tipping bucket recording 45.1 mm of rain in 1.5 hours, which is approximately equal to the 1:5 year 24-hour recurrence interval estimate for 1,300 m (Table 5-9). The effects of this rainfall event were highly localized, and while high flows occurred in Halfway Creek and Latte Creek in response, the YT-24 basin bore the brunt of the event.

This rainfall event resulted in an estimated peak flow of approximately 8.1 m^3/s, which corresponds to a discharge event exceeding a 1:200-year recurrence interval, as calculated from the regional data. This discharge estimate was derived from a survey of the high-water marks to obtain a stage estimate (1.495 m). It is notable that there is a high degree of uncertainty in this estimate, however it indicates that very high-magnitude peak flow events

resulting from high-intensity localized convection cells are possible at the Project site. In any event, given the extent of damage to the YT-24 channel caused by this event, it appears that the peak flow magnitude recurrence interval likely exceeded the corresponding recurrence interval calculated for the rainfall event depth, indicating that the rainfall estimates carried forward for engineering design are conservative.

Table 5-9:
July 15, 2017 rainfall totals and recurrence interval estimates

Station	Camp Tipping Bucket	Climate Station	High Elevation Tipping Bucket
Elevation (m asl)	430	975	1,300
Rainfall Depth (mm)	3.9	18.3	45.1
1:5-year 24 hour (mm)	40	44	56
1:100-year 24 hour (mm)	69	75	98
1:200-year 24 hour (mm)	77	84	106
24-hour PMP (mm)	--	--	283

Post-event photos of the YT-24 channel at the hydrometric station location are provided below (Figure 5-13 through Figure 5-16) to show the extent of the instream changes that resulted from this event.

Figure 5-13: YT24-0.1 looking upstream. Evidence of overbank flow and sediment deposition is apparent, behind the survey benchmarks (tree with orange flagging tape).

Figure 5-14: YT-24 looking upstream

Figure 5-15: Aerial photo of YT-24 showing extensive erosion resulting from July 15th rainfall event.

Figure 5-16: Post-event sediment deposition in upper YT-24 catchment.

5.1.2.3 Low Flows

A robust characterization of the low flow regime is required to inform potential water quality sensitivities, as well as the potential for shortfalls in water required for process makeup or dust control, for example. A low flow analysis is presented below that considered inspection of regional- and site-specific hydrometric data. Consistent with provincial guidance (see BC MOE, 2012), low flow values returned by the Log Pearson (Type III) (LP3) distribution are reported in this section. In some instances, the LP3 distribution did not fit the data, in which case the Weibull distribution was used.

Both annual and summer (June-September) low flow events ($7Q_2$ [median], $7Q_5$, $7Q_{10}$ and $7Q_{20}$) were considered in this assessment, where recurrence interval estimates for summer low flows were derived from the synthetic discharge records. Due to limited site data available for the winter period, and extensive aufeis conditions documented in Project basins, the same approach was not taken for the annual low flow metrics. Instead, all available spot flow measurements for the winter months are presented for the site stations to give indication of expected annual low flow condition.

Summer Low Flow Regime

The low flow recurrence interval estimates for the summer period (June to September) are presented in Table 5-10 (regional) and Table 5-11 (site). The values are presented as unit yields to allow for easy comparison between basins.

The regional stations represent basins that span three orders of magnitude for area (km^2), and therefore, there is substantial variation in the calculated low flow yields. The most representative regional basins are assumed to be those with drainage areas <10,000 km^2. With the exception of 09EA004, which has anomalously high yields for a basin of this size, and to a lesser extent 09DD004, remaining basins (*i.e.*, 09AH003, 09AH004, 09CA006, 09EB003 and 09EB004) return summer $7Q_{10}$ yields that range from 0.7 to 1.2 L/s/km^2 (Table 5-10). For a parallel analysis conducted using the synthetic streamflow data, these data returned estimated summer $7Q_{10}$ values for the Project stations ranging from 0.03 to 0.78 L/s/km^2 (Table 5-11), with average of the summer $7Q_{10}$ values for the eleven Project stations being 0.38 L/s/km^2.

5.1.3 Regional Flow Data

5.1.3.1 Regional Flow Summaries

To obtain the input data required for the regional streamflow analyses (peak and low flows, annual runoff, trend analyses, *etc*.), the daily time-series (in m^3/s) for ten of the hydrometric stations listed in Table 3-7 were run through a customized routine to extract the relevant metrics. As indicated in Section 3.3.5.1 the extracted metrics included the following:

- Average annual (calendar year and water year [October to September]) discharge;
- Annual maximum and minimum daily discharge;
- Annual and June-September minimum 7-day average discharge;
- Average monthly discharge (m^3/s) and runoff (mm);
- Date of freshet initiation (pulse date; after Cayan *et al.*, 2001);
- Date of freshet peak discharge, and;
- Date of centre of hydrograph mass (calendar year; after Stewart *et al*., 2005).

Summaries of the extracted metrics from regional monitoring locations are provided in table format in Appendix E.

5.1.3.2 Yukon River Flow Data

As described in Section 1.4, contact waters associated with the Coffee Gold Project will report passively to Halfway Creek, YT24-0.1 (unnamed tributary) or Latte Creek – a headwater tributary of Coffee Creek. Ultimately, these three receiving creeks (*i.e.,* Halfway, Latte, YT24-0.1) report to the Yukon River, and therefore, an understanding of the Yukon River flow regime is critical.

The Yukon River is gauged at several locations in the Yukon Territory and Alaska. The Water Survey of Canada hydrometric station Yukon River above White River (09CD001) is situated a short distance downstream of the Coffee Gold Project (~15 km). Period of record for this station is 65 years (1956-2021), and the drainage area for the basin at the location of the gauge is 149,000 km^2.

The drainage area of the Yukon River at locations relevant to the Project are essentially identical in magnitude. For example, the estimated drainage of the Yukon River above Coffee Creek is 147,317 km^2 (*i.e*., an area 1.2% less than that area at 09CD001). The Yukon River downstream of Halfway Creek compares within 0.8% of the drainage at 09CD001 and is 147,839 km^2.

Average, minimum, and maximum discharge data (period of record, daily) for the Yukon River above White River are shown in Figure 5-17. These data show that winter flows for the Yukon River are typically 400-500 m^3/s but may reach winter minima on the order of 250 m^3/s upon occasion. Flows for months May through November, can reasonably be expected to range between 1,000 and 3,000 m^3/s at the Project site. Period of record daily flow data are also presented for the Big Creek near the Mouth station in Figure 5-17 – the record upon which the synthetic streamflow series are based. In Appendix E, available stage data are presented for the Yukon River above White River. So too are hydrometric data (stage, flow) for the Stewart River, as they are relevant to barging and ice-road passage proposed for the Project.

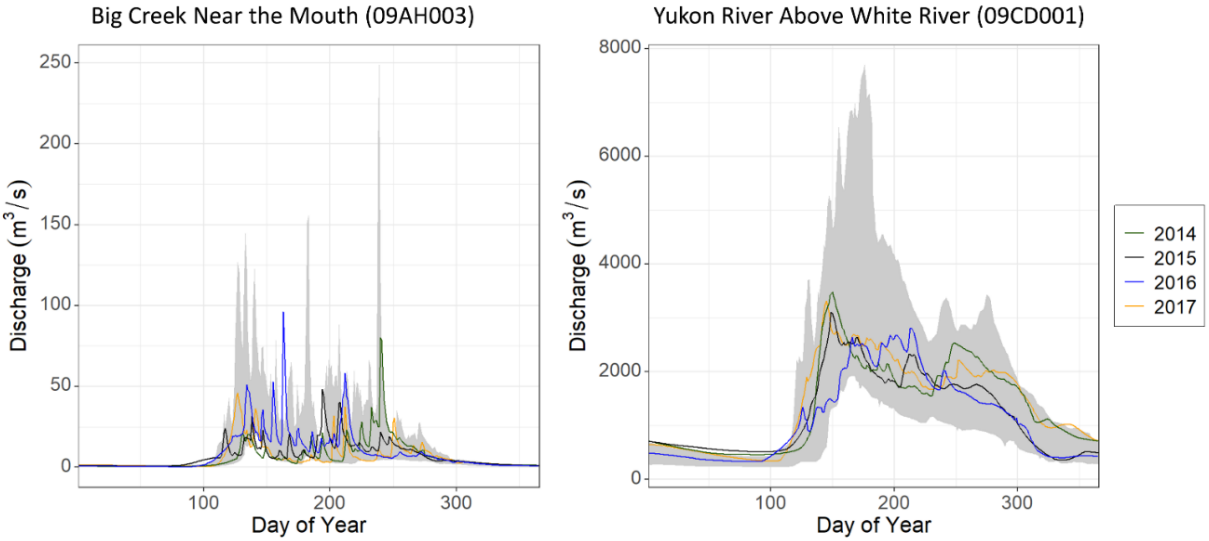

Figure 5-17: Recent years of data (2014 - Green; 2015 - Black; 2016 - Blue; 2017 - Orange) from Water Survey of Canada stations Big Creek Near the Mouth (left) and Yukon River Above White River (right). Historical minimum and maximum discharge data for Big Creek (1975-2013) and Yukon River (1956-2013) are shown in grey.

6. Conclusions

6.1 Site Climate Characterization

The baseline climate record for the Project site covers the period from 2012 to present, and the data for the 2012-2021 period are summarized in this report. A Campbell Scientific climate station has been in continuous operation for this period at an elevation of 975 m and was complemented by tipping bucket rain gauges installed in 2015 at the Coffee Creek exploration camp (430 m) and at the ridge-top laydown (1,300 m). Another research grade climate station was installed at 1,340 m near the proposed HLF in October 2018 to further refine the understanding of site climate conditions. Snow course measurements were carried out at various elevations (*i.e.*, low, mid, and high elevation) and oriented to discern effects of aspect on local snow accumulation. There are currently five snow courses surveyed according to Territory protocols within a 10-day window centred on the 1st of March, April, and May.

To allow robust estimates of site climate metrics (*e.g.*, recurrence interval estimates of annual precipitation) to be made, the daily Dawson A climate station record was adjusted using the site-specific air temperature lapse rates and orographic precipitation gradients to generate a daily record of minimum, mean and maximum daily air temperature and daily precipitation, extending from 1945 to 2018.

6.1.1 Air Temperature

Over the period of record at Coffee Creek (2012-2021), measured average annual temperature is -2.2°C, and monthly average air temperatures range from -16.8°C (December) to +13.9°C (July) at 975 m while the hourly minimum and maximum air temperatures recorded are -38.2°C (measured January 2020) and the maximum temperature is 29.7°C (June 2017). At the Kona station (1,340 m), measured average annual temperature is -2.6°C, and monthly average air temperatures range from -15.4°C (January) to +11.7°C (July), while the hourly minimum and maximum air temperatures recorded are -36.2°C (measured February 2021) and the maximum temperature is 23.7°C (July 2021). During the summer months, the local lapse rate is -3.3°C/1000 m.

At the elevation of the Km 11 climate station, a notable departure from the regional temperature signal occurs during winter months. Valley bottom temperature inversions during winter months and ridgetop temperatures may be 10°C higher than measurements recorded at valley bottom stations with the lapse rate averaging 5.8°C/1000 m from October through April. These inversions result in a reversal of the normal lapse rate (decreasing

temperature with increasing elevation) and are commonly caused by cold Arctic air masses pooling in the valley bottoms from late October to early March.

6.1.2 Precipitation

The period of record mean annual precipitation (MAP) is 331 mm at the 975 m elevation, with 72% of this falling as rain, and 28% realized as snow. Based on the extended synthetic precipitation record, MAP at the proposed undertaking (~1,300 m above sea level) is estimated to be 504 mm, with 67% of this total precipitation realized as rain during the months of May through September, and the remaining 33% occurring as snow from October through March. This estimate of MAP combined site-measurements of rainfall and snow accumulation assessed along with regional precipitation data (*i.e.*, from Federal/State weather stations, snow courses, snow pillows).

It is common in areas with high topographic relief for precipitation amounts (annual, low-frequency/high-magnitude events, *etc*.) to increase with elevation due to orographic effects - primarily cooling of the air mass as it is forced upward by topography and subsequent condensation of the entrained water vapour. Precipitation gradients were ascertained through an inspection of site and regional precipitation data and were established at Coffee Creek as follows: 4%/100 m elevation gain for rainfall; and 7%/100 m elevation gain for snow.

Recurrence interval estimates for rainfall (various durations), annual maximum SWE and snowmelt rates are presented in Section 4.4. The 24-hour duration rainfall events are estimated to be 67 mm for the 1:10-year event and 98 mm for the 1:100-year event. The 1:100-year annual maximum SWE at 1,300 m is estimated to be 272 mm, and maximum daily snowmelt rates are estimated to lie between 30-50 mm/day based on regional snow pillow data. Finally, the Probable Maximum Precipitation for a 24-hour duration at 1,300 m informs the design criteria for the HLF event ponds, and is estimated to be 283 mm, or 56% of the MAP value.

6.1.3 Potential Evaporation

Annual potential evaporation (PE) for the Project area is estimated to be 460-480 mm with monthly rates being highest in May, June, July, and August and considerably lower for autumn, winter, and spring months. Consistent with other studies in the Yukon, the evapotranspiration estimate for the Coffee Gold site is roughly 40% of the assumed PE value or 170 mm per year. At a daily time-step, average evapotranspiration rates are highest in May, June, and July and roughly 3.0 mm/day.

6.2 Hydrometric Monitoring

Gauged watersheds at the Coffee Creek site range in size from ~3 to 500 km^2, with nine of these having drainage areas of less than 25 km^2. In addition to capturing a range of drainage areas, the watersheds gauged for the baseline hydrology study differ in elevation characteristics (*i.e.,* mean catchment elevations range 800 to 1,300 m asl) and represent varying aspects as well. Mean elevation, basin area, a detailed basin map, aspect and hypsometry information are presented per hydrometric station in Appendix C.

Twelve of the surface water monitoring stations at the property are instrumented with metric staff gauges and continuously recording water level recorders set in stilling wells. These stations allow high-resolution (*i.e.*, 15-minute) data records at each site. Streamflow was measured several different ways for this study, including: Wading with a current meter, salt dilution gauging, using an acoustic Doppler current profiler, and slope-area approaches. Rating curves are well constrained, with all but one of the stations (YT24-4.9) based on 10 or more paired stage:discharge measurements, and a site-wide average error of -2%.

In similar fashion to the derivation of the synthetic climate dataset, the site hydrometric data were extended using a piece-wise ranked regression approach, based on the Big Creek (WSC; 09AH003) streamflow record. This allowed daily streamflow time-series to be derived for eleven of the Project site stations, which were then used to generate recurrence interval estimates of mean annual runoff and summer low-flows.

6.2.1 Local Streamflow Measurements

At Coffee Creek, patterns of streamflow are dominated by a snowmelt freshet that typically occurs between late April and early June. Following freshet, patterns of streamflow are punctuated by several rainfall-induced runoff events which occur throughout the summer and autumn. In general, these high flow events are short duration, typically persisting for a 1 or 2-day time period. Flows in local creeks and streams abate in October in response to freezing temperatures and it is notable that local watersheds typically experience zero flow conditions throughout the winter (*i.e.,* November through end March). Aufeis (*i.e.,* frozen groundwater seepage that accumulates within- and adjacent to- local watercourses) is common in creeks and streams at the Project site and melts during the freshet but may persist into the early summer.

Based on measurements at Coffee Creek hydrometric stations, average unit yields across the Project site are 10.6 L/s/km^2 for the open water season (May to October) and range from 4 to 16 L/s/km^2, with specifics of the runoff regime for each monitoring station being dependent on drainage characteristics (*i.e.,* basin area, shape, mean elevation, extent of

permafrost, *etc.*). Unit yields range from 2.0 - 5.1 L/s/km^2 in October and decrease steadily to annual minima in March (*i.e.,* 0 - 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rains. At Coffee Creek, instantaneous peak flows, expressed as unit yields, are typically between 120 and 200 L/s/km^2, but measurements vary widely across the site (from 60 to >300 L/s/km^2).

6.2.2 Mean Annual Runoff

Based on the measured streamflow data and the synthetic streamflow records, MAR varied by roughly a factor of four in Project site basins (from 48 mm to 205 mm) and when regressed against mean basin elevation (m), basin area (km^2) and dominant aspect within the drainage, showed strong correlation with elevation, and indicate that MAR increases an average of 7%/100 m, which is comparable to the average annual orographic precipitation gradient of 6%/100 m. Results of the annual runoff recurrence interval analysis indicate that the spread between the 1:200 dry- and wet-years is substantial in the Project area drainages, and generally, an extreme wet-year are expected to produce ten times more runoff than an extreme dry-year.

6.2.3 Instantaneous Peak Flows

At Coffee Creek, instantaneous peak flows, expressed as unit yields, are typically between 120 and 200 L/s/km^2, but measurements range widely across the site (from 60 to >300 L/s/km^2). Recurrence interval estimates of annual instantaneous peak flows from a suite of regional records were plotted against drainage area, and an enveloping power law function was then fit to the data. The enveloping power law functions derived from the regional data for each recurrence interval (*e.g.*, 1:100-year peak flow) were used to estimate the corresponding peak flow for all Project drainages. The results of this analysis indicate that the 1:100-year instantaneous peak flow is expected to generate unit yield flows of 327 L/s/km^2 for a basin of 100 km^2.

6.2.4 Summer and Annual Low Flows

Following freshet, baseflows in the lower reaches of the Project site creeks are enhanced by active layer melt and soil moisture recharge. At the upper elevation stations (*e.g.*, LC-15.5) and those situated in alluvial deposits (*e.g.*, LCT20-0.1) effective yields can drop to near zero flow conditions. Summer (June-September) low flow estimates were derived based on a combination of regional and synthetic site records. Based on the regional stations assumed most representative of Project site conditions, the analysis returned summer 7Q$_{10}$ yields that range from 0.7 to 1.11 L/s/km^2. A parallel analysis conducted using the synthetic streamflow data returned estimated summer 7Q$_{10}$ values for the Project

stations ranging from 0.04 to 0.78 L/s/km^2 (Table 5-11). The summer 7Q_{10} low flow value based on an average of the eleven Project station synthetic records is 0.34 L/s/km^2.

Site data show that yields range from 2.0 – 5.1 L/s/km^2 in October and decrease steadily to their annual minima by March (0 – 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rainfall. Based on the site data alone, winter low flows are expected to range from 0 to 0.7 L/s/km^2

An important component of the winter flow regime at the Project site is the extensive icing of the local channels. This ice growth, or aufeis, is the result of shallow groundwater discharge and/or baseflow in the stream channel freezing. This ice impedes subsequent flow, which is forced on top of the existing ice sheet, where it freezes. This process repeats continuously throughout the winter, and results in laminated ice sheets that can approach 2 m in thickness and 50+ m in width in the Project channels.

TECHNICAL MEMORANDUM

To:	**Allison Rippon Armstrong, Kaminak Gold Corp**	**Date: March 1, 2016**
From:	**Scott Jackson and Colin Fraser**	**Project #: A362-3**
Subject:	**Regional Hydro-meteorological Trend Analysis – Coffee Creek**	

1. Introduction

1.1 Memo Objectives and Layout

This memo presents the results of a trend analysis exercise carried out to characterize current rates of change for hydro-meteorological parameters relevant to the Coffee Gold Project (hereafter, 'the Project').

Many operational and regulatory decisions related to water quantity, and secondarily water quality (*e.g.*, loading calculations) are based on limited site-specific streamflow and climate data. Such decisions then often necessitate the review of, and integration, of long-term regional hydrometric and climate data analogues showing longer record periods. This approach is commonly adopted for a regional frequency analysis that targets pertinent hydro-meteorology variables (*e.g.*, mean annual precipitation and runoff, 7-day low flow, peak flows).

Two important questions related to usage of regional data are: 1) the regional hydro-meteorological record(s) are transferable to the site being studied; and 2) are the regional (and site specific) data of sufficient length to adequately represent long-term variability. The latter assumption often implies that the streamflow records being utilized are statistically stationary. In other words, a metric calculated from the historic record will retain the same value when re-calculated from future data.

As the understanding of anthropogenic and climatic influences on hydro-meteorological variables improves, it is apparent that this latter assumption is often not valid. An assessment of the potential influences of long-term change in climate/streamflow metrics was undertaken to ensure that estimates of future streamflow conditions are as robust as possible. The goal of this analysis is to present the current trends for several ($n = 45$) streamflow and climate variables of interest, where the objectives are two-fold:

1. Calculate trends in various streamflow and climate variables for the region in which the Project is situated, and;
2. Determine whether the calculated trends are statistically significant at $p < 0.05$;

2. Methods

2.1 Sources of Data

2.1.1 Climate Data

The Coffee Creek property is situated ~80 km from the Alaska border. Two main sources of climate data were used to assemble this memo:

1) Environment Canada daily climate station data (within 200 km radius of proposed heap leach facility) from the Adjusted and Homogenized Canadian Climate Dataset.
2) Daily average streamflow data from hydrometric stations located within the same radius of the Project. Data were sourced from the Water Survey of Canada and the United States Geological Survey hydrometric networks.

Further details on the datasets, information used in the frequency analyses and assumptions are provided in Lorax (2016).

State of Alaska and Yukon Territory climate stations situated near the Coffee Creek property are listed in Table 2-1 of the EIA Baseline Hydro-meteorology report (Lorax, 2016). Of these 20 stations (*i.e.*, Coffee Creek location excluded), three were selected for the climate trend analysis. The Pelly Ranch and Dawson A stations are located close to the property and possess long-term, high quality records. For comparative purposes, the Dawson A record was truncated to 1955 and 1952, for temperature and precipitation, respectively, to match the available record from the Pelly Ranch station.

Also selected was the McQuesten station record which is shorter, beginning in 1982, and therefore, a corrected AHCCD dataset was not available. However, as this station's record forms the basis of the reconstructed climate data set used as the primary input to the site-wide water balance model, it was necessary to determine the extent of non-stationarity present in the temperature and precipitation data.

2.1.2 Streamflow Data

Streamflow records of average daily discharge were downloaded from HYDAT (WSC, 2015), for the twelve stations listed in Table 2-4 in Lorax (2016). The criteria used in the station selection were as follows:

- Station active as of 2010;
- Record period of >10 consecutive years;
- Basin is non-regulated (*i.e.*, no major diversions or impoundments).

Missing data or incomplete records were accounted for using the following methods:

- Discharge time-series were truncated to ensure annual time-series was continuous (*i.e.*, a minimum of 5 years of data was present before and after a missing year, gaps greater than one year were disallowed);
- Where a month had > 5 days of missing data, this month was removed from the time-series, and;
- No missing data were estimated or infilled.

The following streamflow timing metrics were calculated in addition to the various discharge metrics:

- PULSE_DATE – The date of freshet initiation calculated as the day when the cumulative departure from that years mean annual discharge is most negative (Cayan *et al.*, 2001). The cut-off date is set as August 31, to ensure that autumn rain events in mixed rainfall/snowmelt driven regimes are not inadvertently counted as the freshet date.
- DATE_CM – Date of centre of hydrograph mass (calendar year), calculated following Stewart *et al.* (2005).

In the context of mine effluent management, regulatory criteria are often based on concentrations in the effluent and the receiving environment. Concentration is a mass of a given contaminant in a given volume of water, and thus any reduction in the volume of water without a concurrent reduction in loadings will result in higher concentrations. This means that periods of sustained low flows in the receiving environment are often the constraining factor in an effluent discharge regime.

Low flows are most commonly assessed for two time periods: annual (usually representative of winter flows in nival and glacial regimes); and summer (*e.g.,* June-September). Low flow indices are commonly based on a rolling 7-day average of discharge (7Q) or, less commonly, a rolling 30-day average (30Q) (Smakhtin, 2001). The minimum 7- or 30-day averages are then tabulated on an annual basis, and recurrence interval analyses conducted (*e.g.*, $7Q_{10}$). In this assessment, time series for low flow indices were examined, to determine whether water balance estimates may need to consider potential shifts in these metrics over time. In some cases, where winter flow data was limited or non-existent (*e.g.*, Wade Creek Tributary near Chicken, AK), the winter metrics were not calculated.

While every attempt has been made to ensure that the identified trends are reflective of long-term changes in streamflow, trends may be influenced by several complicating factors, including, but not limited to:

- Land cover change (*e.g.*, urbanization, forestry, linear development, *etc.*);

- Large scale climate cycles (*e.g.*, Pacific Decadal Oscillation [PDO], El Niño Southern Oscillation [ENSO]; Cayan and Peterson, 1989; Stewart *et al*., 2005), and;
- Changes in measurement techniques, QA/QC practices, rating curves, *etc.*

These impact of these factors must be carefully contemplated when results are assessed and conclusions drawn.

2.2 Trend Analysis Methodology

Annual time-series of these parameters were analysed for trend using the *zyp* package in R (Bronaugh and Werner, 2013). The full details of the calculations performed by this package are provided in the reference above, but in brief, initial trend slopes were estimated using the Theil-Sen approach. To address serial correlation effects on statistical hypothesis tests for trend, if a trend was noted, the time-series was detrended using the slope (Yue *et al*., 2002). The trend and residuals are then blended, and the Mann-Kendall's test for trend significance (p-value) is then applied. The *zyp* package re-inflates the values that trend significance are calculated by dividing by (1-AR(1)). All trends are presented as annual values (*i.e.*, rate of change per year in the variable of interest).

Discharge trends (calculated in m^3/s) were converted to unit runoff (in $L/s/km^2$) prior to plotting to account for the influence of basin area on relative trend magnitude. Table 1 lists the complete suite of variables considered in this assessment.

3. Results

3.1 Temperature

The results of the temperature trend analysis are presented in Table 2.

All trends are positive (*i.e*., warming over time), and significant at $p < 0.05$. For the Dawson A and Pelly Ranch climate stations (1955-2013; 59 years), the largest positive trends are noted in the winter season (December through February), and are on the order of 1°C/decade. The smallest positive trends occur in the summer and autumn seasons (0.3°C/decade), and for autumn, only the trend in minimum temperatures is significant at all stations. The results for the Dawson A and Pelly Ranch stations are presented in Figure 1.

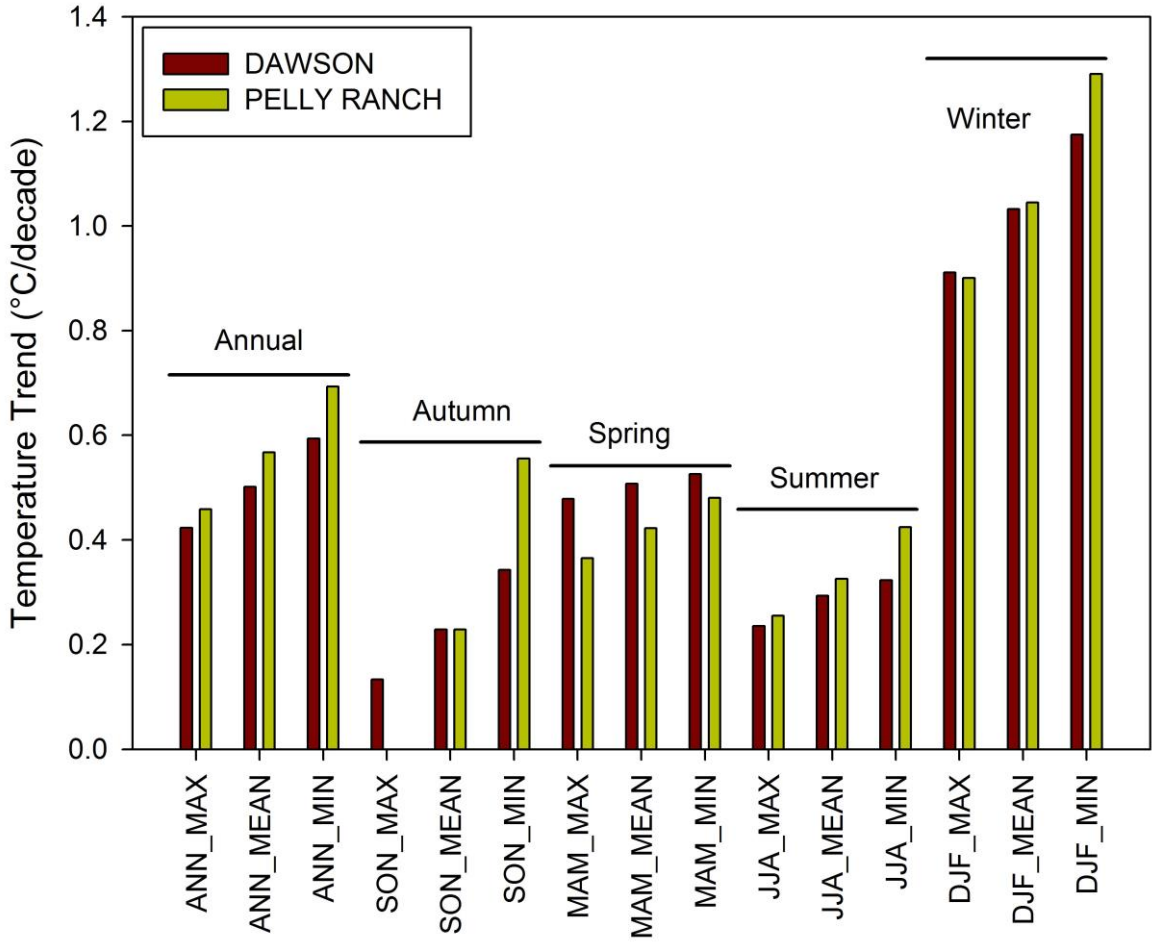

Figure 1: Temperature trends by season for the Dawson A and Pelly Ranch climate stations.

3.2 Precipitation

The results of the temperature trend analysis are presented in Table 3. The trends in seasonal and annual precipitation totals are mixed, although in general, precipitation is increasing across the Project area. For the Dawson A and Pelly Ranch climate stations (1952-2013; 62 years), the largest seasonal trends are noted in the autumn season (September through November), and are on the order of +4-6 mm/decade. The signal is mixed for summer precipitation, with the Dawson A station recording a negative trend of -6 mm/decade, and the Pelly Ranch summer totals increasing by +5 mm/decade. The annual precipitation trends for the Dawson A and Pelly Ranch stations are presented in Figure 2. Only one of the seasonal trends was significant at $p < 0.05$ (autumn total precipitation at Dawson A), while three more trends were significant at $p < 0.10$ (summer total precipitation at Dawson A, and annual and autumn total precipitation at Pelly Ranch).

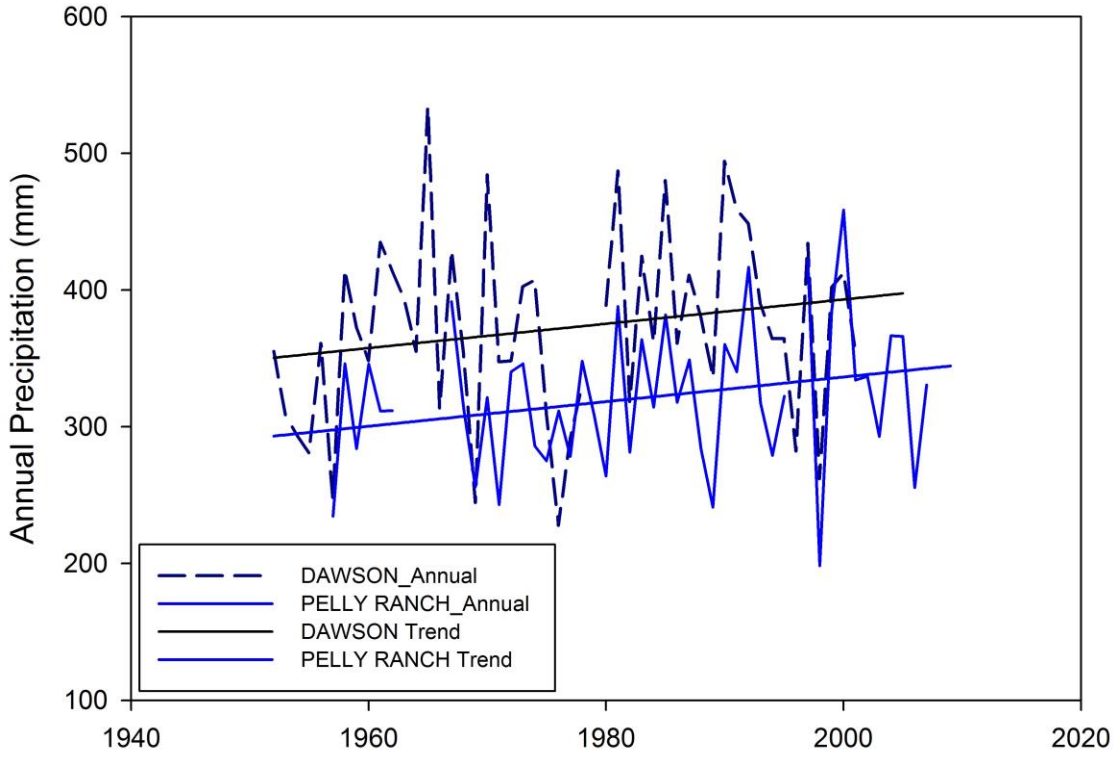

Figure 2: Annual total precipitation trends for the Dawson A and Pelly Ranch climate stations.

3.3 McQuesten Climate Record

The data from the McQuesten climate station was used as the basis for the reconstructed site climate data time-series described in the Hydro-meteorological Baseline Report. The results for the McQuesten climate record are presented in Table 4.

It is notable that this record does not show any evidence of significant trends ($p < 0.10$) for the parameters analysed, which is not consistent with the longer records from the Dawson A and Pelly Ranch stations. The reason for this is not clear, but it is possible that it is an artefact of the shorter record available for this station (28 years).

3.4 Streamflow

The results of the streamflow trend analysis are presented in Table 5. The regional basins analysed have basin areas that span five orders of magnitude (11 – 149,000 km^2). In general, streamflow is increasing across the region, regardless of the metric analysed, which is consistent with the precipitation trends presented here. Low-flows in particular are increasing, and the slope of the trends in summer low-flows are approximately four times higher than those for winter baseflows. An example of the winter baseflow trends is presented in Figure 3.

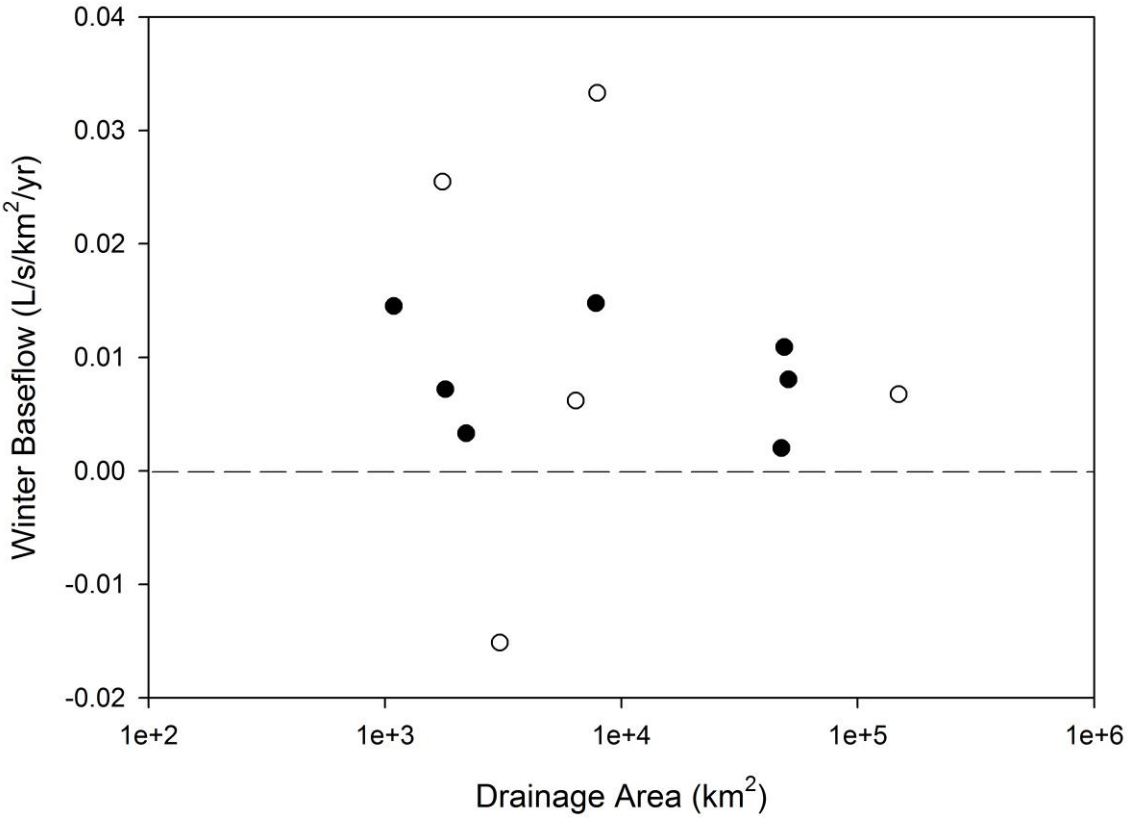

Figure 3: Winter baseflow trends for the regional hydrometric stations. Trends that are significant at p < 0.05 are denoted by black markers, and those stations that do not show a significant trend are shown with open circles.

In addition to the broad ranging increases in winter and early spring streamflows, the only other metric that showed a significant trend (at $p < 0.05$) was the date of freshet initiation (PULSE DATE). Freshet is occurring earlier at several stations (negative trend), which is consistent with similar studies conducted in snowmelt and mixed snow/rain dominated streamflow regimes in North America (Cayan *et al*., 2001, Stewart *et al*., 2005), and likely a result of warming spring temperatures.

It is possible that the increase in winter baseflows is a result of both increased autumn precipitation and warmer winter temperatures, although the fact that winter temperatures are still often well below freezing would add support to the former mechanism. However, the most likely cause is the increased rate of permafrost melt that has been observed throughout the discontinuous permafrost zone (*e.g.,* Walvoord and Striegl, 2007; Janowicz, 2008; and Brabets and Walvoord, 2009).

4. Summary

A suite of hydro-meteorological parameters were analysed for trends using standard statistical tests. Statistical significance of the trends was identified where present.

Overall, temperatures are warming across the Project area, and with the greatest warming occurring during the winter months. Precipitation is increasing on an annual basis, and most strongly in the autumn, but the signal is somewhat mixed for the other seasons, and summer in particular. The climate record used as the basis for the reconstructed site climate data time-series (McQuesten) does not show any evidence of significant trends for the parameters analysed, but it is not clear whether this is an artefact of the shorter record.

Annual streamflow minima are increasing at almost every hydrometric station included in this analysis, and several stations show evidence of an earlier start to the freshet over time. These results are consistent with those presented in Appendix D.1 of the Hydro-meteorological Baseline Report (Lorax, 2016), and with similar analyses conducted in the region.

Table 1:
Hydro-meteorological metrics analysed for trends

Variable[1]	Description
Streamflow (m^3/s)	
MIN_Q	Minimum annual average daily discharge
MAX_Q	Maximum annual average daily discharge
AVG_Q	Average annual average daily discharge (calendar year)
MED_Q	Median annual average daily discharge (calendar year)
AVG_WAT_YR	Average water year discharge (Oct. 1 - Sept. 30)
MED_WAT_YR	Median water year discharge (Oct. 1 - Sept. 30
MAX_Q_DATE	Date of maximum annual average daily discharge
PULSE_DATE	Date of freshet pulse initiation
DATE_CM	Date of hydrograph centre of mass - calendar year
ANN_7Q_MIN	Annual minimum 7-day average low flow
ANN_30Q_MIN	Annual minimum 30-day average low flow
BASEFLOW	Average winter flow (Dec. 1 – Mar. 31)
JUN-SEP_7Q_MIN	Annual June-September minimum 7-day average low flow
JUN-SEP_30Q_MIN	Annual June-September minimum 30-day average low flow
All months (n = 12)	Median daily discharge
Temperature (°C)	
ANN_MAX	Annual maximum daily temperature
ANN_MEAN	Annual mean daily temperature
ANN_MIN	Annual minimum daily temperature
DJF_MAX	Winter (Dec.-Jan.) maximum daily temperature
DJF_MEAN	Winter (Dec.-Jan.) mean daily temperature
DJF_MIN	Winter (Dec.-Jan.) minimum daily temperature
MAM_MAX	Spring (Mar.-May) maximum daily temperature
MAM_MEAN	Spring (Mar.-May) mean daily temperature
MAM_MIN	Spring (Mar.-May) minimum daily temperature
JJA_MAX	Summer (Jun.-Jul.) maximum daily temperature
JJA_MEAN	Summer (Jun.-Jul.) mean daily temperature
JJA_MIN	Summer (Jun.-Jul.) minimum daily temperature
SON_MAX	Autumn (Sept.-Nov.) maximum daily temperature
SON_MEAN	Autumn (Sept.-Nov.) mean daily temperature
SON_MIN	Autumn (Sept.-Nov.) minimum daily temperature
Precipitation (mm)	
ANN_TOT	Annual total precipitation
DJF_TOT	Winter (Dec.-Jan.) total precipitation
MAM_TOT	Spring (Mar.-May) total precipitation
JJA_TOT	Summer (Jun.-Jul.) total precipitation
SON_TOT	Autumn (Sept.-Nov.) total precipitation

FIGURE 6-3: ESTIMATED LENGTH OF THE GROWING SEASON FOR THE COFFEE CREEK REGION FOR BOTH THE PAST (1961-1990) AND THREE FUTURE DECADES. THE GROWING SEASON LENGTH IS DEFINED AS THE NUMBER OF DAYS WHERE THE AVERAGE TEMPERATURE EXCEEDS 0°C, AND IS EQUAL TO THE NUMBER OF DAYS BETWEEN THE DAY OF THAW AND THE DAY OF FREEZE, SHOWN RESPECTIVELY IN FIGURES 6-1 AND 6-2. 6-4

1. Introduction

Kaminak Gold Corporation (Kaminak) is in the process of developing and permitting the Coffee Gold Project (Project), a proposed heap leach operation located in west-central Yukon, approximately 180 km south of Dawson City. The Project is located within the traditional territory of the Tr´ondëk Hwëch´in and the asserted traditional territory of the White River First Nation. A portion of Kaminak's claim block is located in Selkirk First Nation's traditional territory. Currently the Project is undergoing a detailed Feasibility Study with project engineering and design progressing with full consideration of environmental conditions within the project area.

Climate, meteorological conditions and attendant hydrological systems at the Coffee Gold Project influence engineering design parameters, in particular the heap leach design, heap leach water balance, site wide water balance and ultimately comprehensive site wide water management systems. Existing climate conditions at the Coffee Gold Project are unlikely to remain static and consideration of potential climate change scenarios are being incorporated into project planning. Kaminak commissioned Lorax Environmental Services Ltd. (Lorax) to conduct a climate change analysis for the Coffee Gold Project. The analysis, the subject of the following report, was prepared by Dr. Thomas Pedersen, Director, Lorax and current Director, Pacific Institute for Climate Solutions, University of Victoria; Dr. Pedersen also serves as Chair, Canadian Climate Forum.

Within a few to several decades global warming is projected to have a profound impact at high latitudes in both hemispheres. Impacts are already being widely felt: in the polar and sub-polar regions of northern Canada, average annual temperatures are rising—dramatically in some areas; regional snow cover is declining; glaciers are retreating; permafrost is thawing, particularly at lower elevations; and the areal coverage and frequency of wildfires are both on the rise. Such phenomena are summarized in the 2014 Yukon State of the Environment Report (http://www.env.gov.yk.ca/publications-maps/documents/SOE_2014_Web.pdf).

Climate-model projections suggest that the character of seasonal climate will also change significantly over the course of this century: winters on the whole will be warmer and wetter in the North while summers will be hotter and drier. Weather extremes, including heat waves and intense rainfall events are projected to become more frequent. There will also be, and already are, associated biological and ecological changes. Biomes are moving north, while optimal habitats for some plant and animal species are moving upward to higher-elevation (thus, cooler) areas. Each of these physical and biological impacts will

have effects across the Coffee Creek region that need to be considered in planning over the longer term.

As discussed in the following sections, if human society continues to follow the greenhouse-gas emissions pathway that is currently in place, within several decades the climate of the North, including the south-central Yukon, will be notably different. By the year 2100, average temperatures at the Coffee Creek Project site can reasonably be expected to be 3°C to 5°C warmer relative to the waning decades of the last century. Average annual precipitation at Coffee Creek may not change so notably. However, summer and winter can be expected to be slightly wetter in the future, with spring and fall seasons projected to see little net change in precipitation abundance.

Overall, warming is anticipated to be particularly pronounced in the summer at Coffee Creek and this will lead to a later freeze-up in fall and an earlier thaw in spring, according to the model results. In tandem, this yields a growing season that is as much as one month longer by the end of the century and implies a significantly lengthened duration for above-zero temperatures and consequent negative implications for permafrost integrity in the region.

2. Background to Climate Change Projections

Global climate models (GCMs) use a physical representation of the ocean-land-atmosphere system under various climate-forcing scenarios to project future mean climatic states. Over the last two decades, the international modeling community has established two sets of potential emissions pathways, the first published in 2000 by the Intergovernmental Panel on Climate Change (IPCC), as a Special Report on Emissions Scenarios (SRES). Four 'scenario families' (A1, A2, B1, B2) were outlined in that report that spanned possible 21st Century (and beyond) emissions pathways resulting from different global population and economic growth trajectories, varying emphases on energy sources (renewables versus fossil fuels) and materials energy intensities, and variable emphasis on local to global solutions (IPCC SRES, 2000). The A2 scenarios encompassed continuously increasing population and regional economic development in a world of independent, self-reliant nations. These defined the most rapid increases in emissions trajectories over the next 100 years.

A more recent set of scenarios, 'Representative Concentration Pathways' (RCPs) was produced for the Fifth Assessment Report of the IPCC released in 2014. RCPs describe four potential emissions trajectories (RCP2.6, RCP4.5, RCP6.0 and RCP8.5, Figure 2-1) that, like SRES pathways, could be possible depending on future international climate mitigation policies and primary socioeconomic influences including economic and population growth, fossil-fuel-derived energy intensity per unit of GDP, and technological advances.

The number associated with each RCP refers to an assumed change in radiative forcing by the year 2100 in Watts/m^2, relative to pre-industrial time. RCP 8.5 (*i.e.,* 8.5 W/m^2 of additional forcing by 2100) represents the "worst-case" scenario, and includes all greenhouse gas contributions, not just that from carbon dioxide. Two key points emerge when all four RCP scenarios are considered. First, regardless of which pathway is chosen, there is little difference in impact on global average surface temperature prior to mid-century, but after that point, the divergence is progressive and striking. By the year 2100, for example, should we follow the RCP 8.5 scenario, global average surface temperature increases relative to pre-industrial time will be on the order of 4-5°C (Figure 2-2). This outcome is very similar to that projected by the SRES A2 scenario. In contrast, temperature change can be held to <2°C by 2100 (Figure 2-2) if global society instead follows the RCP 2.6 pathway (the green curve in Figure 2-1, and the royal blue curve in Figure 2-2). Second, current emissions rates define a trajectory that is actually slightly *worse* than the RCP 8.5

pathway (note the labelled star in Figure 2-1). Given that, and considering the need to be conservative in forecasting potential future climatic changes, we adopt the worst-case scenario here. The SRES A2 pathway is very similar to the more recent RCP 8.5 trajectory, and is used in the future-climate projections that follow.

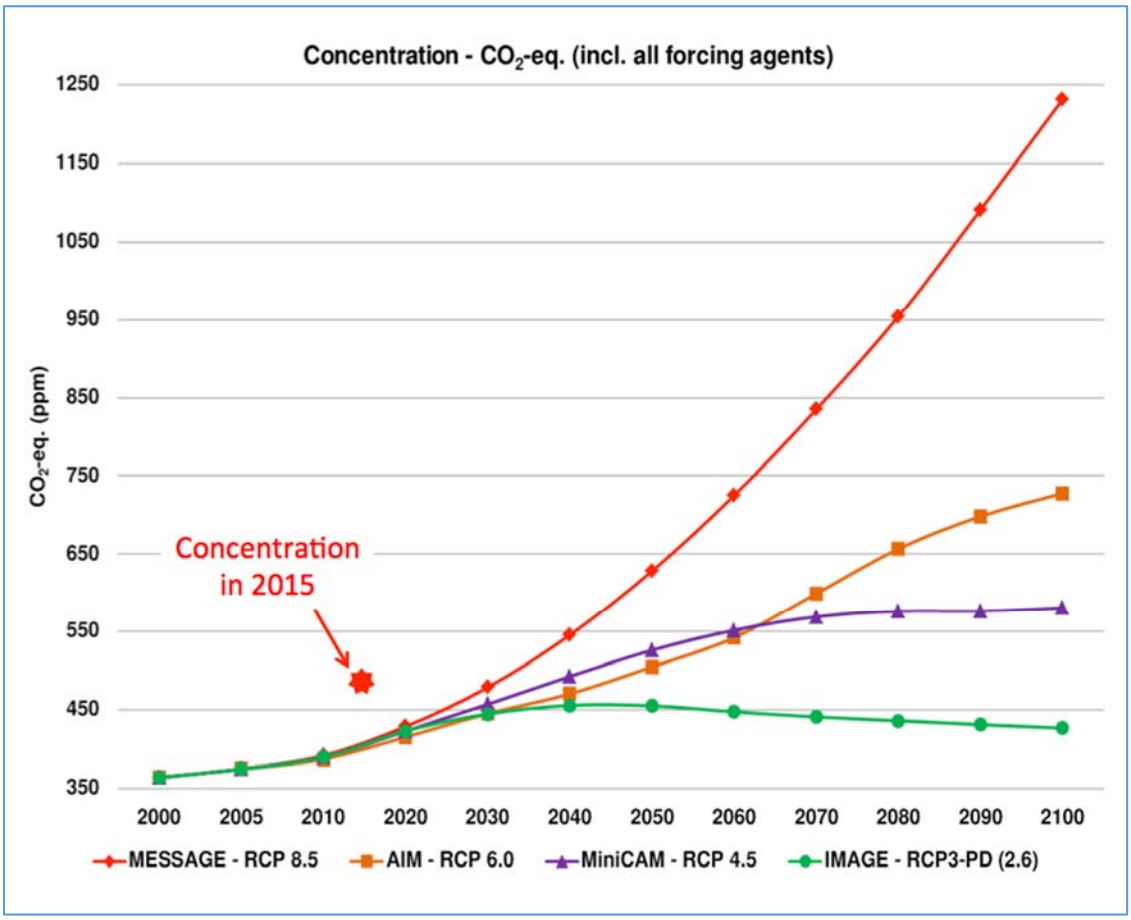

Figure 2-1: **Adapted from Moss et al. (2008), and https://en.wikipedia.org/wiki/Representative_Concentration_Pathways#/media/File:All_forcing_agents_CO2_equivalent_concentration.png. The red star illustrates the approximate concentration of all greenhouse gases at present, scaled as CO2-equivalent, equal to about 480 ppm of carbon dioxide in the atmosphere. The four IPCC Representative Concentration Pathways are shown to the year 2100 by the four coloured lines, each of which was calculated based on sets of socioeconomic and population growth assumptions**

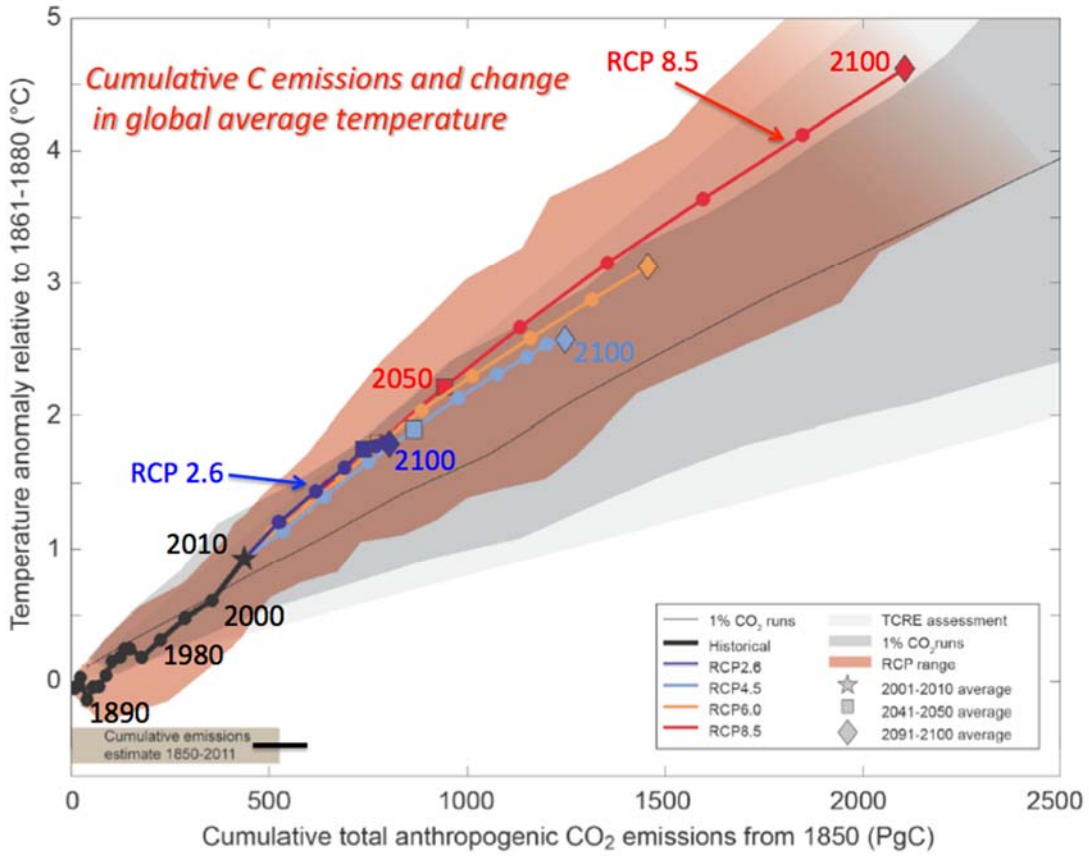

Figure 2-2: Projected global average temperature changes to the end of the Twenty-first Century relative to the late 19th Century, as a function of CO_2 emissions and time. Change in global temperature from 1870 to 2010 as a function of estimate emissions is shown by the black line. Dots for each pathway mark decade endpoints. If humanity follows the RCP 8.5 pathway, average global temperature at the end of this century will be ~4.5 ± 1.5 °C higher than in the 1861-1880 period. The figure has been modified from Figure 10 of: www.ipcc.ch/pdf/presentations/ar5/wg1/pc270913_appr_spm_stocker.pdf.

3. Methods and Data Sources

The two principal climate variables, temperature and precipitation, are discussed here for the region approximately bounded by longitudes 138.6 and 139.8°W and 62.7 and 63.0°N. The Coffee Creek heap leach site sits near the centre of this ~2300 km^2 quadrant. Projected dates of spring thaw and fall freeze are also included in the following discussion.

Modeled historical climate averages and future projections were obtained from the Scenarios Network for Alaska and Arctic Planning (SNAP) at the University of Alaska, Fairbanks, which produces climate information for Alaska and the Yukon region. All parameters specified for the projections that follow (Figure 4-1 through Figure 6-3). The following periods have been selected from the SNAP data to represent key phases of the proposed Coffee Gold Project:

- Historical (1961-1990)
- End of operations/closure (2030-2039)
- Post-closure (2060-2069)
- End of projections (2090-2099)

SNAP uses a statistical downscaling approach to apply baseline climate states projected by general circulation models (GCMs) onto high-resolution topography. The approach used– –"the delta method", descriptions of which can be found at https://www.snap.uaf.edu/methods/downscaling and http://www.ccafs-climate.org/statistical_downscaling_delta/ - draws on a suite of five top-ranked climate models of both past and future climate. Outputs discussed here are based on downscaled five-model averages.

Data sources, described at https://www.snap.uaf.edu/methods/data, yield a 2 km spatial resolution for the Yukon region that relies on PRISM (Parameter-Elevation Relationships on Independent Slopes Model) data and technology developed originally by Daly *et al.* (2008) at Oregon State University. PRISM technology is considered by regional climate modelers internationally to be state of the art. As noted above, the projections below are based on the IPCC SRES (2000) A2 scenario, which can be considered to be the 'worst case' future emissions trajectory. It must be emphasized, however, that global emissions today and over the previous decade *exceed* the pathway assigned by the constructed A2 scenario. "Worst case" may, therefore, prove to be an understatement.

4. Temperature Projections

Average annual temperatures are projected to rise significantly in the Coffee Creek region over the course of this century. The current annual average, about -3°C at the Coffee Gold Project site (Lorax, 2015), is forecast to rise by 3 to 5 degrees C by the end of the century, to on the order of +1 ± 1°C (Figure 4-1).

Average seasonal temperatures are projected to increase by a similar amount in spring, fall and winter, but will likely rise more dramatically in summer (compare Figure 4-2, Figure 4-4 and Figure 4-5 with Figure 4-3). Lorax (2015) estimated that June-July-August temperature for the project site at present is +11.3°C. By the end of the century, that 'summer average' temperature is projected to be between 14.9 and 16.5°C using the A2 scenario (Figure 4-3), an increase of some 3 to 5°C relative to average conditions today. Note that this projection is scenario dependent and therefore uncertain. Should greenhouse gas emissions increase at a rate less than that proscribed by SRES A2, end-of-century temperature increases in all seasons across the North would likely be lower. However, current global practices, as described above, do not support grounds for optimism: it is certain to warm at Coffee Creek over the course of this century, with a high probability that the increase will be several degrees across all seasons, with summer showing the largest change.

There is one caveat that applies at the seasonal level: episodic temperature inversions are common in Yukon valleys in winter, particularly January, as noted by Lorax (2015). Anecdotally, these can lower temperatures by as much as 15°C on a valley floor relative to nearby elevations upslope (personal communications, S. Mooney, Yukon Research Centre, Whitehorse, and Prof. David Atkinson, University of Victoria). PRISM-based reconstructions take into account such abrupt climatic shifts with elevation across Alaska and the Yukon by assigning two layers to the atmosphere: the boundary layer and the free atmosphere above it (Simpson *et al.*, 2005). Inversions are determined in the PRISM database by comparing surface station data with the Global Gridded Upper Air Statistics data set, as noted by Simpson *et al* (2005), and are taken into account in the SNAP projections (personal communication, Dr. Faron Anslow, Pacific Climate Impacts Consortium, University of Victoria). Thus, winter average temperatures along the Yukon River projected by SNAP for the Coffee Creek region incorporate the statistical likelihood that inversions will continue to occur episodically.

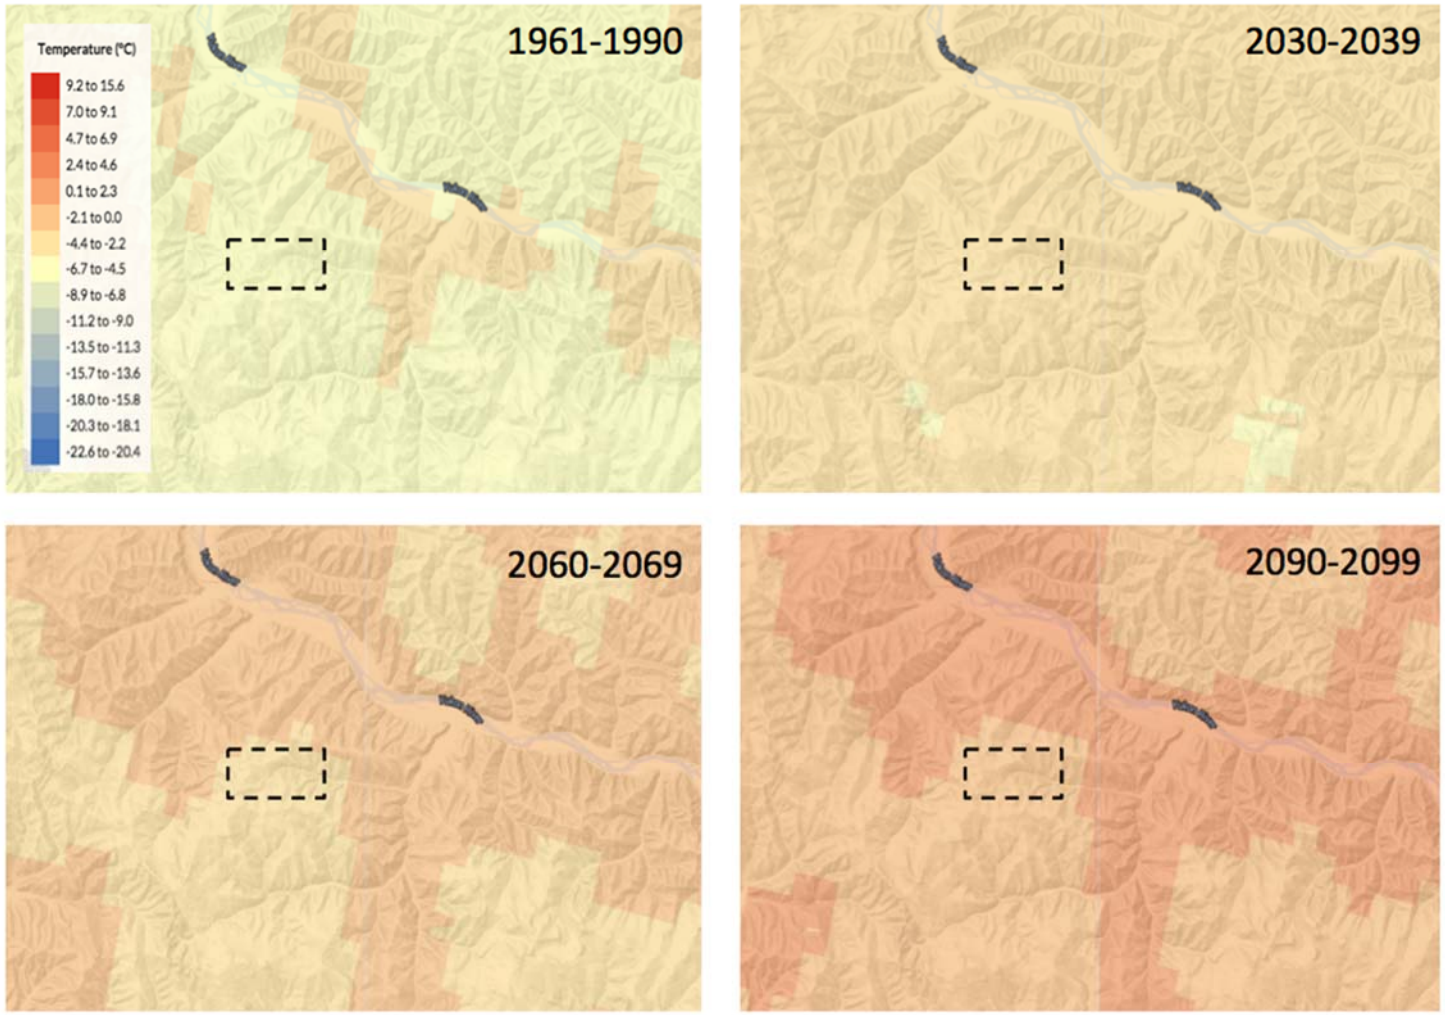

Figure 4-1: Temperature averages modeled using SNAP (see text) across the Coffee Creek region for both the past (1961-1990) and three future decades (2030-2039 – End of operations/Closure; 2060-2069 – Post-closure; and 2090-2099 – End of projections). The dashed rectangle marks the project site. The Yukon River (labelled) runs across the northeast corner of each panel. The 1961-1990 average is scaled using PRISM technology (see text) from data collected at multiple Yukon weather stations, and the constructions for three future decades are based on the SRES A2 scenario (see text). Spatial resolution of the model output is 2 km, as illustrated by the square grid cells (2 km per side).

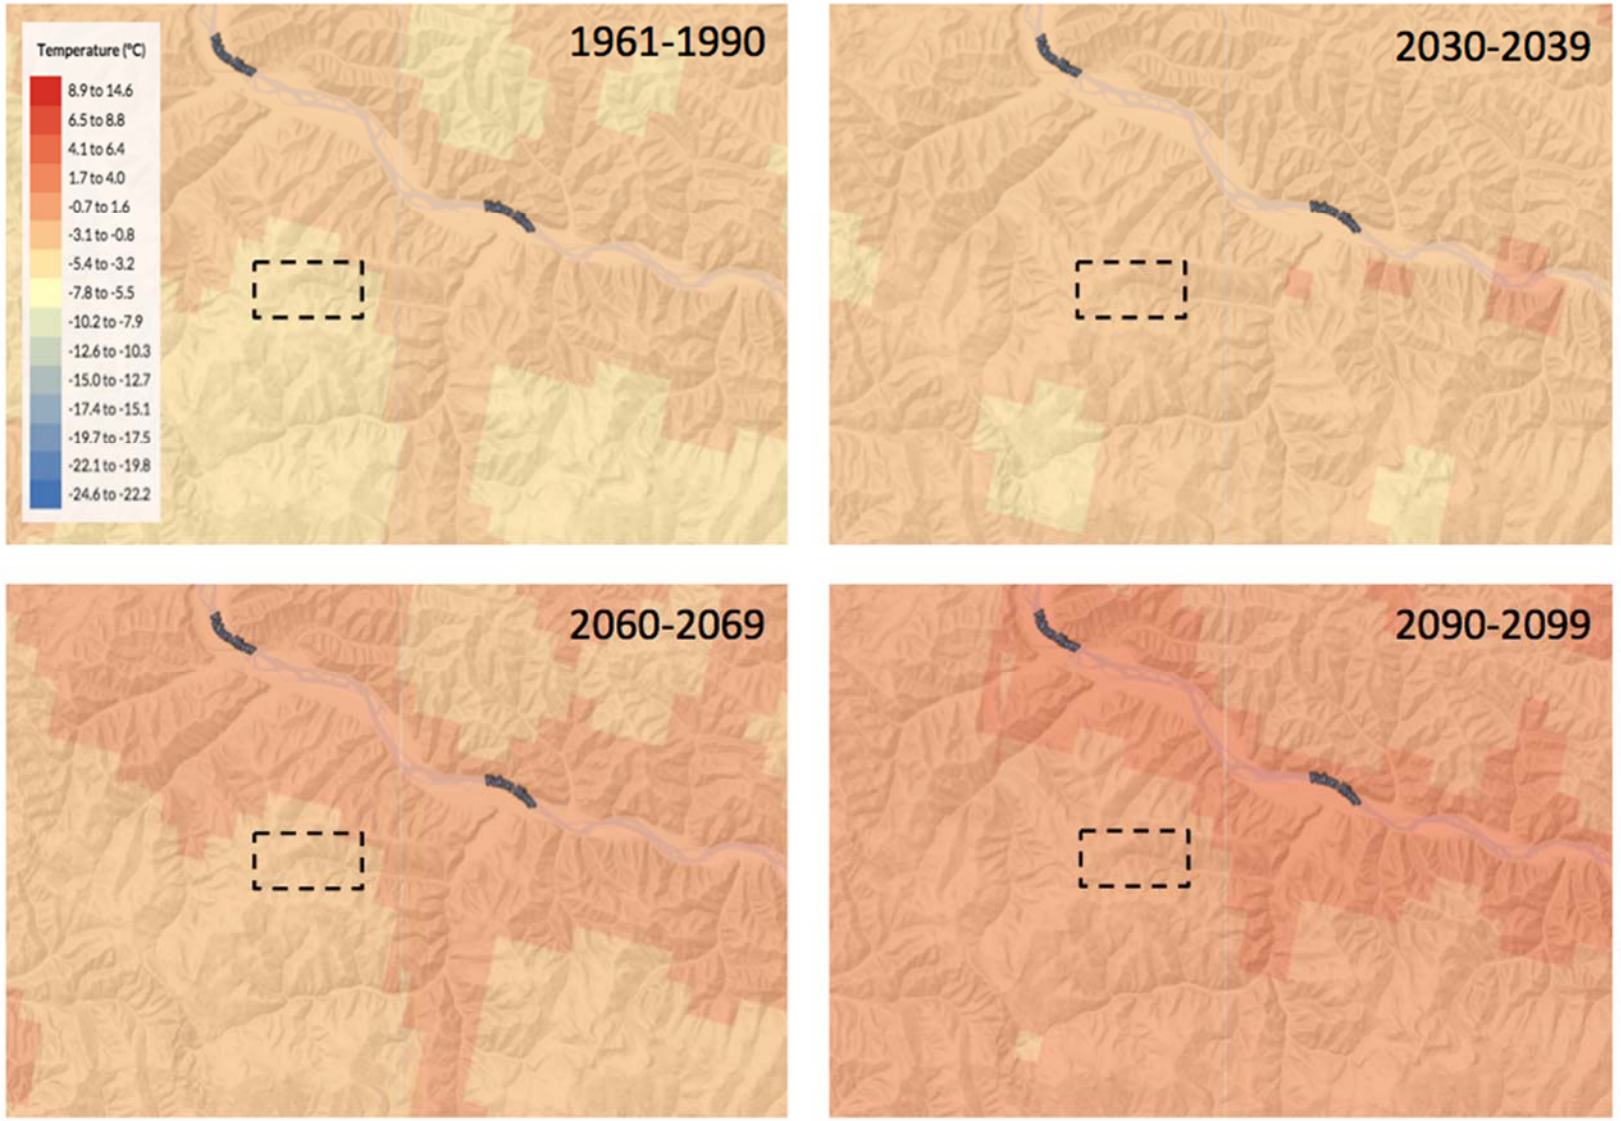

Figure 4-2: Temperature averages for Spring across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP. See Figure 4-1 caption for additional details.

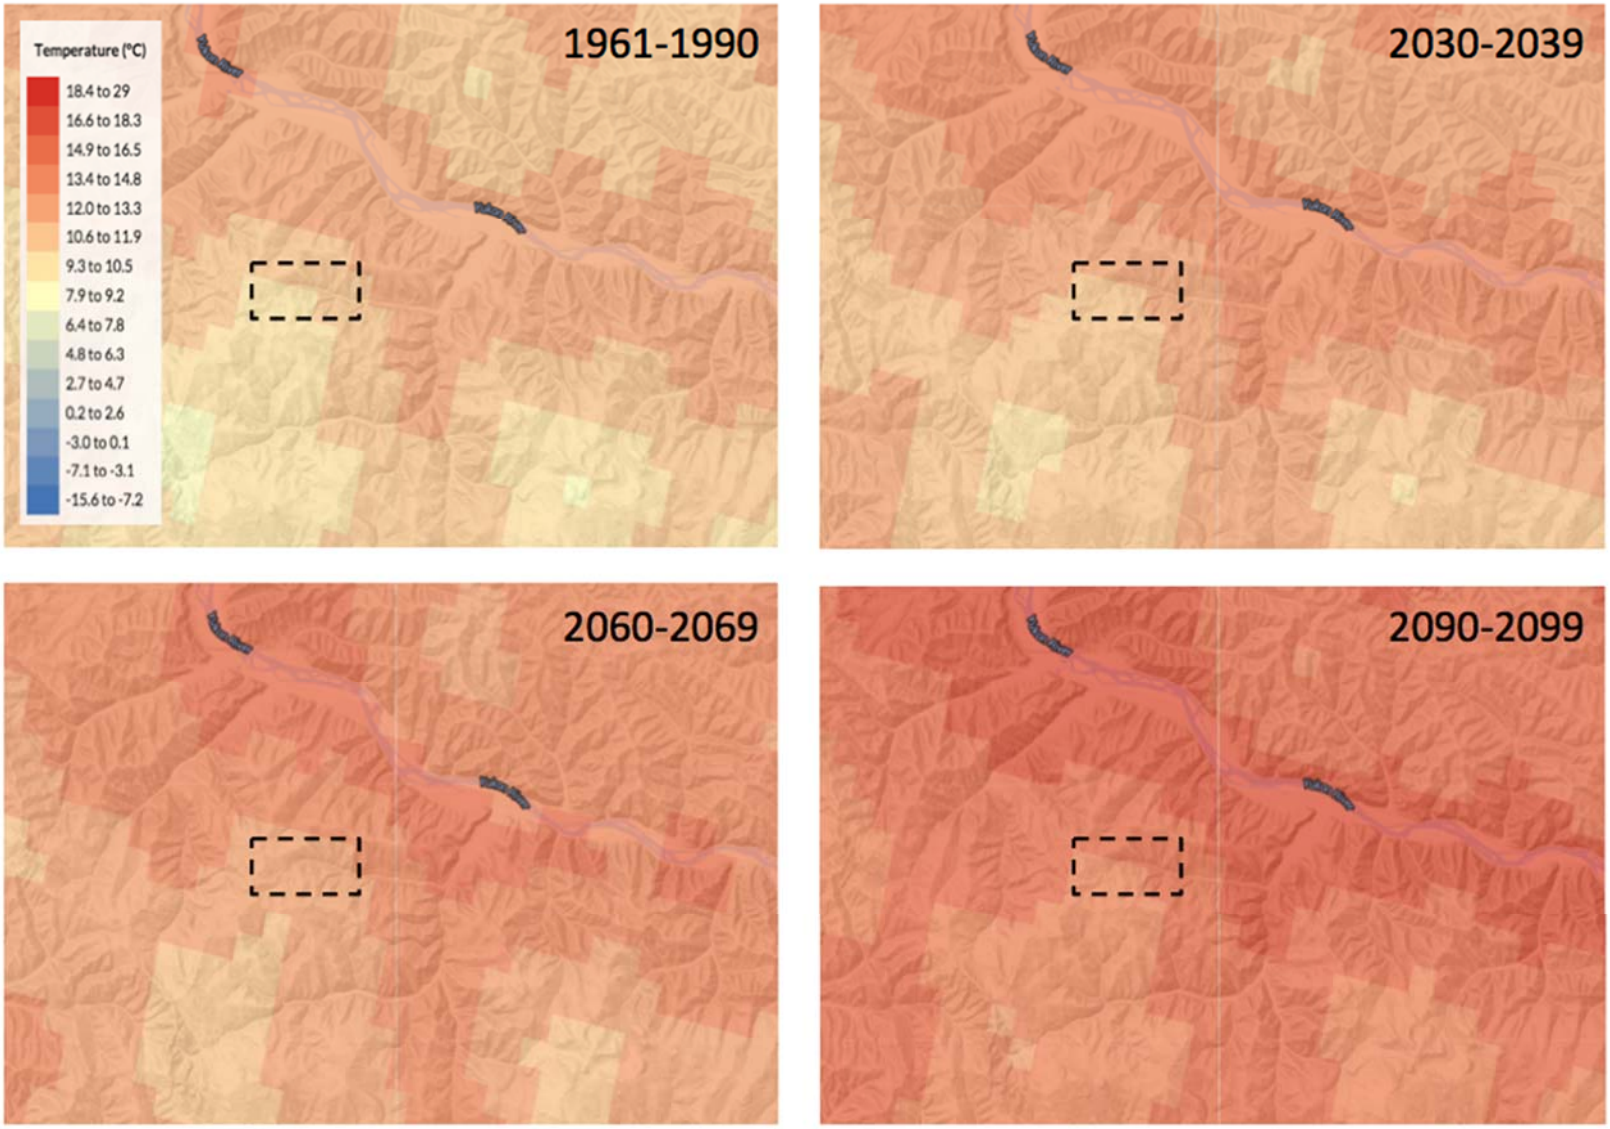

Figure 4-3: Temperature averages for Summer across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP. See Figure 4-1 caption for additional details.

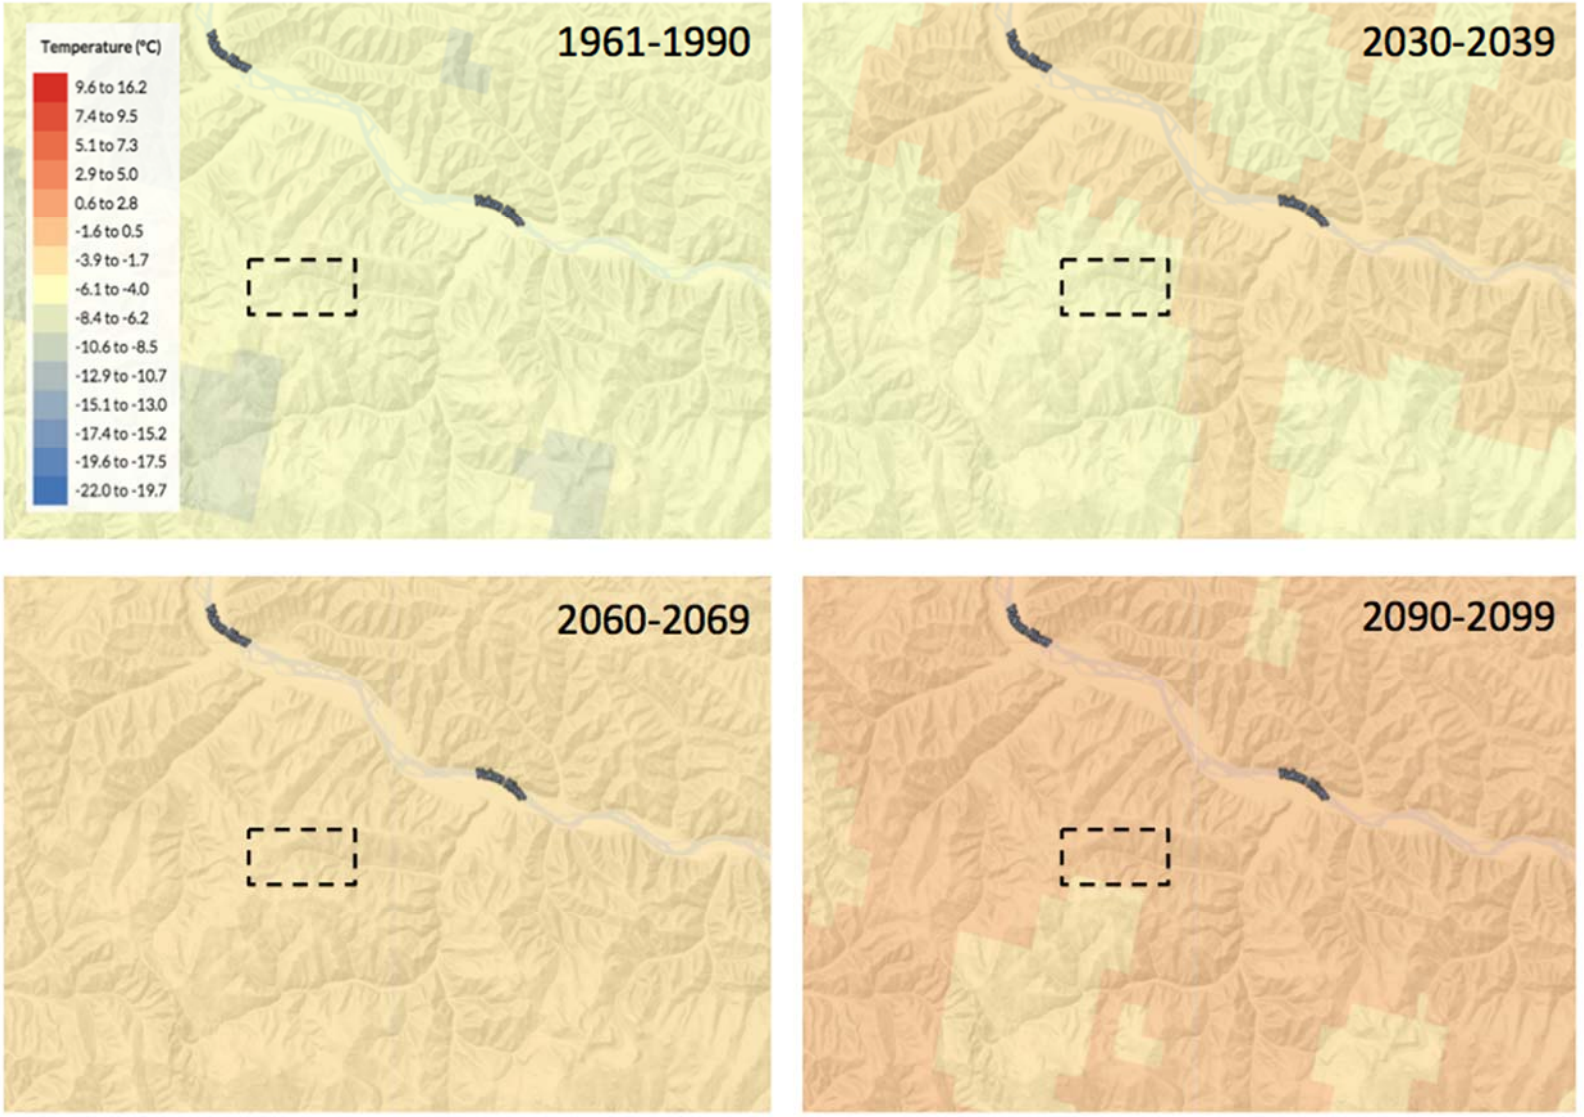

Figure 4-4: Temperature averages for Fall across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP. See Figure 4-1 caption for additional details.

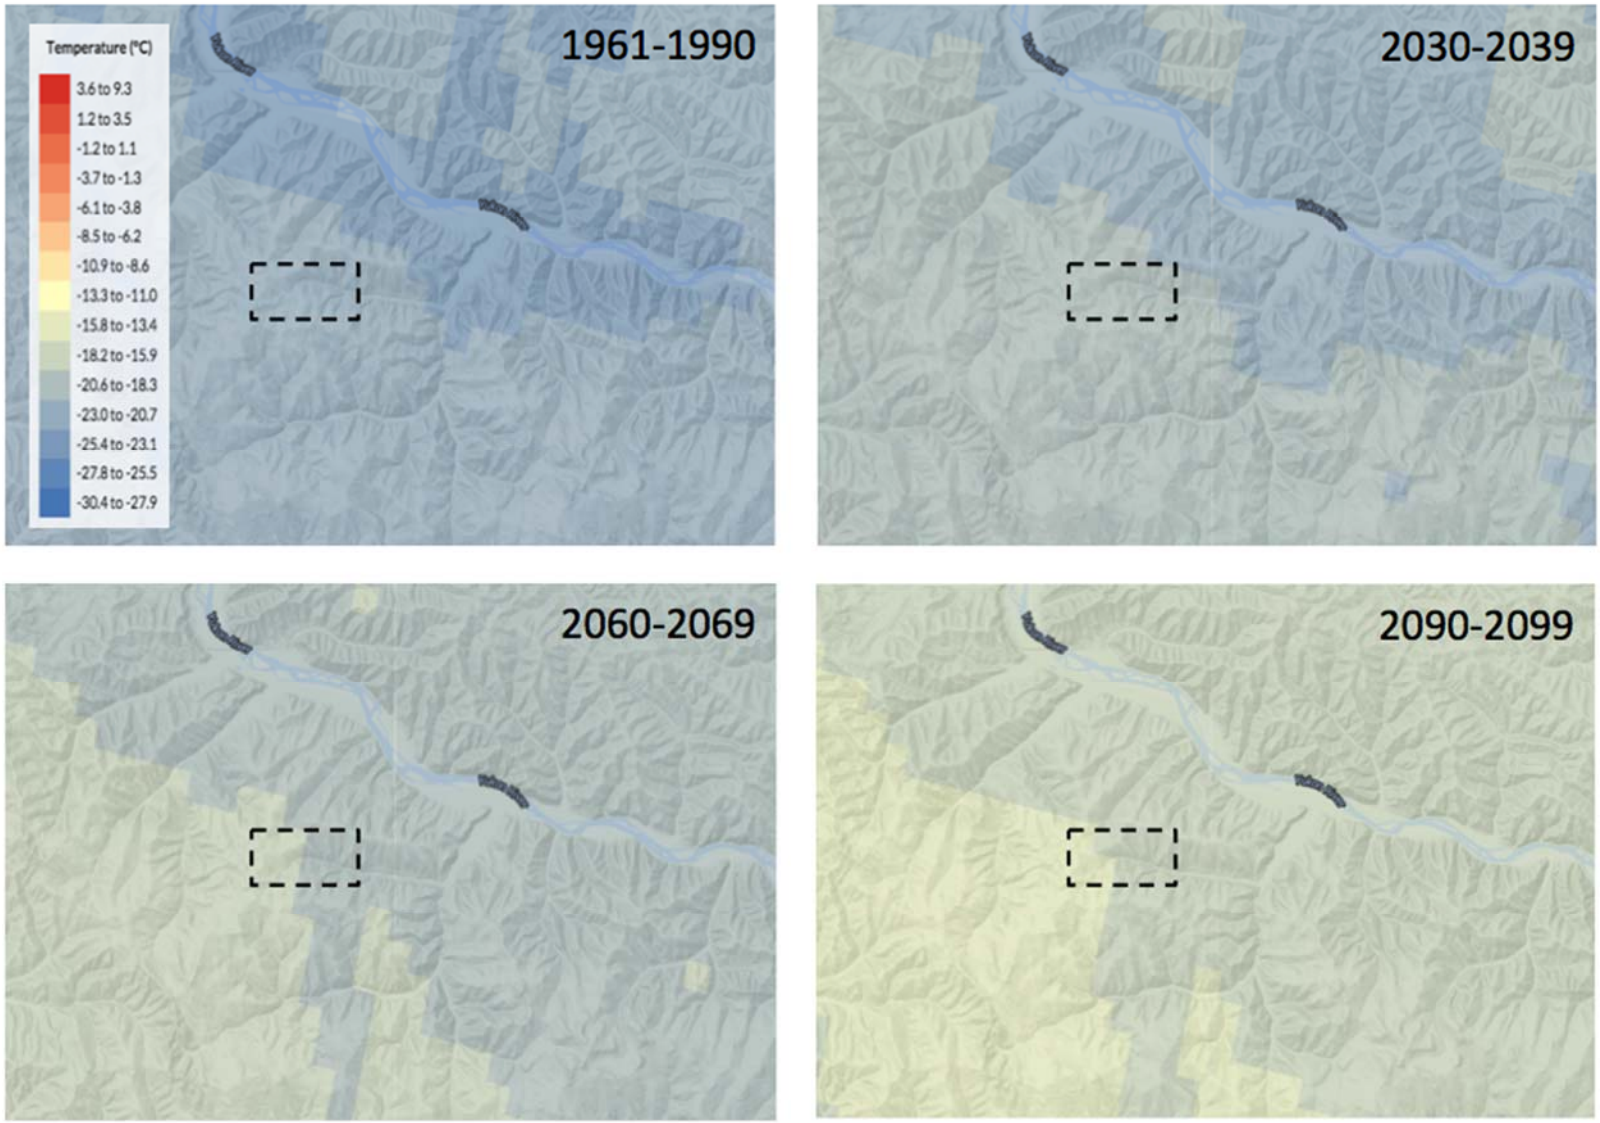

Figure 4-5: Temperature averages for Winter across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP.

Colder valley-bottom temperatures in winter notwithstanding, implications of the projected temperature increases for permafrost integrity in the region are obvious. The active layer can be expected to grow in thickness in the warmer months of coming decades, while the depth to intersection with permanently frozen ground will slowly increase. But how fast such changes will be witnessed remains a question largely dependent on the rate of change in radiative forcing with time.

5. Precipitation Projections

As for mean temperature, net precipitation in the Coffee Creek region overall is projected to increase over the course of this century (Figure 5-1). Lorax (2015) computed an average precipitation rate of 485 mm yr^{-1} for the project site at present, slightly higher than the 428-476 mm yr^{-1} modeled at the valley floor as the average over the 1961-1990 interval (Figure 5-1). At that same valley-floor elevation, average annual precipitation by the end of this century is projected to increase marginally to 477-525 mm yr^{-1}, while across much of the broader region, an increase of some 20% to some 574-670 mm yr^{-1} can be anticipated by the year 2100 (compare the lower right and upper left panels of Figure 5-1), given the emissions pathway specified by the SRES A2 scenario.

At present, the bulk of annual precipitation at Coffee Creek falls between May and September, with March and April, being particularly dry months (Lorax, 2015, Table 3-1). This contrasting pattern is projected to persist over the course of the century, albeit with Summer and Winter receiving greater precipitation than historically at the project site (compare Figure 5-2 through Figure 5-5; note that legend scales differ for each season), and little change being witnessed in Spring or Fall.

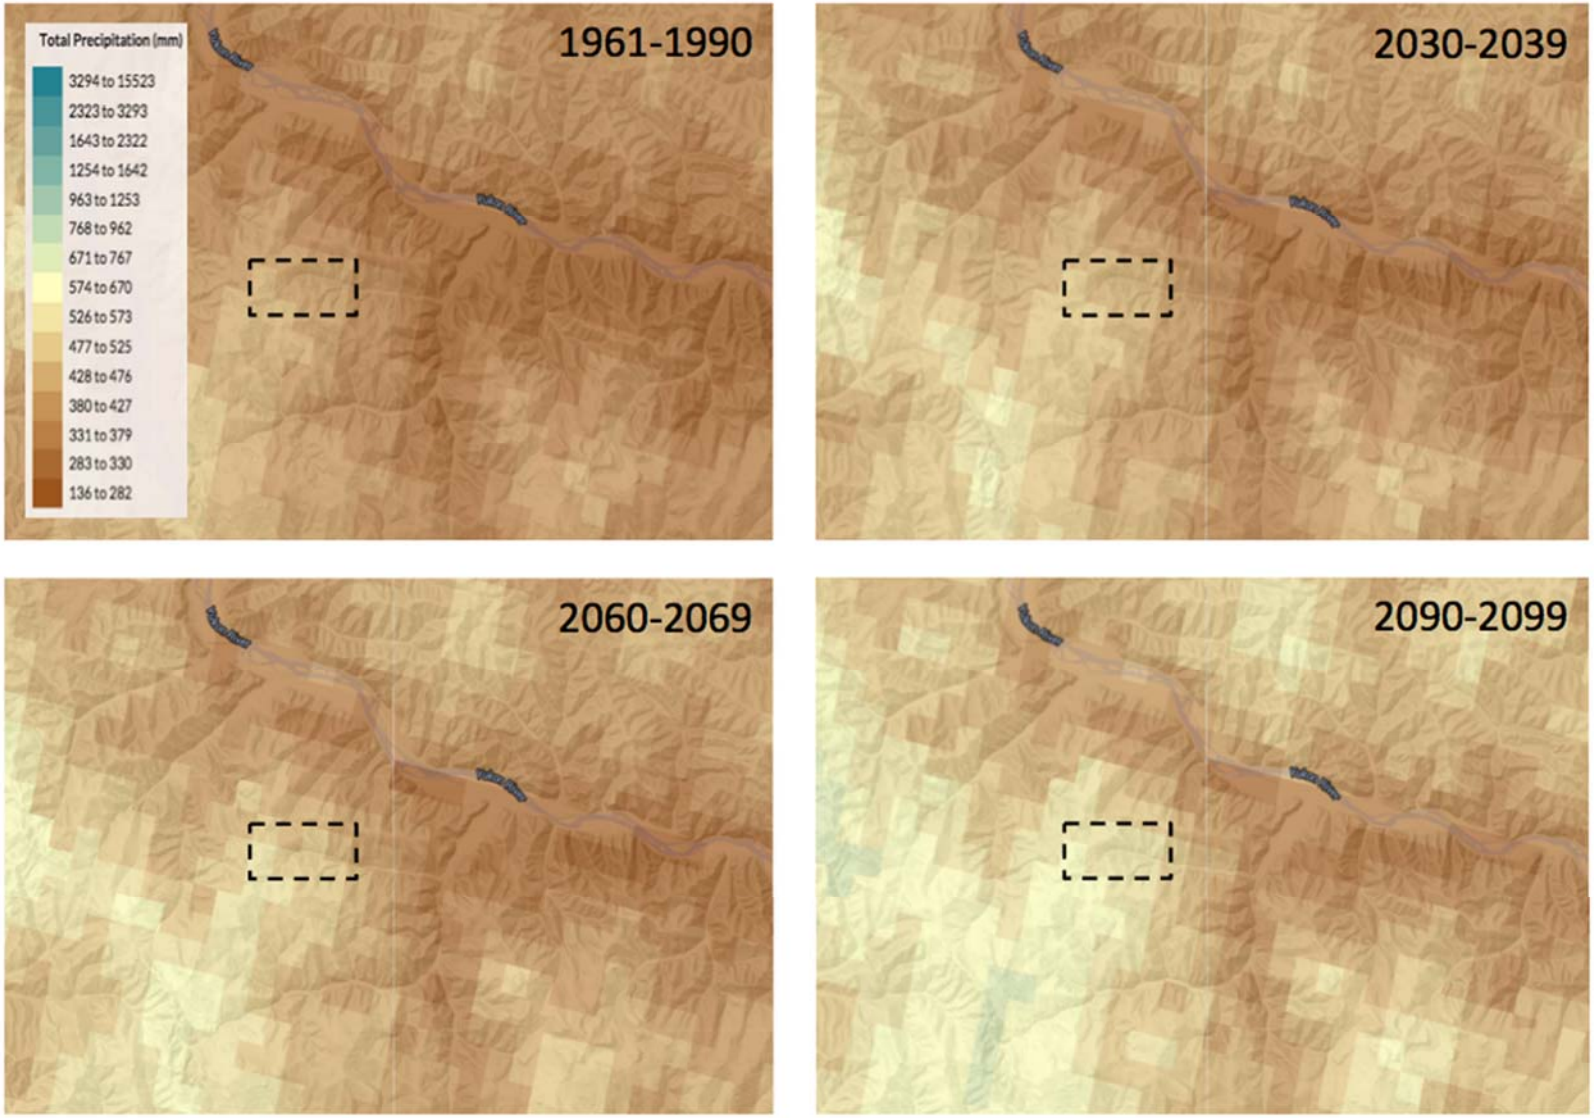

Figure 5-1: Annual precipitation averages in millimeters of water equivalent modeled using SNAP (see text) across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP. See Figure 4-1 caption for additional details.

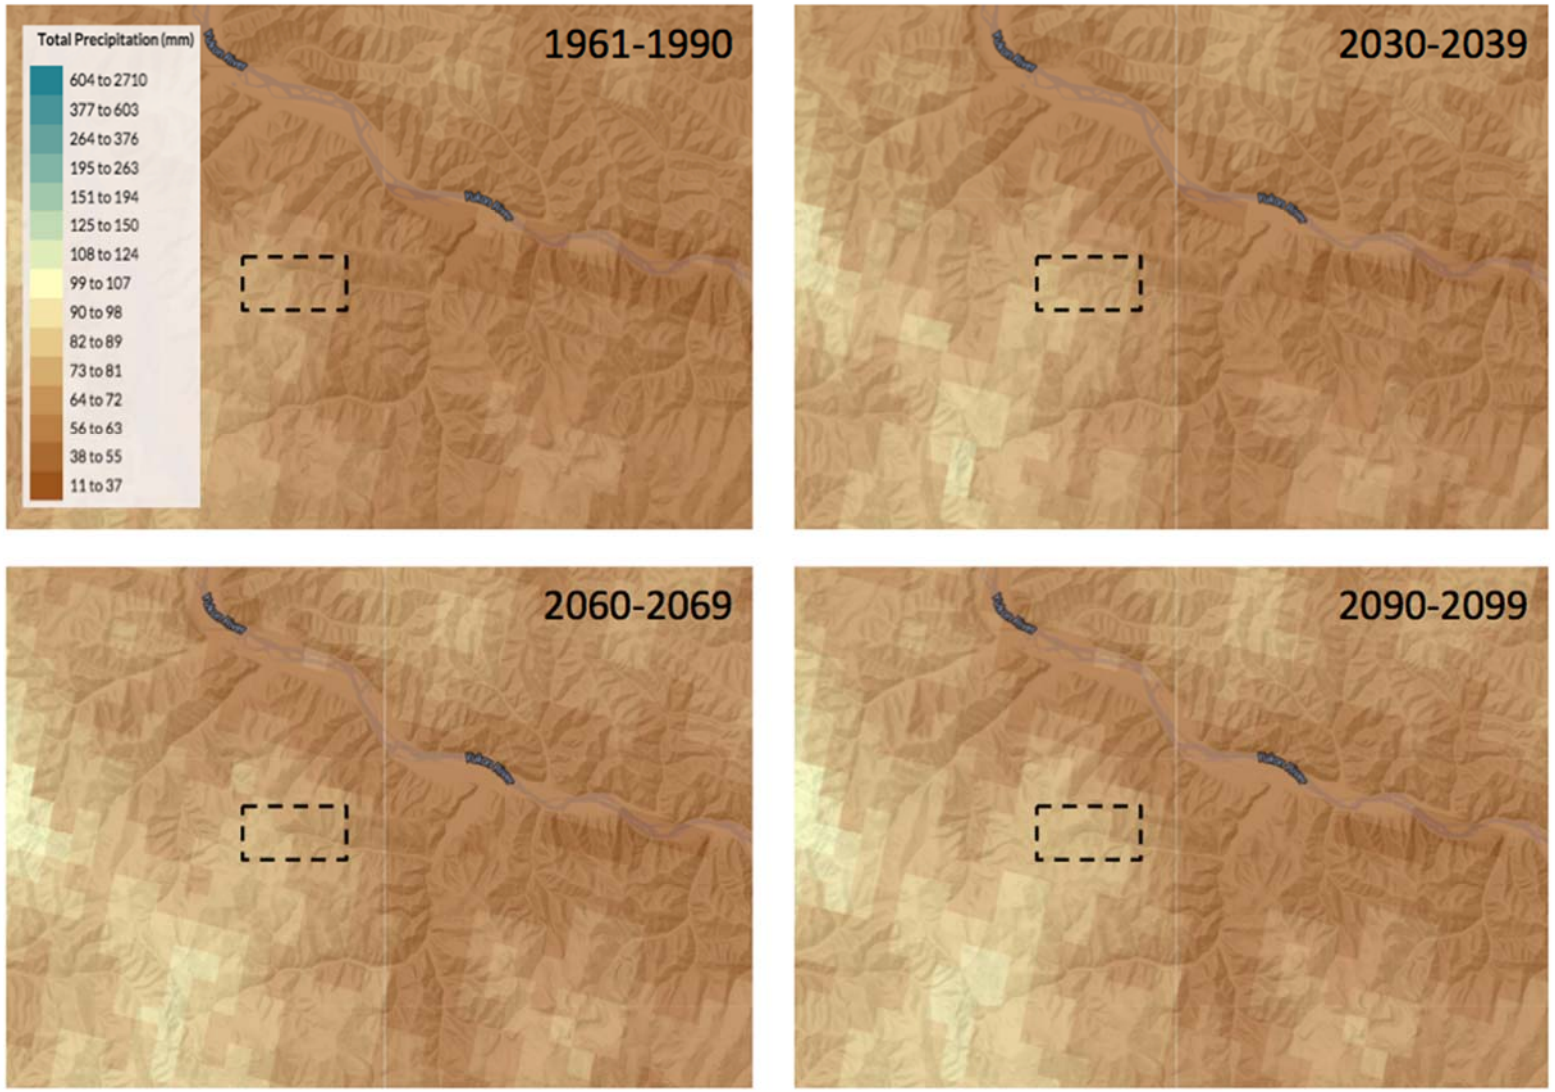

Figure 5-2: Precipitation averages for Spring in millimeters of water equivalent across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP.

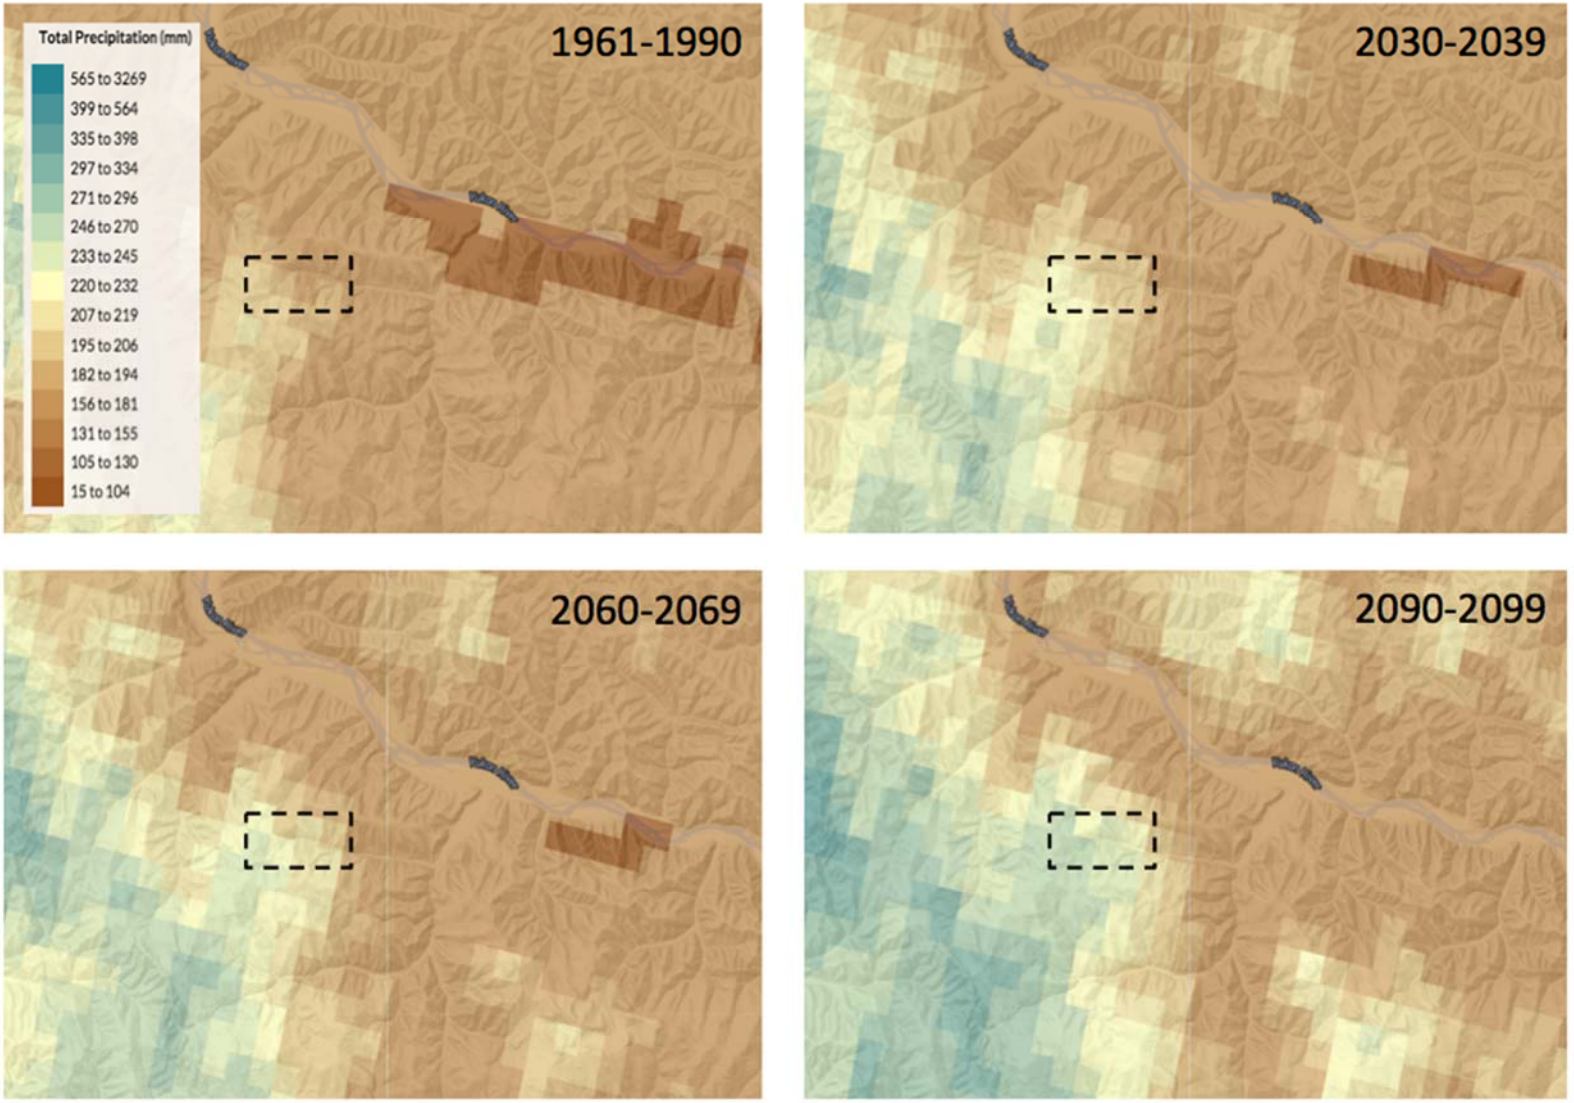

Figure 5-3: Precipitation averages for Summer in millimeters of water equivalent across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP.

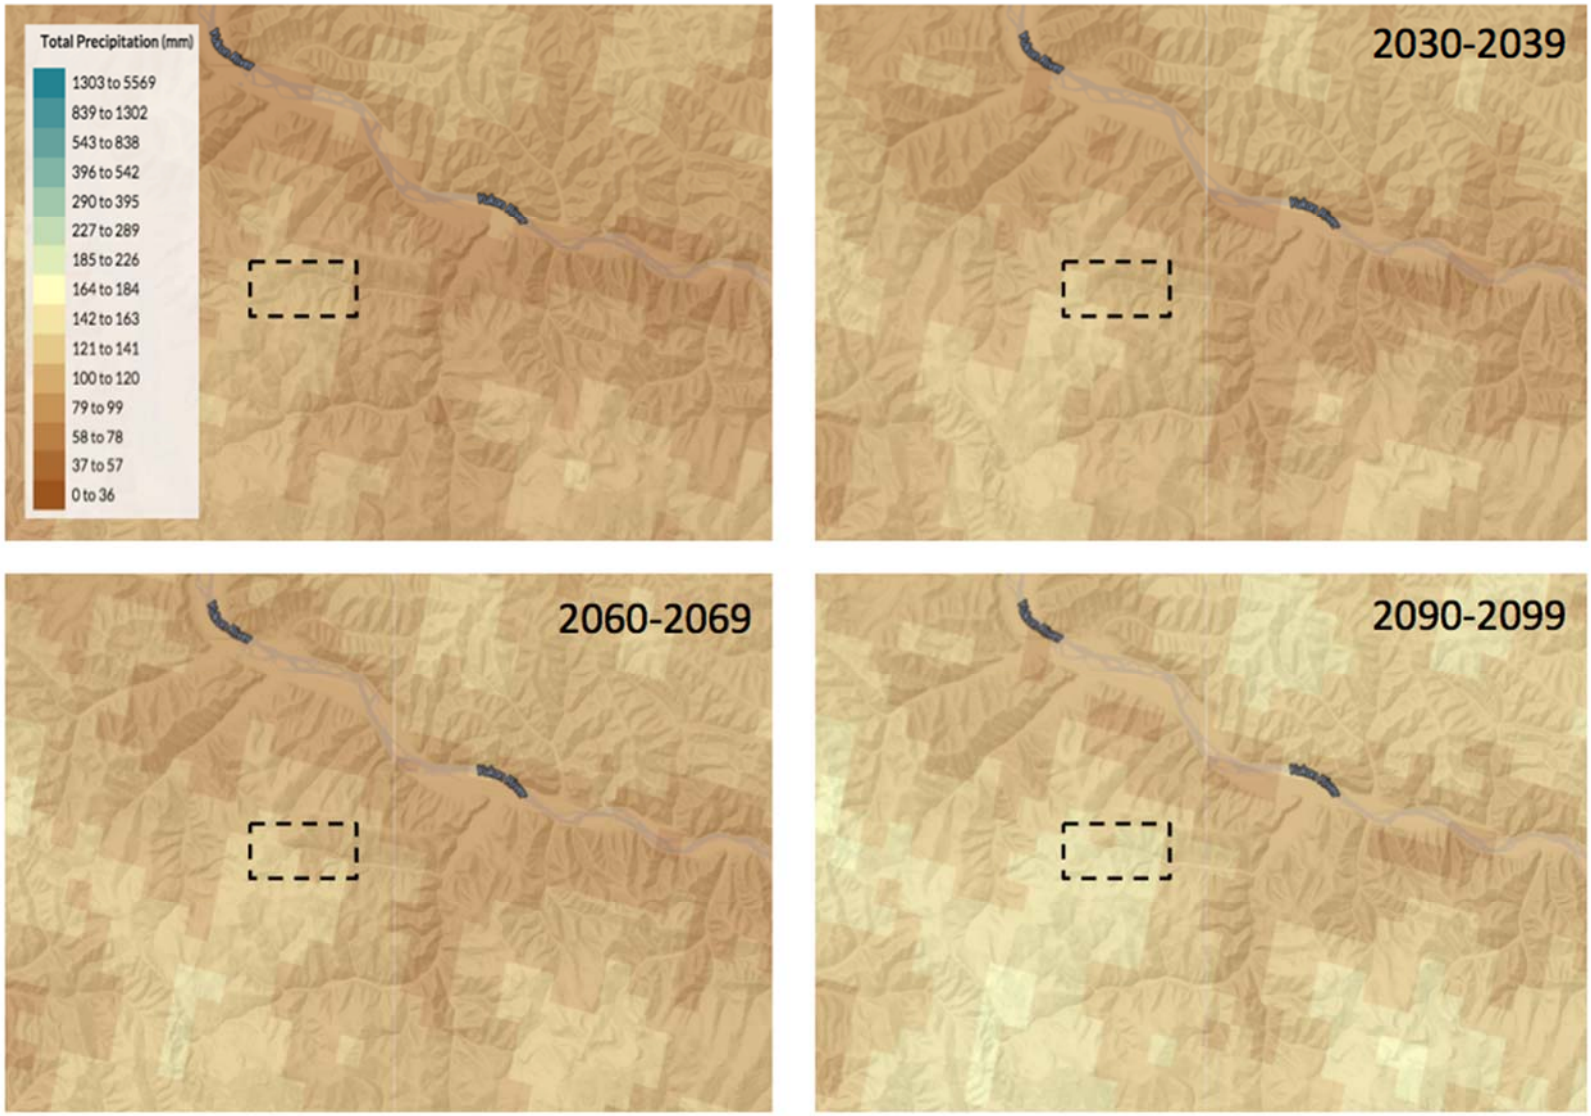

Figure 5-4: Precipitation averages for Fall in millimeters of water equivalent across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Modeled using SNAP.

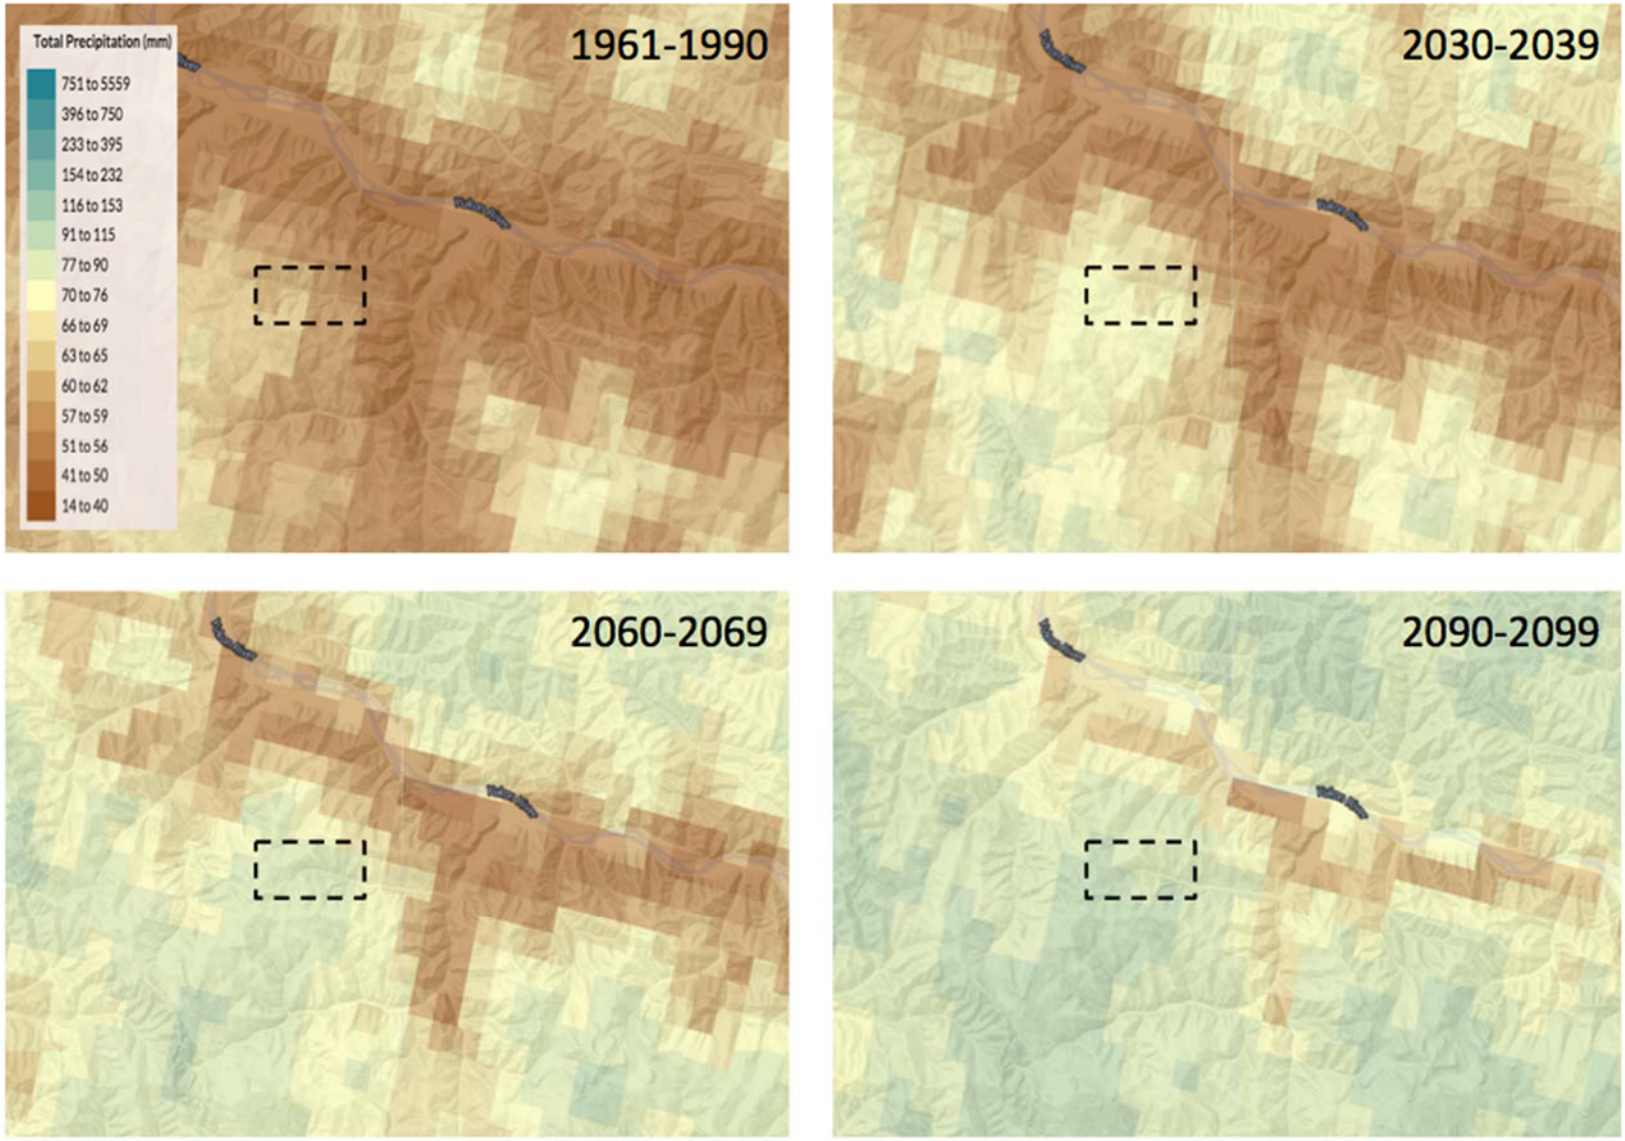

Figure 5-5: Precipitation averages for Winter in millimetres of water equivalent across the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP.

6. Freeze and Thaw Dates and Growing-Season Length Projections

SNAP defines the Day of Freeze (Day of Thaw) as "the day when consecutive monthly mid-point temperatures transition from positive to negative (negative to positive)." As average annual and seasonal temperatures rise as the century progresses, the projections under SRES A2 indicate that the historical Day of Freeze at the elevation of the Yukon River will shift from about the first to the third week of October by the 2030s (Figure 6-1). Similarly, as mean conditions warm, by the year 2100 the Day of Thaw is projected to shift about a fortnight earlier to near the beginning of April (Figure 6-2). These changes—later freeze-up and earlier thaw—increase the length of the growing season (*i.e.*, the number of days between the Day of Thaw and Day of Freeze) in the Coffee Creek region by nearly a month by the end of this century (Figure 6-3).

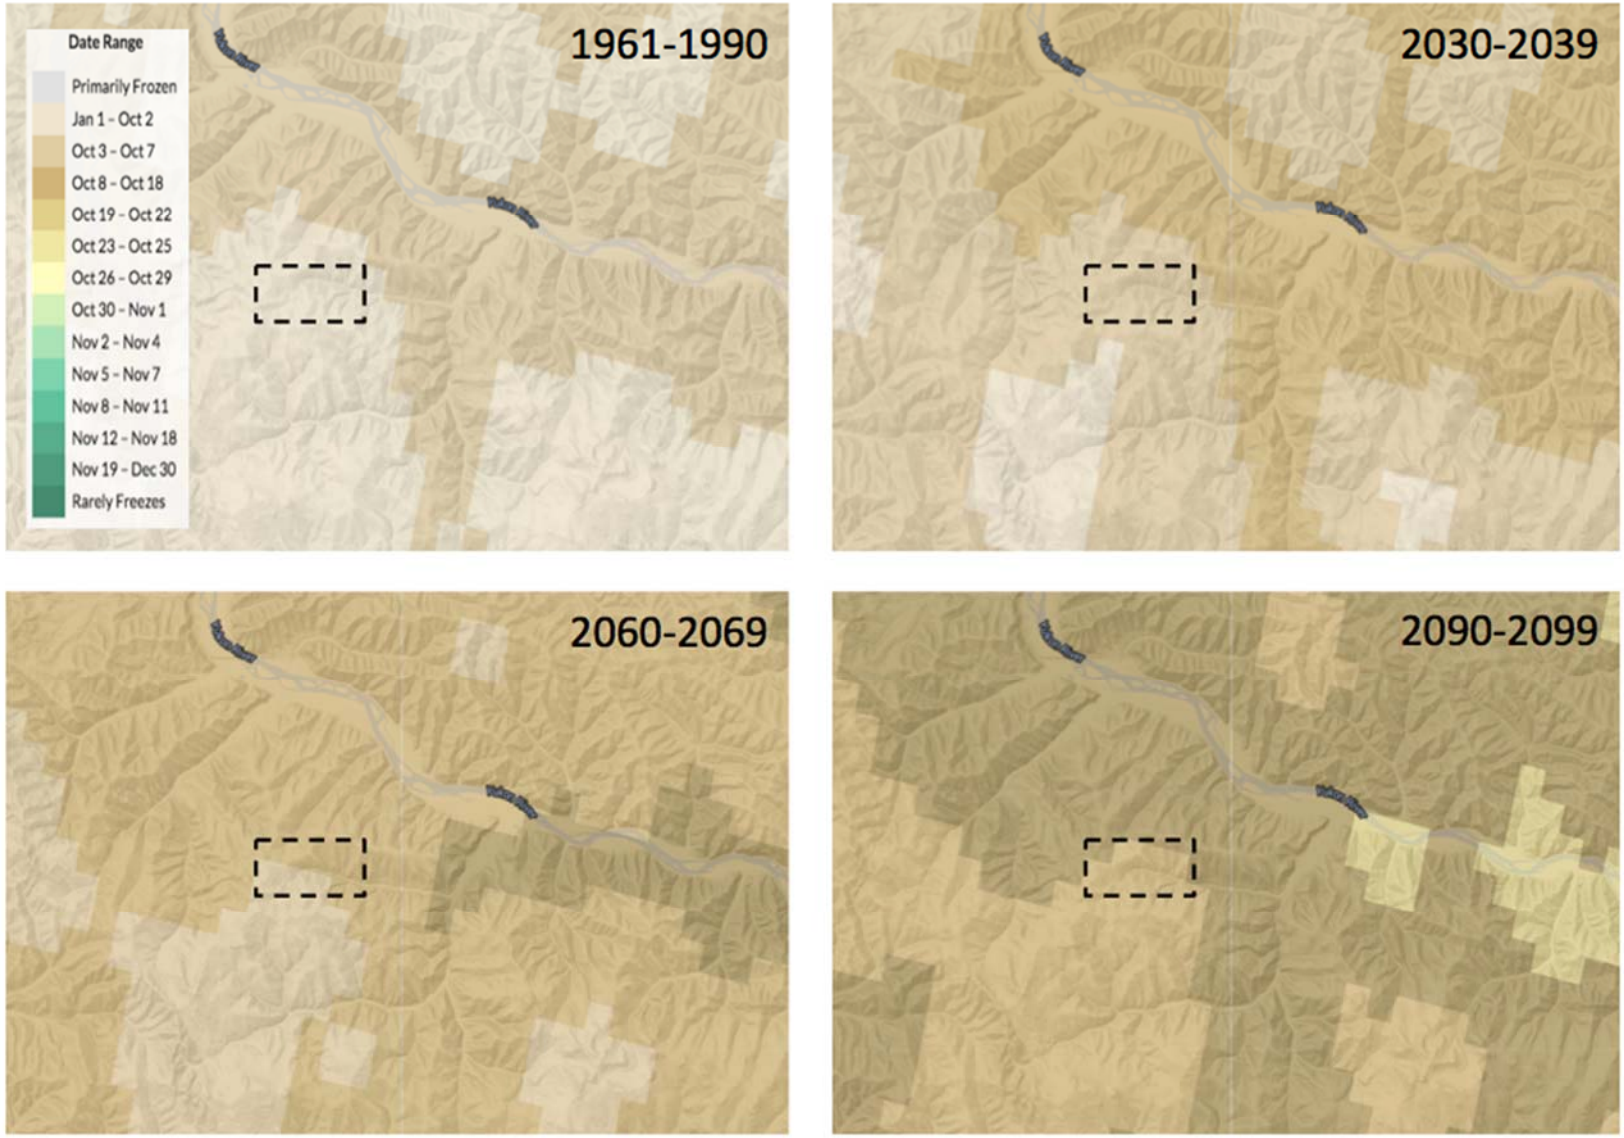

Figure 6-1: Estimated Day of Freeze for the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP.

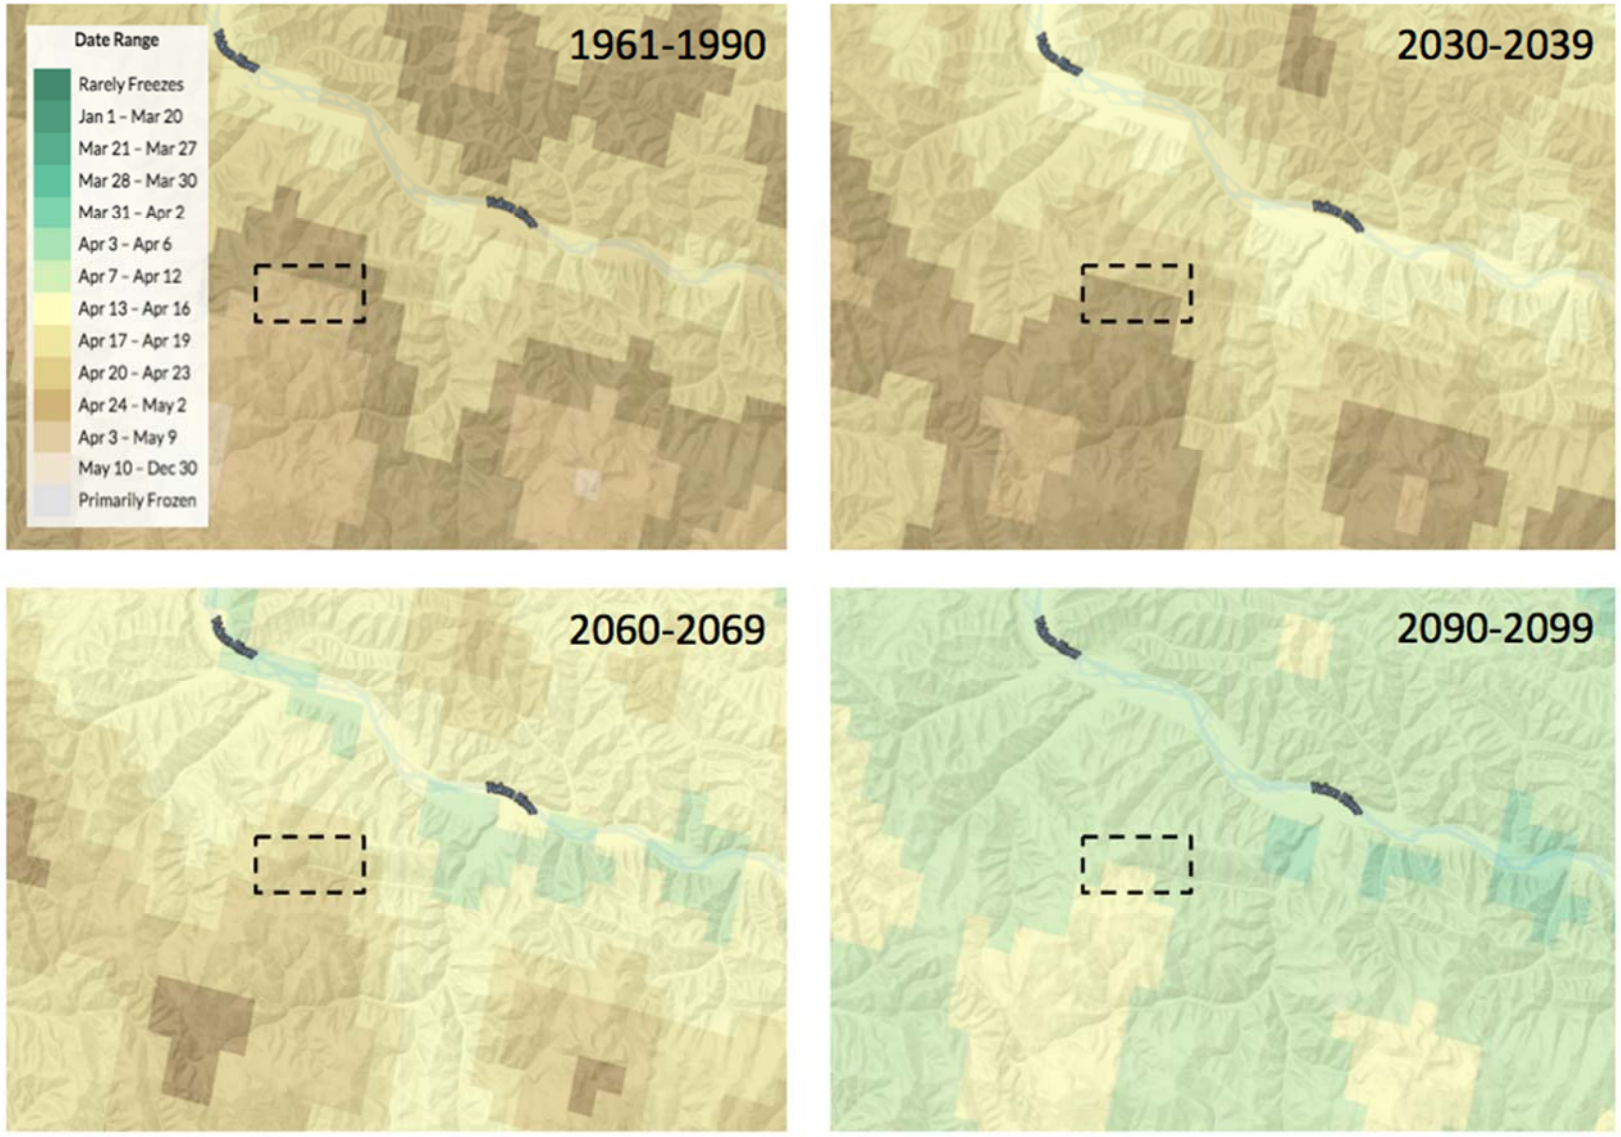

Figure 6-2: Estimated Day of Thaw for the Coffee Creek region for both the past (1961-1990) and three future decades. The dashed rectangle marks the project site. Spatial resolution of the model output is 2 km. Data shown are from SNAP.

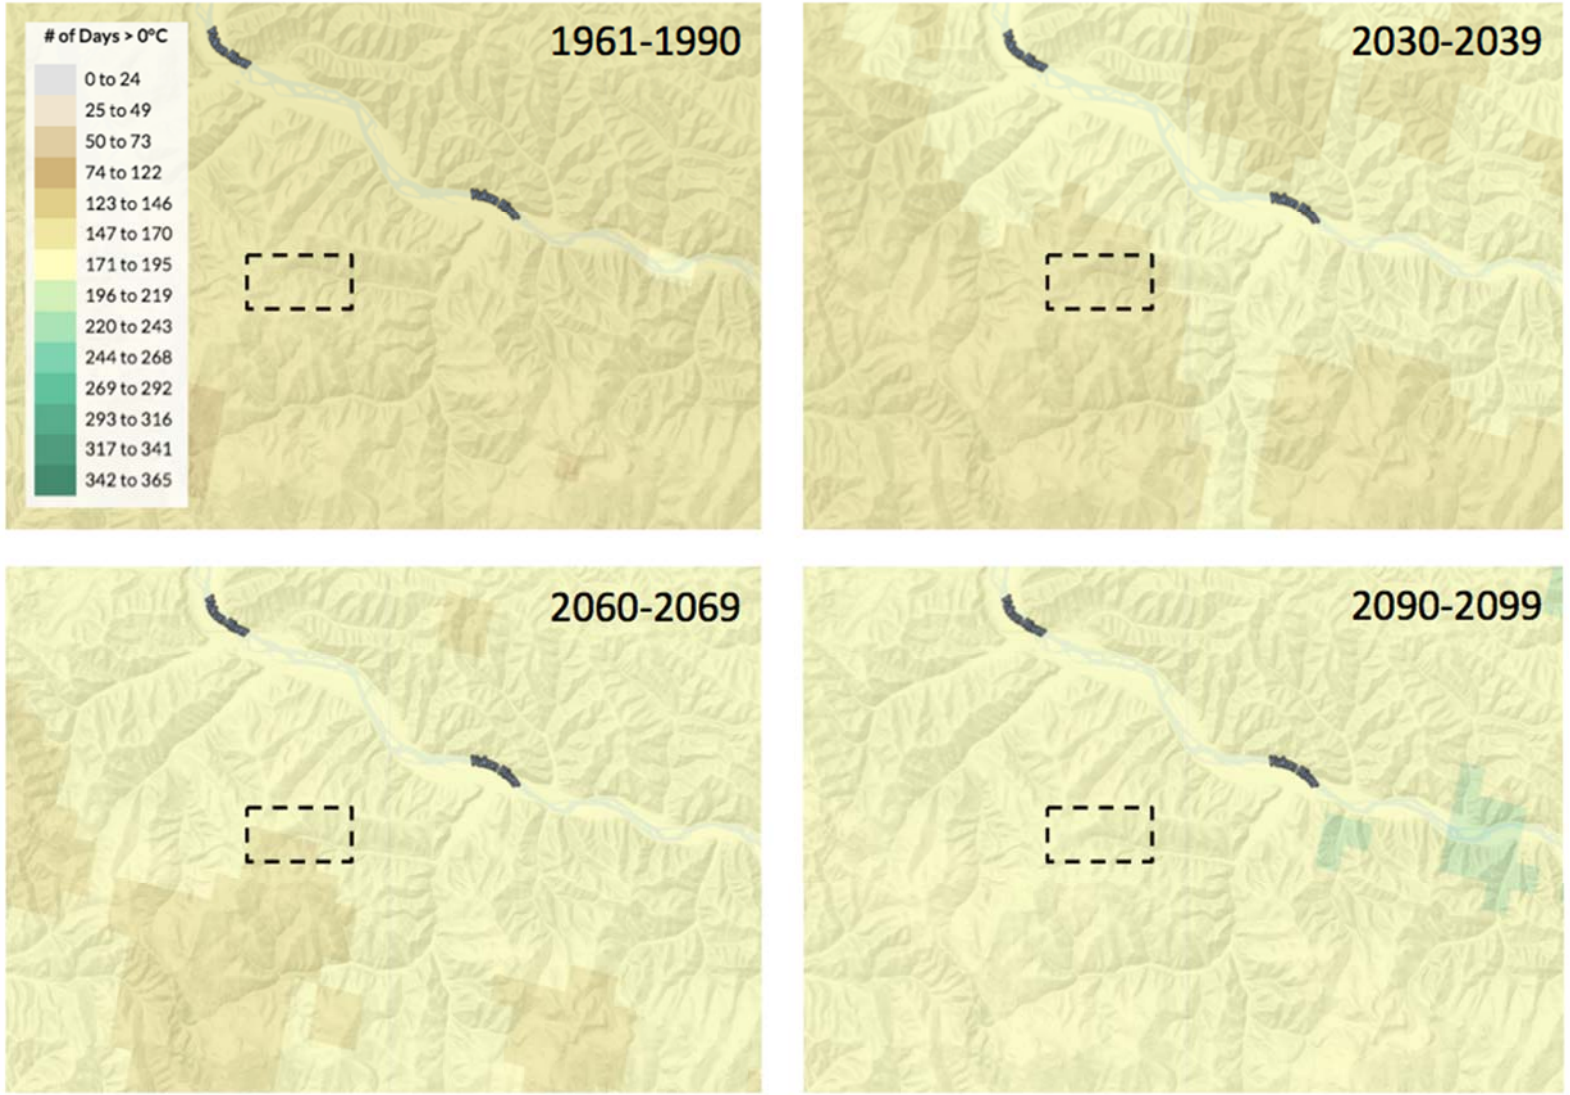

Figure 6-3: Estimated length of the growing season for the Coffee Creek region for both the past (1961-1990) and three future decades. The growing season length is defined as the number of days where the average temperature exceeds 0°C, and is equal to the number of days between the Day of Thaw and the Day of Freeze, shown respectively in Figures 6-1 and 6-2.

7. Summary and Conclusions

The pace at which climate is changing in the high latitudes of the Northern Hemisphere North is already amongst the highest in the world. There is every reason to believe that this trend will continue. Without exception, the best global climate models project ongoing warming and a progressively wetter climate at these latitudes. Seasonality will also be enhanced with, on average, drier summers and wetter conditions in the colder half of the year.

By the year 2100, average temperatures at the Coffee Creek Project site can reasonably be expected to be 3 to 5°C warmer relative to the waning decades of the last century. The warming is anticipated to be particularly pronounced in the summer. In contrast, average annual precipitation at Coffee Creek may not change dramatically. Summer and Winter can be expected to be slightly wetter, but the Spring and Fall seasons are projected to see little net change in precipitation abundance.

The warming will lead to a later freeze-up in fall and an earlier thaw in spring, according to the model results. In tandem, this will yield a growing season that is as much as one month longer by the end of the century. This implies a significantly lengthened duration for above-zero temperatures, with consequent negative implications for permafrost integrity in the region.

Note: Values in italics indicate that data for that month is not complete.

Note:
This site has a V-notch weir installed; therefore no rating curve was necessary.
Rating equation is $Q=1362.9*(h)^{2.5}$.

TABLE OF CONTENTS I

1. INTRODUCTION 1-1
   1.1 BACKGROUND 1-1
   1.2 REPORT STRUCTURE 1-5

2. BASELINE WATER QUALITY PROGRAM 2-1
   2.1 OVERVIEW AND OBJECTIVES 2-1
   2.2 FIELD AND ANALYTICAL METHODS 2-10
      2.2.1 SAMPLING FREQUENCY AND LOCATIONS 2-10
      2.2.2 FIELD SAMPLING METHODS 2-10
      2.2.3 LABORATORY METHODS 2-10
      2.2.4 DATA ANALYSIS 2-13
      2.2.5 QUALITY ASSURANCE/QUALITY CONTROL 2-13

3. WATER QUALITY RESULTS 3-1
   3.1 LATTE CREEK 3-1
      3.1.1 UPPER LATTE CREEK – STATION LC-15.5 3-2
         3.1.1.1 SUMMARY STATISTICS 3-4
         3.1.1.2 MAJOR IONS 3-4
         3.1.1.3 NUTRIENTS 3-4
         3.1.1.4 TRACE ELEMENTS 3-6
      3.1.2 MID AND LOWER LATTE CREEK – STATIONS LC-11.4 AND LC-0.2 3-8
         3.1.2.1 SUMMARY STATISTICS 3-9
         3.1.2.2 MAJOR IONS 3-11
         3.1.2.3 NUTRIENTS 3-13
         3.1.2.4 TRACE ELEMENTS 3-15
         3.1.2.5 5 IN 30 SAMPLING RESULTS STATION LC-11.4 3-24
   3.2 COFFEE CREEK 3-26
      3.2.1 UPPER COFFEE CREEK – STATION CC-11.6 3-27
         3.2.1.1 SUMMARY STATISTICS 3-29
         3.2.1.2 MAJOR IONS 3-30
         3.2.1.3 NUTRIENTS 3-31
         3.2.1.4 TRACE ELEMENTS 3-31
      3.2.2 LOWER COFFEE CREEK – STATION CC-3.2 3-36
         3.2.2.1 SUMMARY STATISTICS 3-36
         3.2.2.2 MAJOR IONS 3-36
         3.2.2.3 NUTRIENTS 3-38
         3.2.2.4 TRACE ELEMENTS 3-39
         3.2.2.5 5 IN 30 SAMPLING AT CC-3.2 3-44
      3.2.3 CC-10.9 COFFEE CREEK 3-45
         3.2.3.1 SUMMARY STATISTICS 3-45
         3.2.3.2 MAJOR IONS 3-45
         3.2.3.3 NUTRIENTS 3-47
         3.2.3.4 TRACE ELEMENTS 3-48
         3.2.3.5 5 IN 30 SAMPLING OF CC-10.9 3-53
   3.3 HALFWAY CREEK AND YT-24 3-54
      3.3.1 HALFWAY CREEK – STATIONS HC-6.8 AND HC-1.0 3-54
         3.3.1.1 SUMMARY STATISTICS 3-54
         3.3.1.1 MAJOR IONS 3-58
         3.3.1.2 NUTRIENTS 3-60
         3.3.1.3 TRACE ELEMENTS 3-61
         3.3.1.4 5 IN 30 SAMPLING RESULTS STATION HC-6.8 3-70

3.3.2 YT-24 STATIONS 3-71
3.3.2.1 SUMMARY STATISTICS 3-71
3.3.2.2 MAJOR IONS 3-71
3.3.2.3 NUTRIENTS 3-74
3.3.2.4 TRACE ELEMENTS 3-74
3.4 YUKON RIVER STATIONS 3-78
3.4.1 YUK-51.3 AND YUK-26.1 3-78
3.4.1.1 SUMMARY STATISTICS 3-78
3.4.1.2 MAJOR IONS 3-78
3.4.1.3 NUTRIENTS 3-82
3.4.1.4 TRACE ELEMENTS 3-82
3.4.2 YUK -49.3 AND YUK-37.6 3-87
3.4.2.1 SUMMARY STATISTICS 3-87
3.4.2.2 MAJOR IONS 3-87
3.4.2.3 NUTRIENTS 3-91
3.4.2.4 TRACE ELEMENTS 3-91
3.5 INDEPENDENCE CREEK 3-95
3.5.1 STATION IC-2.7 3-97
3.5.1.1 SUMMARY STATISTICS 3-97
3.5.1.2 MAJOR IONS 3-97
3.5.1.3 NUTRIENTS 3-99
3.5.1.4 TRACE ELEMENTS 3-99
3.5.2 STATION KT-0.3 3-103
3.5.2.1 SUMMARY STATISTICS 3-103
3.5.2.2 MAJOR IONS 3-105
3.5.2.3 NUTRIENTS 3-106
3.5.2.4 TRACE ELEMENTS 3-107

1. Introduction

Newmont™
COFFEE

1. Introduction

1.1 Background

The Coffee Gold Project (the Project) is an open pit gold heap leach operation, located in west-central Yukon, approximately 130 km south of Dawson City and operated by Newmont/Goldcorp Corp. (NG) (Figure 1.1-1). The Project contains several gold occurrences within an exploration concession covering an approximate area of more than 600 km^2.

The Project is located within the Yukon-Tanana Terrane (YTT), an accreted pericratonic rock sequence that covers a large portion of the Omineca Belt in the Yukon and extends into Alaska and British Columbia (BC). The YTT underlies part of the Tintina gold belt and hosts multiple gold deposits, including the Sonora Gulch gold deposit, the Casino copper-gold-molybdenum porphyry, the Boulevard gold prospect, and the Golden Saddle gold deposit.

Under the direction of NG (former Kaminak Gold Corporation [Kaminak]), the Project underwent a detailed Feasibility Study (Coffee Gold 43-101 FS) in 2015 with engineering and design progressing with full consideration of environmental conditions within the Project area. Prior to, and coincident with, exploration activities and feasibility studies, NG commenced several baseline programs (*e.g.*, meteorology, hydrology, surface water quality, groundwater, soils, air, fish and fish habitat, and wildlife) to characterize background site conditions. The overarching objective of these baseline programs is to provide detailed characterization of the pre-mine condition to be used to define environmental benchmarks that potential Project effects may be measured against during Operations and Closure mine Phases. The surface water quality program was initiated by Kaminak in October 2010. In 2014, Lorax Environmental Services Ltd. (Lorax) was retained by NG (former Kaminak) to further advance the surface water quality baseline program and as a result, a number of additional surface water quality stations were added to the existing monitoring program

Since acquisition of the Project by Goldcorp in 2016, the surface water quality baseline monitoring program has continued uninterrupted on a monthly basis to present.

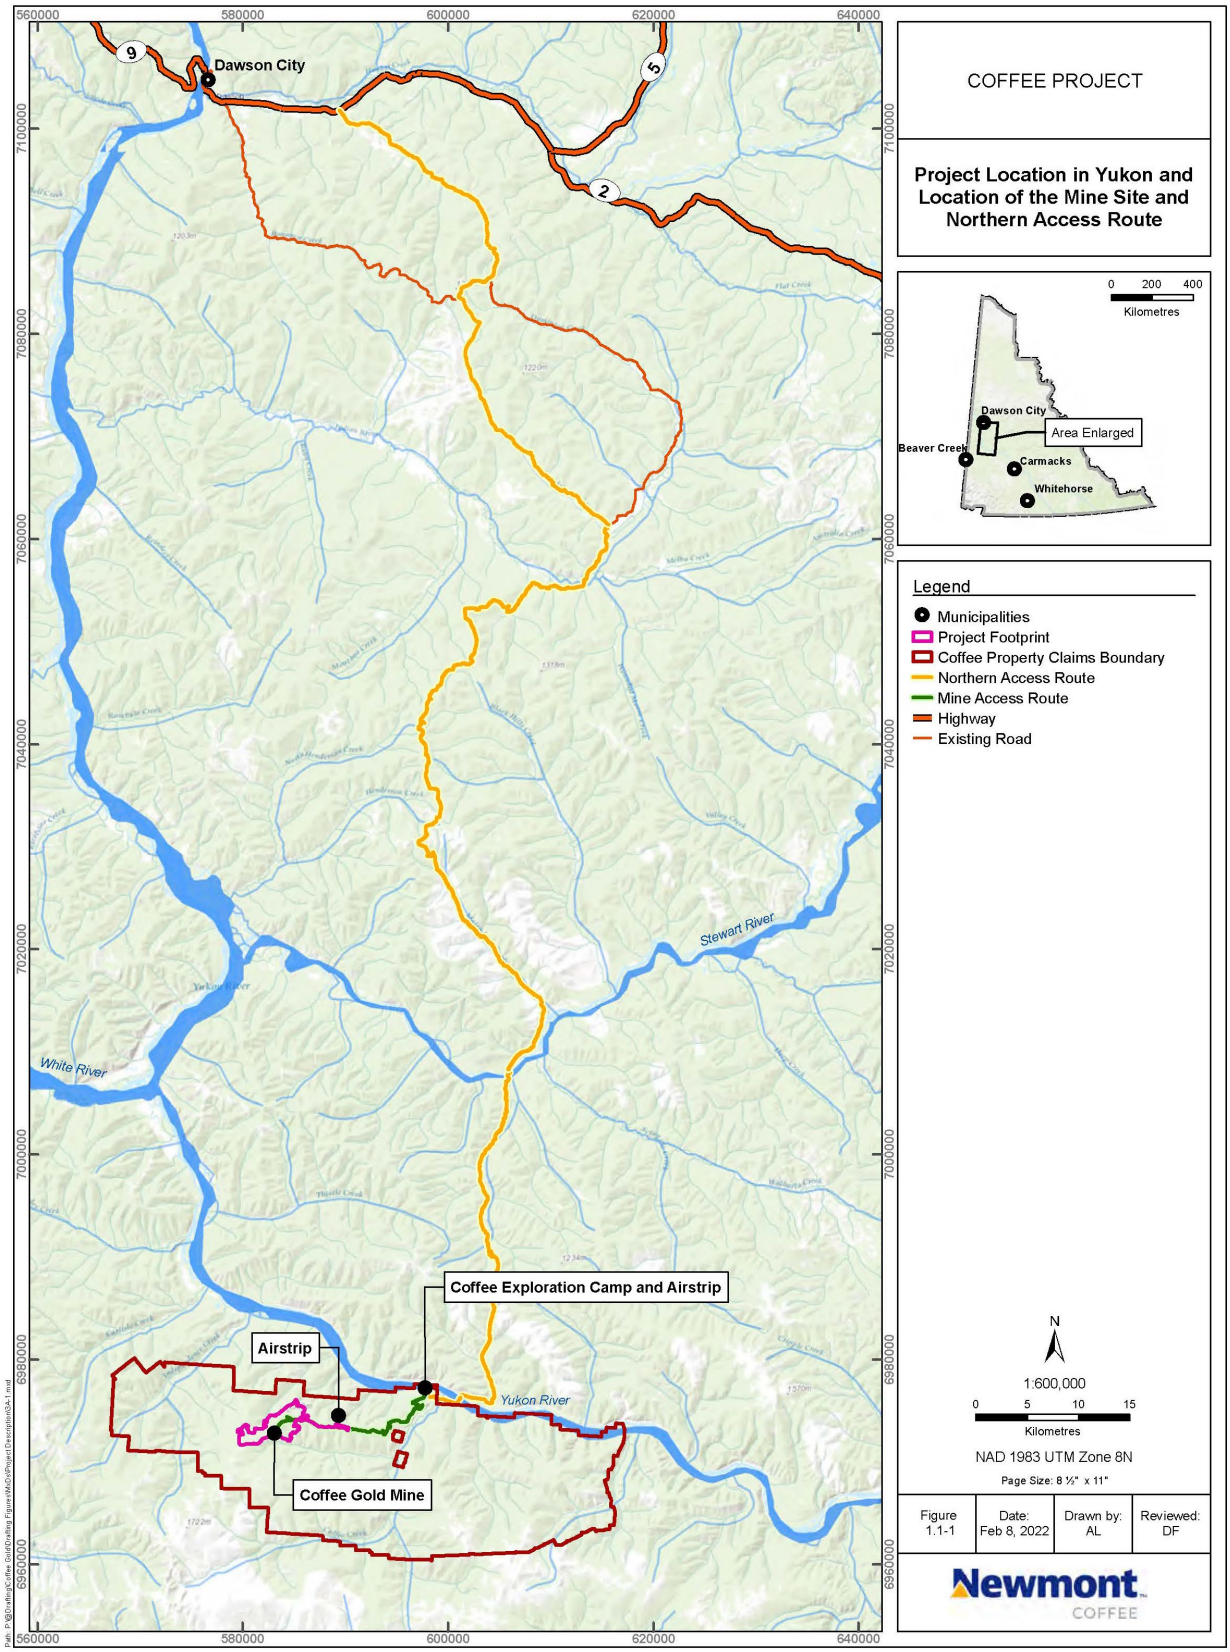

Figure 1.1-1: Coffee Gold Project Location Map

The following report summarizes the baseline surface water quality conditions from 2010 to December 2020 in three catchments proximal to the Project (Figure 1.1-2):

- Halfway Creek;
- Latte Creek; and
- YT-24

Major infrastructure related to the proposed mining and processing operations at the site includes: the primary and secondary crushing facilities; a carbon adsorption plant; a gold refinery; the heap leach facilities; waste rock storage areas (WRSA); water drainage structures and storage ponds; haul roads; the accommodations complex; and an all-weather airstrip.

This baseline report characterizes water quality in receiving environment watercourses with the potential to be affected by project development and operation. In addition, baseline water quality in Independence Creek, which is unaffected by project development and therefore serves as a reference stream, is also characterized. The local study area (LSA) and primary focus of this report is on the following drainages:

- Latte Creek;
- Coffee Creek;
- Halfway Creek;
- YT-24;
- Independence Creek; and
- Yukon River

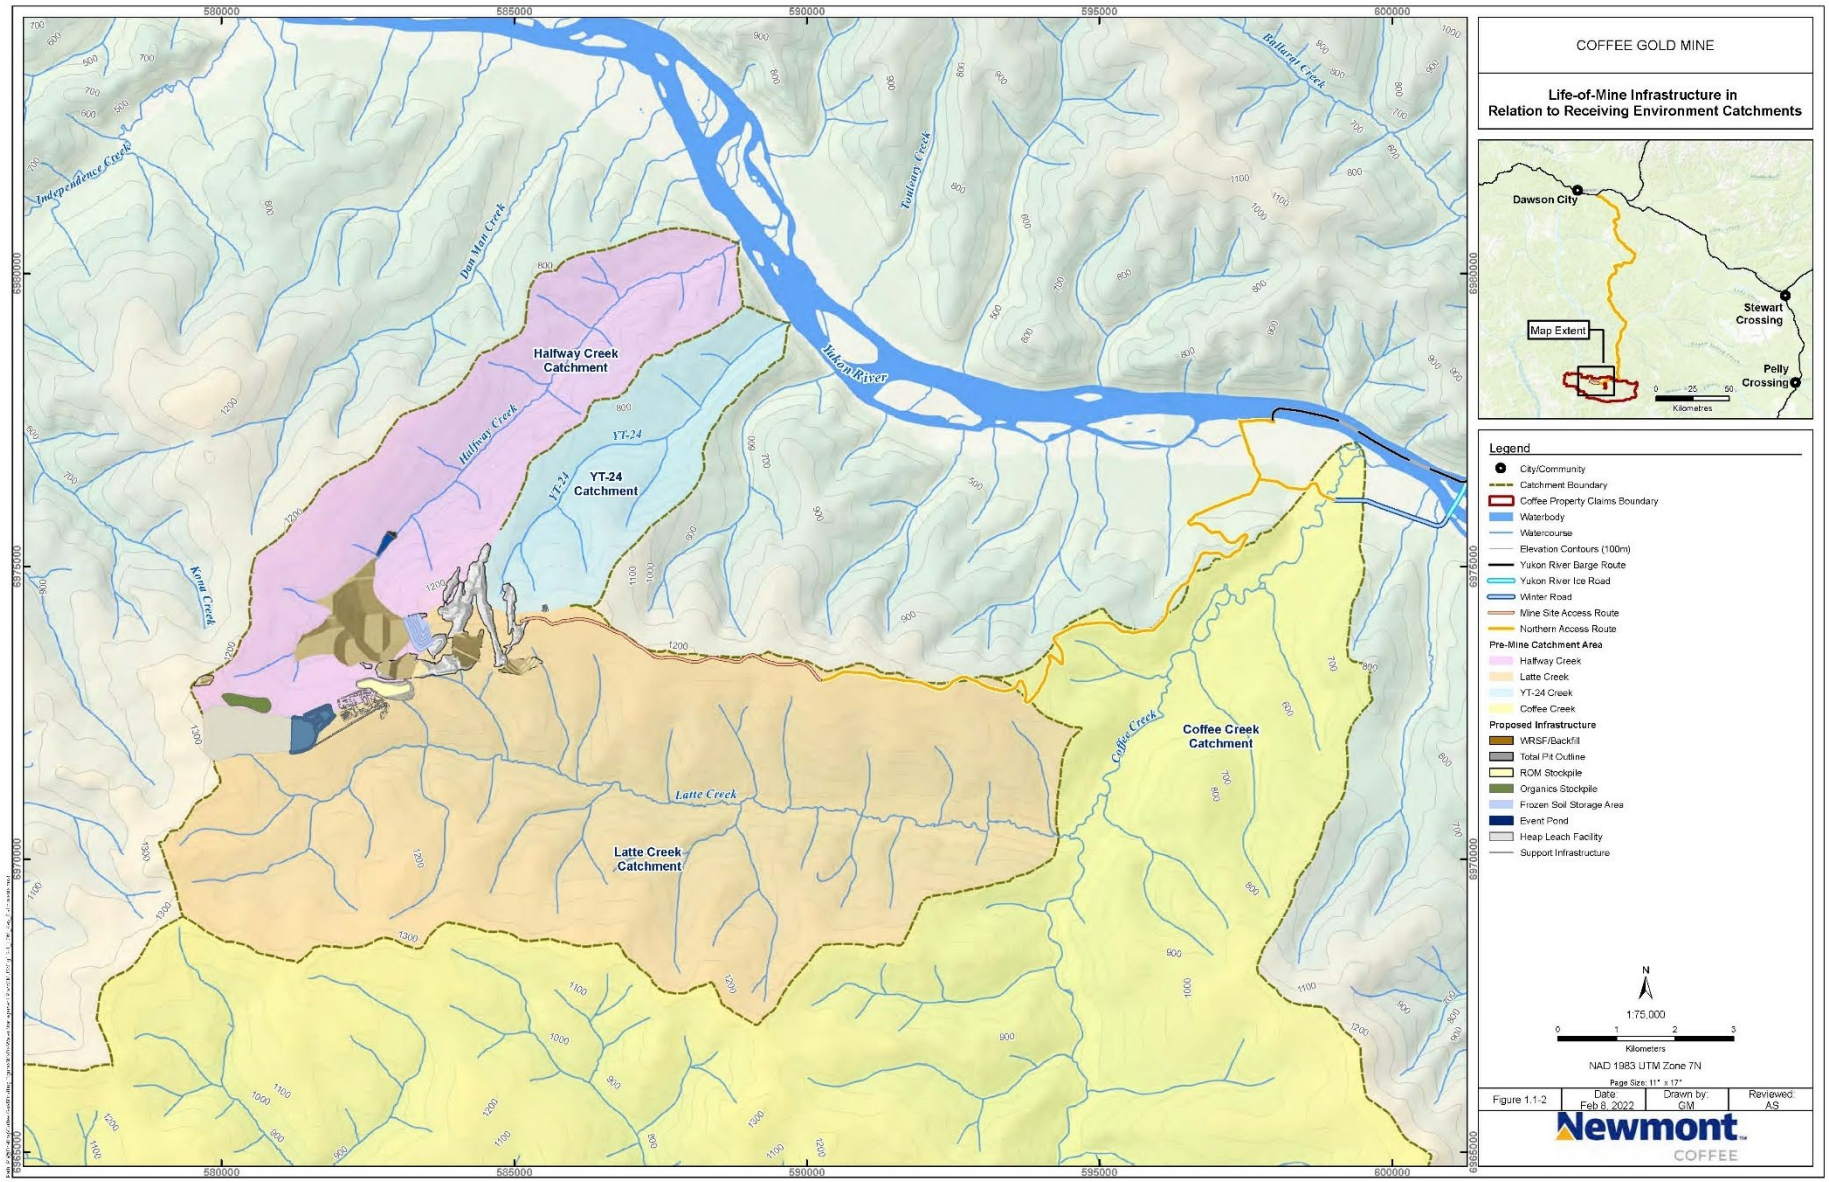

Figure 1.1-2: Life of Mine Coffee Gold Project Infrastructure Layout in Relation to Receiving Environment Catchments

1.2 Report Structure

Section 2 outlines the overarching objectives of the baseline water quality program and provides a description of the sampling stations and locations for each station monitored from 2010 to 2020. In addition, sampling and analytical methods are described along with a brief description of data analysis methods and quality assurance/quality control (QA/QC) programs. Section 3 presents the water quality baseline results for key project drainages on Latte Creek, Coffee Creek, Halfway Creek, YT-24, Independence Creek (reference stream) and Yukon River. The complete datasets for water quality data for each sampling station are provided in Appendix A.

2. Baseline Water Quality Program

Newmont™
COFFEE

2. Baseline Water Quality Program

2.1 Overview and Objectives

The Coffee Gold Project water quality program has been developed to fulfill the following objectives:

- Obtain (pre-mining) baseline data on water quality that can be used to assess potential changes in receiving aquatic environments related to Construction, Operation, Closure, and Post-closure Phases;
- Identify parameters that may naturally exceed water quality guideliens (WQGs) and therefore may require special management and/or site-specific water quality objectives (SSWQOs); and
- Provide baseline surface water quality data to be used as input for the water quality model (WQM) to derive predictions for key mining phases of the project.

As previously stated, the report characterizes surface water quality in receiving environment watercourses that may be affected by the Project, in addition to Independence Creek, which will remained unaffected by project activities and will be used as a reference stream. The immediate LSA includes Latte Creek, Halfway Creek and YT-24 – basins that contain project mining components. In addition, the LSA also includes sampling stations in Coffee Creek (located immediately upstream and downstream of the confluence with Latte Creek) and selected reaches of the Yukon River (from upstream of the Coffee Creek confluence to immediately downstream of the Independence Creek confluence) (Figure 2.1-1,Figure 2.1-2,Table 2.1-1).

Water quality monitoring is ongoing at the Project site and is planned to continue throughout the permitting phase. Upon issuance of mine licenses, an approved water quality program will continue throughout the mine development, operation and into closure phases.

Photographic records of key monitoring stations are provided in Plate 2.1-1 through Plate 2.1-5. Specifically, monitoring stations within Independence Creek are presented in Plate 2.1-1; Latte Creek stations are shown in Plate 2.1-2; Halfway Creek and YT-24 stations are illustrated in Plate 2.1-3; Coffee Creek stations are presented in Plate 2.1-4; and Yukon River stations are illustrated in Plate 2.1-5.

2.2 Field and Analytical Methods

2.2.1 Sampling Frequency and Locations

Figure 2.1-2 illustrates water quality sampling stations within the LSA sampled during the period of 2010 to present. Information pertinent to each station is provided in Table 2.1-1 including, coordinates; type (*e.g.*, reference or exposure); date of initial monthly sampling; and, rationale for selection. Although sampling is attempted on a monthly basis, site access and/or lack of flow (particularly during winter months) prevented sample collection at some stations. A new station on Coffee Creek named CC-10.9, was initiated in July 2017 aimed to characterize the immediate mixing zone of Latte Creek and Coffee Creek. During the month of October 2017, monitoring stations HC-6.8, LC-11.4, CC-10.9 and CC-3.2 were subjected to a 5 in 30 sampling event to better define water quality variability at these key monitoring stations.

2.2.2 Field Sampling Methods

During the period of October 2010 to May 2014, Access Consulting Group conducted the surface water quality sampling program for the Coffee Project. In June 2014, Lorax assumed responsibility for the surface water quality program and commissioned Laberge Environmental Services (Laberge) to perform monthly water quality sampling. Since June 2014, Laberge has collected all the surface water quality samples on a monthly basis. All collected water samples followed the protocols described in the *British Columbia Field Sampling Manual* (BC MOE 2013).

During open water periods, samples were collected by wading into the small streams to the thal-weg and filling bottles with gloved hands while facing upstream into the current. For larger streams and rivers, the same procedure was followed only closer to the bank and usually in not more than 0.2 m depth. During open water periods, field filtering and sample preservation are completed at the collection site. Water samples collected during winter time are sometimes obtained by drilling or chiseling through the ice, an additional 1-L bottle is filled for processing at the end of the day at room temperature in a clean room.

After samples were collected, a YSI Sonde was placed in the water to log *in-situ* water quality parameters such as temperature, pH, specific conductance, Dissolved Oxygen (DO) and Oxidation-Reduction Potential (ORP).

2.2.3 Laboratory Methods

Collected samples were analyzed for a suite of parameters listed in Table 2.2-1, which include physical parameters (*e.g.*, pH, conductivity, hardness, total suspended solids [TSS], total dissolved solids [TDS], turbidity), major ions, nutrients (*e.g.*, ammonia), total organic

carbon (TOC) and dissolved organic carbon (DOC), weak acid dissociable cyanide (WAD-CN), and total and dissolved metals. Elemental analyses were performed by Maxxam Analytics Laboratory (Burnaby, BC; [Maxxam]) a Canadian Association for Laboratory Accreditation (CALA) certified laboratory. Maxxam also provided all sampling containers and bottles, including the preservative required, and parameter specific sampling instructions.

Conventional parameters, major ions, nutrients, and metals were analyzed using procedures described in APHA Standard Methods for the Examination of Water and Wastewater (2005). Cyanide analysis was carried out using procedures adapted from APHA Method 4500-CN "Cyanide", whereas WAD cyanide was determined by sample distillation and analysis using the chloramine-t colourimetric method. The lowest available limit of detection for metals was achieved by using inductively coupled plasma/mass spectrometry ([ICP/MS]; EPA Method 6020). Mercury analysis in water was carried out by cold vapor atomic fluorescence spectrophotometry (EPA Method 245.7). This procedure involves a cold-oxidation of the acidified sample using bromine monochloride prior to reduction of the sample with stannous chloride.

For the baseline period of 2010 to 2020, laboratory detection limits have been excellent and very low allowing for comparison of monitoring results with applicable water quality guidelines, including Canadian Council of Ministers of the Environment (CCME 1999) and British Columbia Ministry of Environment & Climate Change Strategy ([BC ENV]; 2021).

Table 2.2-1:
Analytical Parameter List and Reportable Detection Limits

Analysis		Reportable Detection Limit
Physical Parameters		
Conductivity	µS/cm	1.0
Hardness (as $CaCO_3$)	mg/L	0.5
pH	pH	0.01 unit
Total Suspended Solids (TSS)	mg/L	1.0
Total Dissolved Solids (TDS)	mg/L	10.0
Turbidity	NTU	0.1
Major Ions and Nutrients		
$Alkalinity_{Total}$ (as $CaCO_3$)	mg/L	0.5
$Alkalinity_{PP}$ (as $CaCO_3$)	mg/L	0.5
Bicarbonate (HCO_3)	mg/L	0.5
Cabonate (CO_3)	mg/L	0.5
Chloride (Cl)	mg/L	0. 5
Sulphate (SO_4)	mg/L	0.5
Fluoride (F)	mg/L	0.01
Nitrate (as N)	mg/L	0.002
Nitrite (as N)	mg/L	0.002
Total Ammonia (as N)	mg/L	0.005
Nitrate plus Nitrite (as N)	mg/L	0.002
Total Phosphorus as P	µg/L	0.002
Cyanide and Organic Carbon		
Weak acid dissociable cyanide (CN_{WAD})	mg/L	0.0005
Total Organic Carbon (TOC)	mg/L	0.5
Dissolved Organic Carbon (DOC)	mg/L	0.5

Titanium (Ti)	µg/L	0.5
Uranium (U)	µg/L	0.002
Vanadium (V)	µg/L	0.2
Zinc (Zn)	µg/L	0.1

2.2.4 Data Analysis

Laboratory results data for all monitoring sites have been compiled into summary data sheets for the period of 2010 to December 2020 (Appendix A). Where applicable, water quality parameters were screened against available CCME guidelines (CCME 1999) and approved and working BC guidelines (BC ENV 2021) for the protection of aquatic life. Most of the CCME guidelines are defined for long-term exposure, although chloride, nitrate and uranium have both short-term (maximum) and long-term (chronic) guidelines.

Parameters that reported *below detection limits* were assumed as full value to perform statistical analysis (*e.g.*, <0.05 µg/L is assumed to be 0.05 µg/L). Following the conversion of below detection limit values for all parameters, monthly and annual summary statistics were compiled for selected sites within all the project drainage basins. Minimum, maximum, mean, 5th percentile, 25th percentile, 50th percentile, 75th percentile and 95th percentile values were calculated for key stations in each basin (Appendix C).

2.2.5 Quality Assurance/Quality Control

Quality Assurance/Quality Control protocols were implemented and designed to provide reliable monitoring data by reducing sampling error, preventing contamination due to sample handling, and quantifying any bias in the results. In the field, nitrile gloves were worn while sampling and changed regularly, particularly between stations. Chain of custody forms describing sampling location, date, time and analytical requirements were submitted with each sample set.

For each monthly sampling event a field blank was prepared using distilled-deionized water (DDW) supplied by Maxxam. Field blank bottles were filled with DDW in the laboratory and were treated similarly to field-collected samples (*i.e.,* exposed to the air for the same amount of time it took to collect and preserve a sample). This allows the evaluation of potential contamination from sources such as airborne dust, sample preservation, or sample handling. To assess the potential variability arising from the collection of field samples, duplicate samples were collected at roughly 10% of surface water quality sites. Travel blanks were collected to provide an assessment of potential contamination associated with travel, storage, or the analytical laboratory. Travel blank bottles were filled with DDW at the analytical laboratory and were stored with field-collected samples without being opened. All samples and blanks were kept cold (~ 4 °C) until analysis. Duplicates, field and travel blanks were analyzed for the same suite of water quality parameters than collected samples (Table 2.2-1).

3. Water Quality Results

Newmont™
COFFEE

3. Water Quality Results

This section presents a characterization of baseline water quality in the drainages of Latte Creek, Coffee Creek, Halfway Creek, Yukon River and the Independence Creek (reference stream). Compiled raw water quality results data for all stations sampled during the period of 2010 to 2020 is provided electronically in excel format (Appendix A).

Baseline water quality characterization is presented and described by catchment:

- Section 3.1 characterizes baseline water quality in Latte Creek utilizing monitoring data primarily from stations LC-15.5 for upper Latte Creek and stations LC-11.4 and LC-0.2 for mid-reach and lower-reach of Latte Creek;
- Section 3.2 provides a summary of water quality in Coffee Creek at locations both upstream and downstream of the project area. Data from station CC-11.6 (upstream of project influences) and CC-3.2 (downstream of confluence with Latte Creek) are utilized to characterize baseline conditions in Coffee Creek;
- Baseline water quality in the Halfway Creek drainage (Section 3.3) is characterized using data from stations HC-6.8 and HC-1.0;
- Section 3.4 provides a brief description of water quality in Yukon River upstream of the project area at YUK-51.3 and downstream of project influence at YUK-26.1; and
- Section 3.5 provides a description of water quality in the Independence Creek catchment using data from station IC-2.7 (mainstem) and KT-0.4 (tributary to Independence and downgradient of Kona deposit).

Monthly summary statistics for each drainage are briefly discussed below and fully compiled in Appendix C.

3.1 Latte Creek

Background water chemistry in Latte Creek can be divided between upper Latte Creek and mid to lower Latte Creek. In general, upper Latte Creek water chemistry is dominated by surface runoff whereas mid to lower Latte Creek water chemistry is influenced by both groundwater discharge, as well as surface runoff during the ice-free periods. No measurable flow has been observed in upper Latte Creek during winter sampling campaigns (*e.g.*, November to March), suggesting little to no groundwater baseflow contributions during these periods. Conversely, mid to lower Latte Creek monitoring stations LC-11.4 and LC-0.2 are more routinely sampled during low-flow periods of the winter owing to groundwater baseflow discharge to these reaches of Latte Creek.

3.1.1 Upper Latte Creek – Station LC-15.5

Upper Latte Creek is characterized by water quality samples taken at Station LC-15.5 (Figure 3.1-1), which includes contributions from two small tributaries (represented by stations CC-5.5 and CC-5.0) in the headwaters.

Upper Latte Creek sampling locations were established in 2014 in the baseline surface water quality monitoring program due to adjustments in mine planning. As previously mentioned, flow is not observed during winter months in this section of the creek, therefore limited water samples have been collected at these locations. Given that seasonal variability in Latte Creek has been well characterised, the water quality dataset is considered reliable and robust.

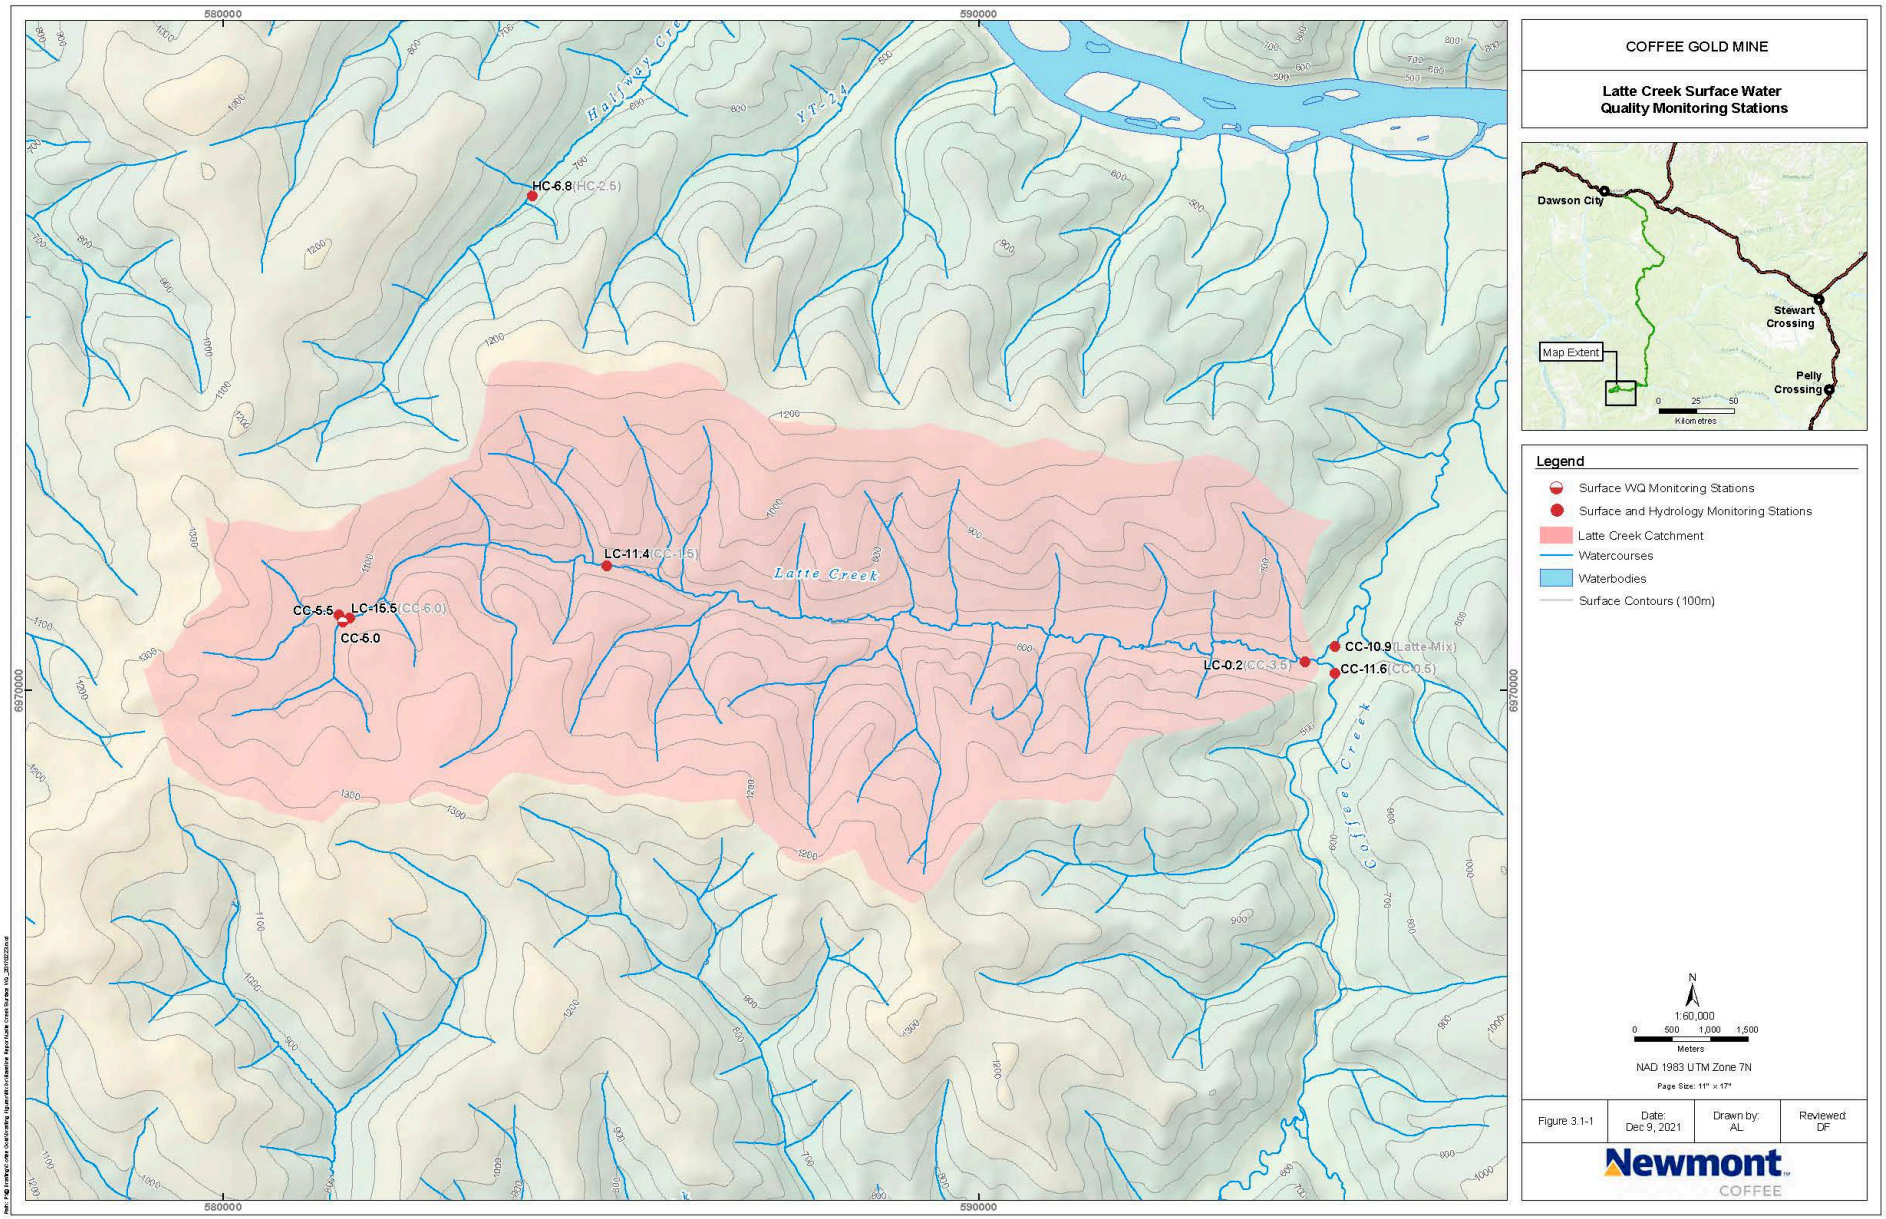

Figure 3.1-1: Detail of Latte Creek drainage illustrating key monitoring station locations

3.1.1.1 Summary Statistics

Table 3.1-1 summarizes the mean monthly values for a suite of the key parameters for station LC-15.5 for the period of June 2014 to December 2020.

3.1.1.2 Major Ions

The major ion chemistry of upper Latte Creek is assessed with respect to conductivity, hardness, alkalinity, sulphate and pH. Upper Latte Creek is characterized by very soft waters, with monthly mean hardness values ranging from only 11 to approximately 21 mg/L (as $CaCO_3$) at station LC-15.5 (Table 3.1-1; Appendix B). Similarly, conductivity values measured at LC-15.5 are very low with values generally < 31 µS/cm (except in April, where mean conductivity values are 57 µS/cm). The low hardness and conductivity values in LC-15.5 are clear characteristics of a system dominated by snow-melt and surface run-off. Indeed, sample collection during the period of November to March has not occurred due to the absence of flow (Table 3.1-1).

The pH in upper Latte Creek is dominantly circumneutral to mildly acidic with values generally ranging between pH 6.1 to 6.9. Observed pH values reported to date have largely remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in upper Latte Creek are very low and generally present at concentrations very near or below the analytical detection limit of 0.5 mg/L (Table 3.1-1). Measured TSS concentrations in upper Latte Creek are generally low with mean values ranging from 1.4 to 17 mg/L (Table 3.1-1).

3.1.1.3 Nutrients

Nutrients quantified in upper Latte Creek include nitrate, nitrite, ammonia, and dissolved phosphorus. In overview, nutrient parameters show low values in upper Latte Creek. Ammonia-Nitrogen (N) concentrations are low with mean monthly values typically below 0.034 mg/L (Table 3.1-1). Similar to ammonia, baseline nitrite-N and nitrate-N concentrations in upper Latte Creek are also low, with mean monthly values ranging from approximately 0.002 to 0.1 mg/L.

Primary productivity in freshwaters is typically limited by available phosphorus. Accordingly, measurements of phosphorus compounds in surface waters can provide an indication of potential changes in trophic status (*i.e.*, productivity regime). Baseline concentrations for mean monthly dissolved phosphorus in upper Latte Creek are low, ranging from approximately 0.004 to a maximum of 0.017 mg/L (Table 3.1-1). Mean dissolved phosphorus for all sampling events at LC-15.5 was 0.0068 mg/L indicative of oligotrophic conditions in upper Latte Creek waters (Appendix C).

Total organic carbon reflects a combination of DOC and particulate phases associated with both aquatic and terrestrial organic matter. Highest values of TOC and DOC are typically observed during high flow periods, likely reflecting contributions of particulate carbon associated with terrestrial runoff. Mean monthly TOC and DOC levels in upper Latte Creek are relatively high, ranging between approximately 7.8 to 20 mg/L, with highest values observed during peak flow periods.

3.1.1.4 Trace Elements

Baseline trace element concentrations in upper Latte Creek were derived from data collected from June 2014 to December 2020 at LC-15.5. In general, mean monthly concentrations of total and dissolved trace elements are low (*e.g.,* Arsenic [As], antimony [Sb], cobalt [Co], copper [Cu], chromium [Cr], lead [Pb], mercury [Hg], nickel [Ni], selenium [Se], uranium [U] and zinc [Zn]). For example, total As and total U concentrations at LC-15.5 are typically well below 1.0 µg/L (Table 3.1-1). Conversely, dissolved aluminum (Al) is consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L, with highest concentrations coinciding with higher flow conditions (Figure 3.1-2) during freshet (*e.g.*, May and June).

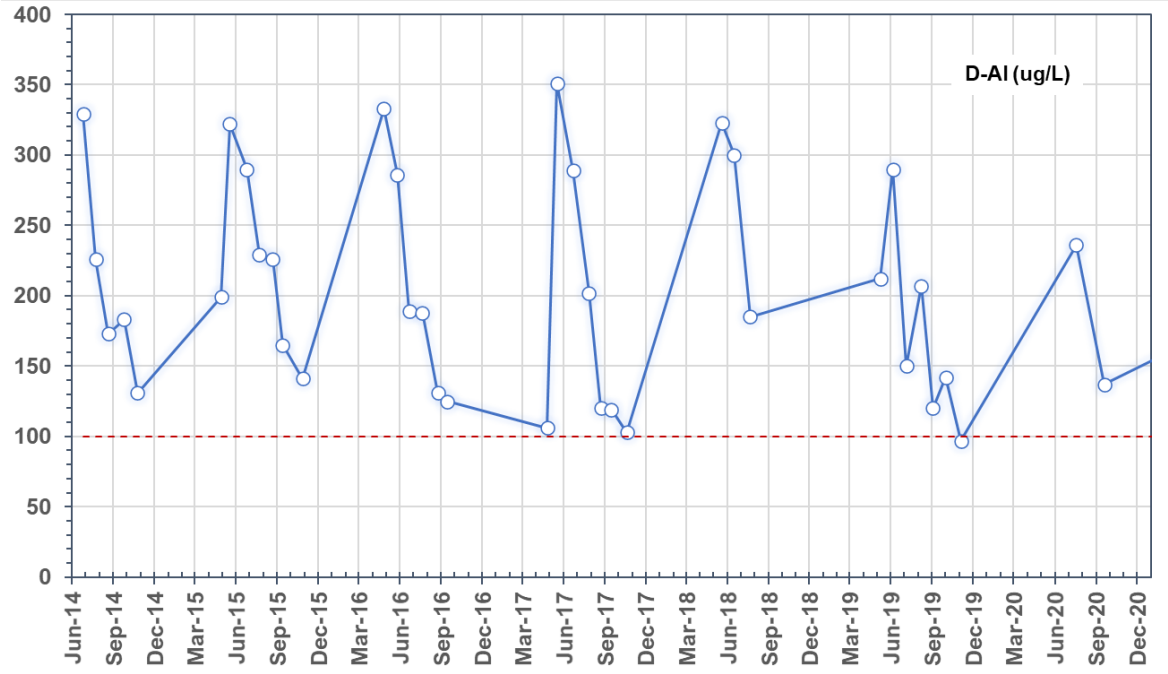

Figure 3.1-2: Dissolved aluminum (D-Al) concentrations (µg/L) at LC-15.5 in upper Latte Creek for the period June 2014 to December 2020 compared to the British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines for protection of aquatic life (dashed red lines).

Concentrations of total Cu show seasonal maxima associated with peak runoff periods (April-May) marginally exceeded the CCME hardness-based total Cu guideline for the protection of aquatic life of 2.0 µg/L (Figure 3.1-3).

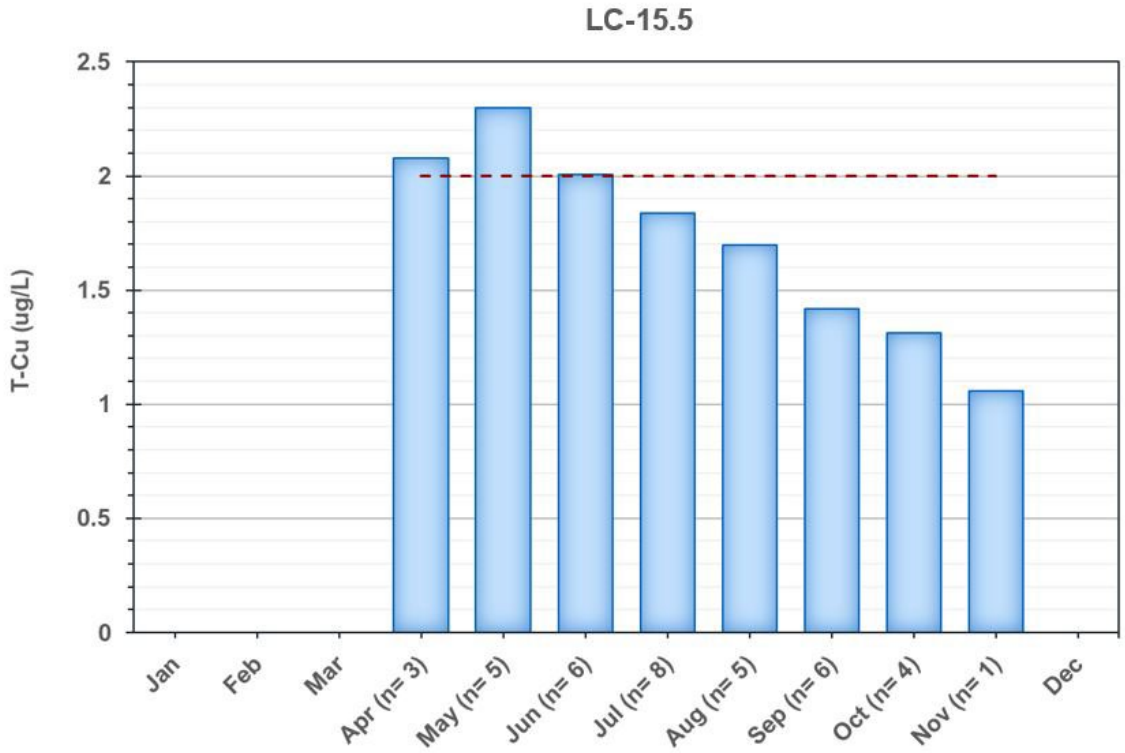

Figure 3.1-3: Total copper (T-Cu) concentrations (µg/L) at LC-15.5 in upper Latte Creek for the period June 2014 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent guideline value (red dashed line) for the protection of aquatic life.

Similar to copper, total Cd concentrations slightly exceed the CCME hardness-dependent chronic guideline (long-term) for protection of aquatic life during peak flow periods in April and May (Figure 3.1-4). However, Cd concentrations did not exceed the CCME acute (or short-term) water quality guidelines for the protection of aquatic life.

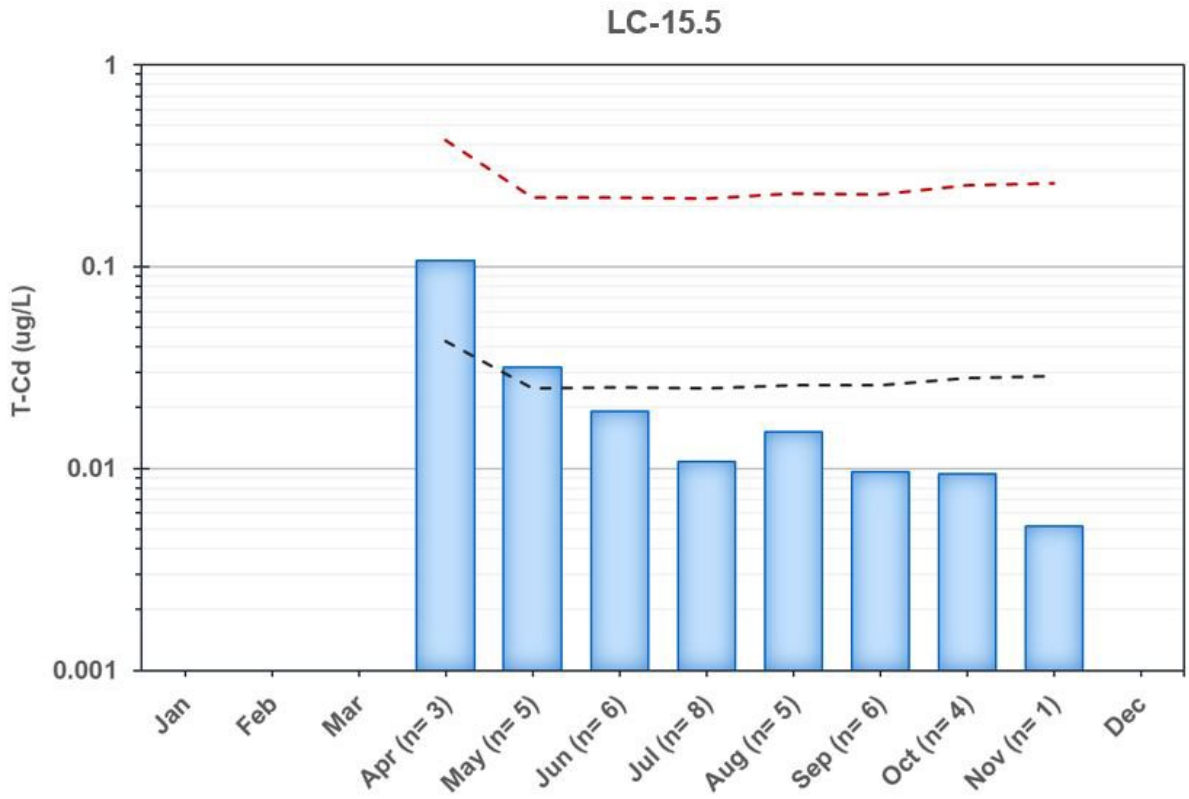

Figure 3.1-4: Total cadmium (T-Cd) concentrations (µg/L) at LC-15.5 in upper Latte Creek for the period June 2014 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent guideline value for the protection of aquatic life.

3.1.2 Mid and Lower Latte Creek – Stations LC-11.4 and LC-0.2

Water quality in mid-reach and lower-reach Latte Creek is distinctly different from the conditions previously described for upper Latte Creek. Groundwater baseflow contributions produce a more pronounced seasonal signature in water chemistry. In addition, with more significant groundwater contributions, periods with little to no surface flow still result in measurable streamflow within Latte Creek. As a result, monitoring of water quality has been possible through all months of the year.

Mid-reach Latte Creek is characterized by water quality data collected at station LC-11.4 for the period of October 2010 to December 2020 (Figure 3.1-1). This station in Latte Creek is located approximately 50 m downstream of the confluence of a small ephemeral tributary that has been monitored at station LCT20-0.1 since June 2014. Lower Latte Creek is characterized by water quality data collected at station LC-0.2 for the period of October 2010 to December 2020.

3.1.2.1 Summary Statistics

Table 3.1-2 and Table 3.1-3 summarize the mean monthly values for a suite of the key parameters for station LC-11.4 and LC-0.2, respectively.

Table 3.1-2:
LC-11.4 Mean Monthly Values

3.1.2.2 Major Ions

The major ion chemistry of mid-reach and lower-reach Latte Creek is assessed with respect to conductivity, hardness, alkalinity, sulphate and pH. Station LC-11.4 is characterized by seasonally soft waters (approximately < 90 mg/L [as $CaCO_3$]) during freshet months (May to June) and hard to very hard waters (ranging from 110 mg/L to > 420 mg/L [as $CaCO_3$]) during lower flow periods and winter low flows (Figure 3.1-5).

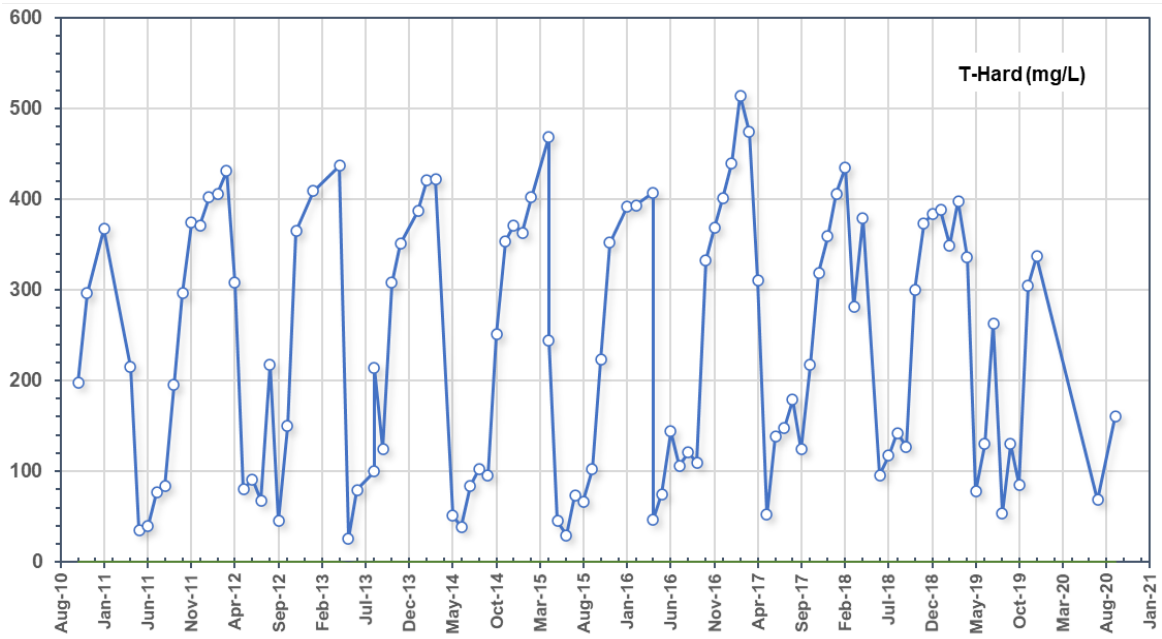

Figure 3.1-5: Total Hardness (T-Hard., as mg/L $CaCO_3$) in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020.

In lower Latte Creek, hardness values show a similar seasonal trend, with minima occurring during freshet or following precipitation runoff events. Hard to very hard waters dominate the fall and winter flow conditions with mean values ranging between approximately 170 mg/L to 240 mg/L $CaCO_3$ (Table 3.1-3; Figure 3.1-6).

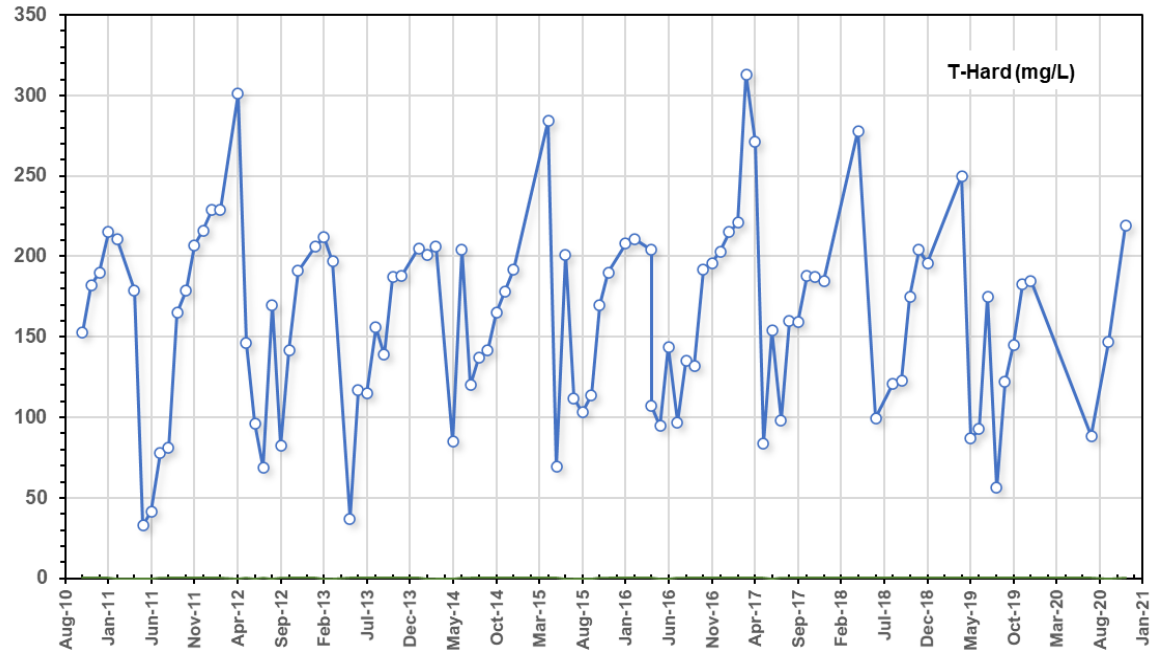

Figure 3.1-6: Total Hardness (T-Hard., as mg/L $CaCO_3$) in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020.

Similar trends for conductivity and alkalinity are also observed with pronounced seasonal fluctuations, with minima coinciding with freshet periods in May and June (Table 3.1-2 and Table 3.1-3). Overall, such trends in stream salinity reflect varying proportions of snow-melt driven surface runoff (lower ionic strength) and groundwater inputs (higher ionic strength) as driven by the seasonal water balance. The stronger seasonal signature observed in mid Latte Creek at LC-11.4 reflects the influence of waters entering Latte Creek from the small tributary monitored at station LCT20-0.1 (Appendix B).

The pH in mid and lower Latte Creek remains relatively uniform throughout the year with values generally ranging between 7.0 and 8.0. The neutral to slightly basic pH conditions can be linked to bicarbonate alkalinity. All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in mid and lower Latte Creek are notably much higher than in upper Latte Creek. While upper Latte Creek had very low sulphate concentrations the reported concentrations in mid to lower Latte Creek (LC-11.4) ranged between 20 to 210 mg/L, and approximately 37 to 110 mg/L in lower Latte Creek (LC-0.2; Table 3.1-2 and Table 3.1-3). Sulphate minima during high flow can be attributed to the influence of low ionic strength melt waters, while higher values during the low-flow periods reflect an increased proportion of groundwater inputs.

Unlike the dissolved ions, higher TSS concentrations in mid and lower Latte Creek generally coincide with the peak snowmelt months or during intense rainfall events in summer months (Table 3.1-2 and Table 3.1-3). At most other flow periods of the year, TSS values in Latte Creek were generally below 3.0 mg/L.

3.1.2.3 Nutrients

Nutrients are found in low concentrations in mid and lower Latte Creek. Ammonia-N concentrations are low with mean monthly values typically between roughly 0.01 to 0.08 mg/L for LC-11.4 and 0.01 to 0.04 mg/L for LC-0.2 (Table 3.1-2 and Table 3.1-3). Nitrate-N and nitrite-N concentrations in mid and lower Latte Creek were comparably higher than upper Latte Creek. Baseline mean nitrate-N concentrations in mid Latte Creek (LC-11.4) ranged from 0.1 to 0.4 mg/L, with highest monthly means observed during winter low flows. Similarly, monthly mean nitrate-N concentrations in lower Latte Creek (LC-0.2) ranged from 0.06 to 0.5 mg/L, again with highest monthly means observed during winter low flow conditions. Dissolved phosphorus concentrations at both stations were low (LC-11.4 mean of 0.0058 mg/L and LC-0.2 mean of 0.0052 mg/L) and indicative of oligotrophic conditions.

Similar to upper Latte Creek, TOC and DOC exhibit a marked seasonal signature with highest values observed during peak runoff periods. The DOC concentrations range from less than 5.0 mg/L during baseflow periods, dominated by groundwater inputs, to upwards of 22 mg/L during higher flow periods reflecting carbon contributions associated with terrestrial runoff (Figure 3.1-7 and Figure 3.1-8).

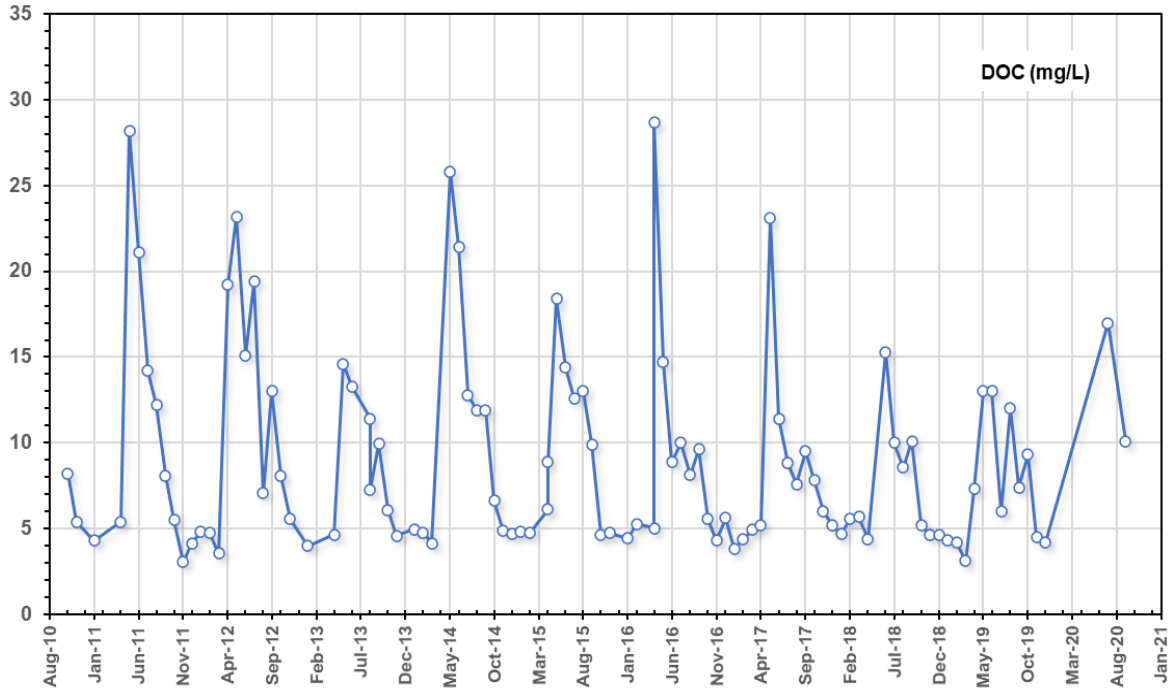

Figure 3.1-7: Dissolved organic carbon (DOC mg/L) in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020.

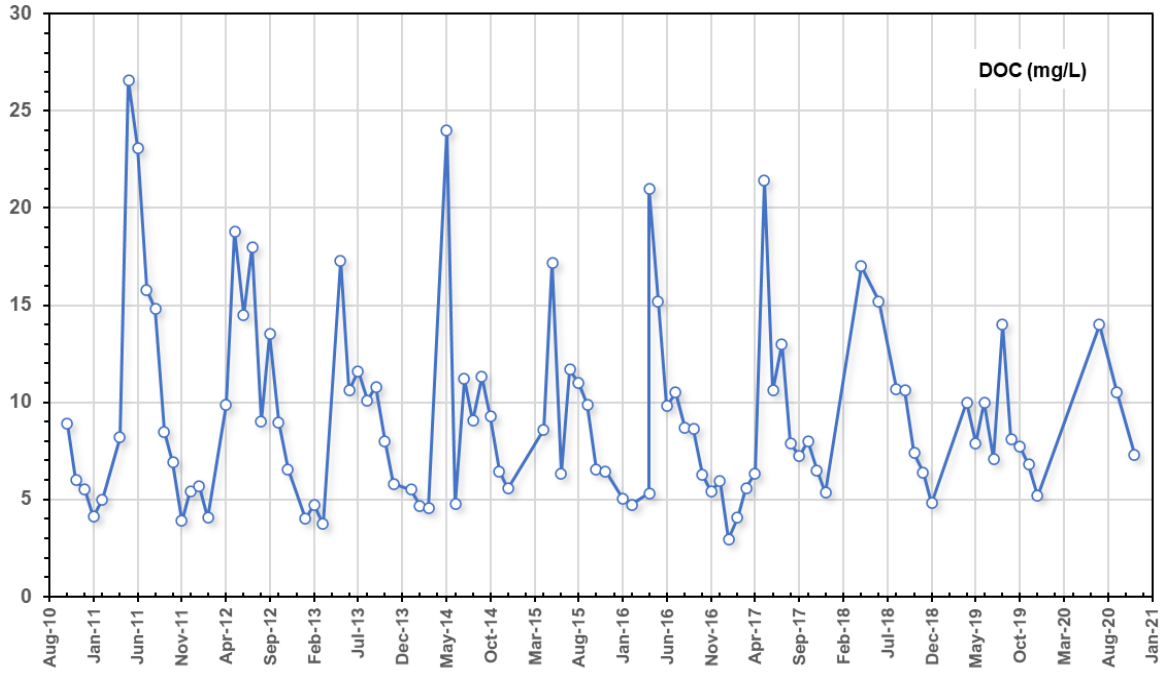

Figure 3.1-8: Dissolved organic carbon (DOC mg/L) in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020.

3.1.2.4 Trace Elements

Baseline trace element concentrations in mid (LC-11.4) and lower Latte Creek (LC-0.2) were derived from data collected from October 2010 to December 2020. For most parameters, mean monthly concentrations of total and dissolved trace elements are considered to be low (*e.g.*, As, Sb, Co, Cr, Pb, Hg, Ni, Se, and Zn). Total As concentrations in mid Latte Creek at LC-11.4 are typically around 0.6 to 2.4 µg/L with maximum concentrations of total As observed coincident with high flow events (Figure 3.1-9).

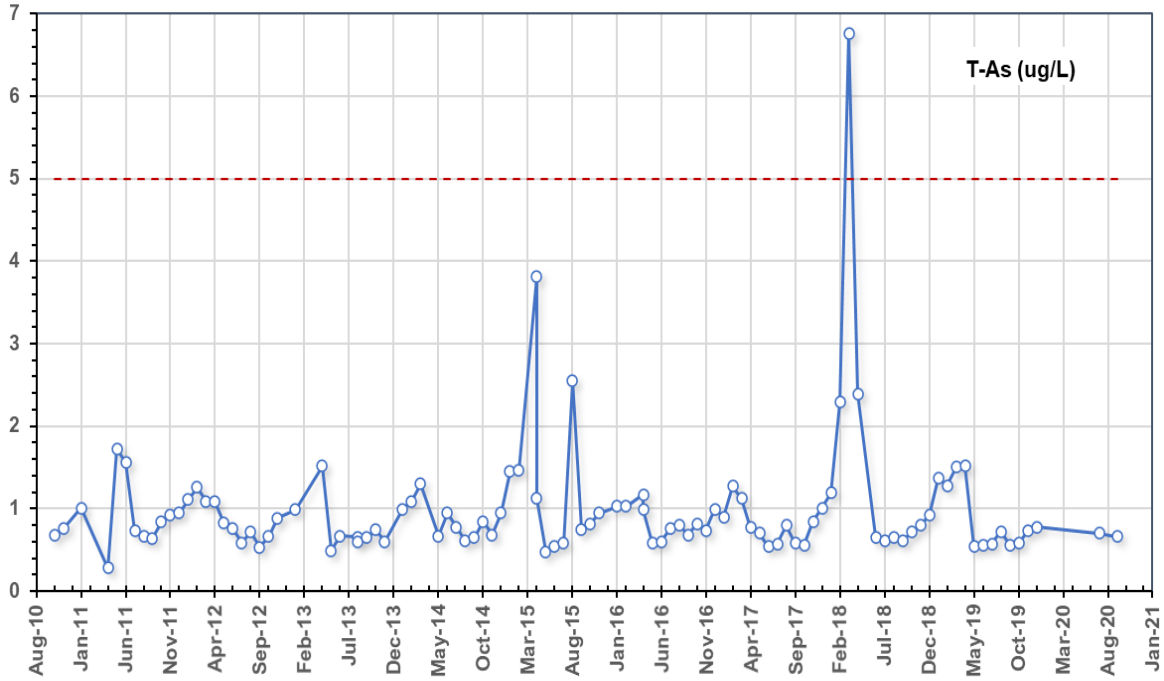

Figure 3.1-9: Total arsenic (T-As) in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020 compared to Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed line) for the protection of aquatic life.

In lower Latte Creek at station LC-0.2, total As concentrations are lower and consistently below 0.6 µg/L (Table 3.1-3 and Figure 3.1-10) and well below the CCME guideline of 5.0 µg/L for the protection of aquatic life.

Total Se concentrations in mid (LC-11.4) and lower (LC-0.2) Latte Creek are typically less than 0.3 µg/L (Table 3.1-2 and Table 3.1-3).

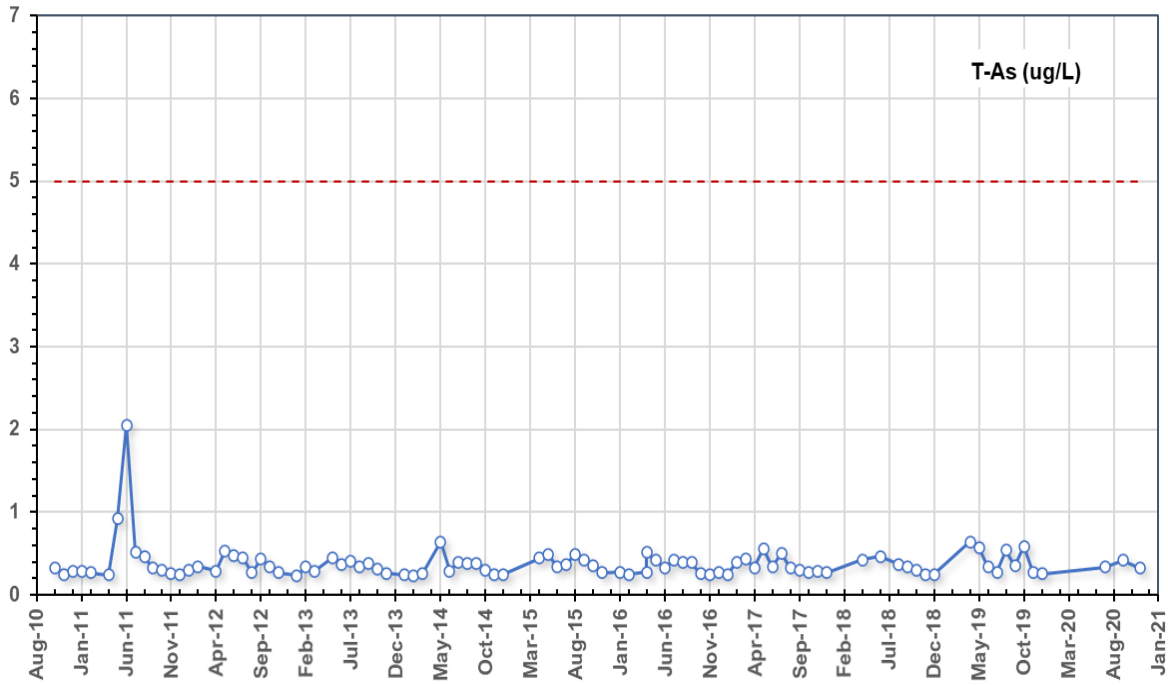

Figure 3.1-10: Total arsenic (T-As) in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020 compared to Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed line) for protection of aquatic life.

Similar to upper Latte Creek, dissolved Al is consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L throughout Latte Creek, with peak concentrations coinciding with higher flow conditions (Figure 3.1-11 and Figure 3.1-12). During baseflow periods, dissolved Al concentrations throughout Latte Creek are generally below 40 µg/L (Figure 3.1-11 and Figure 3.1-12).

Concentrations of total Cu in mid (LC-11.4) and lower (LC-0.2) Latte Creek show seasonal maxima associated with peak runoff periods that can episodically exceed the CCME hardness-dependent Cu guideline for the protection of aquatic life (Figure 3.1-13 and Figure 3.1-14.

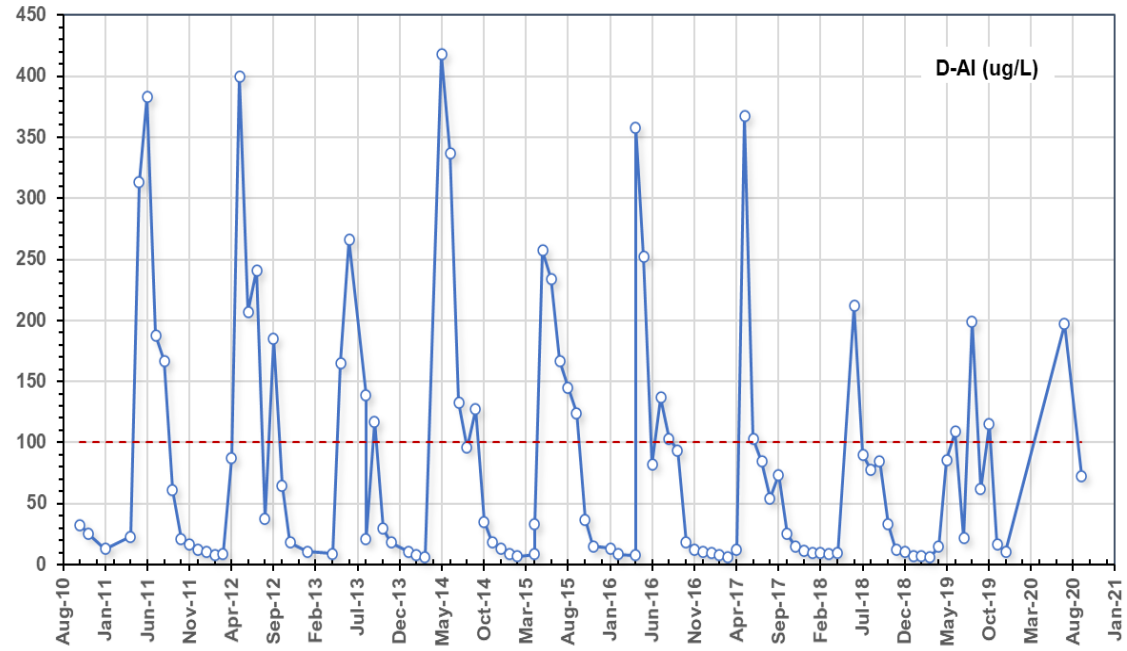

Figure 3.1-11: Dissolved aluminum (D-Al) in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020 compared to the British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

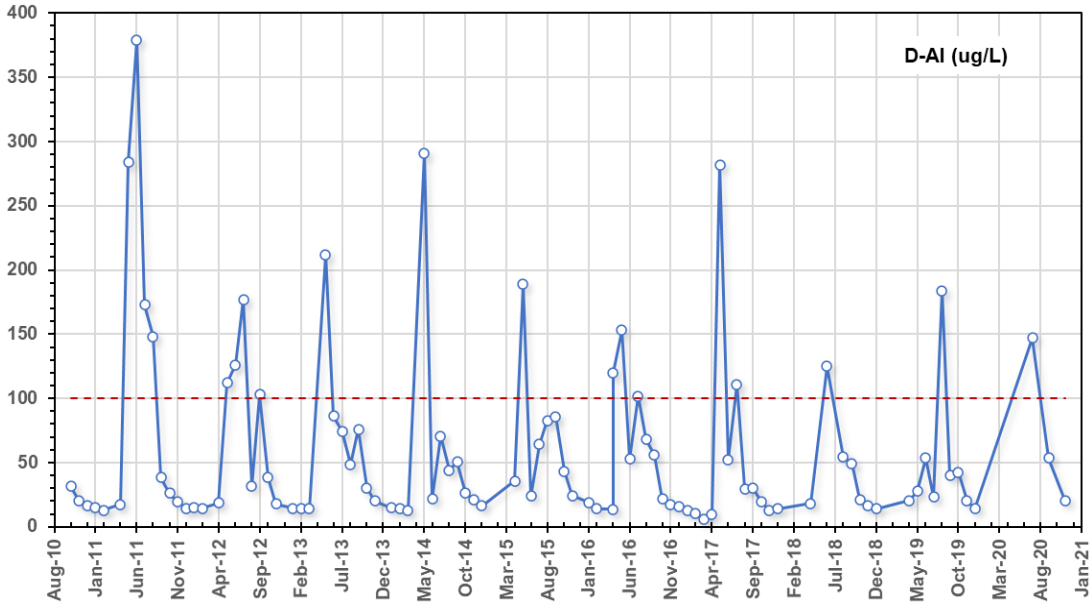

Figure 3.1-12: Dissolved aluminum (D-Al) in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life

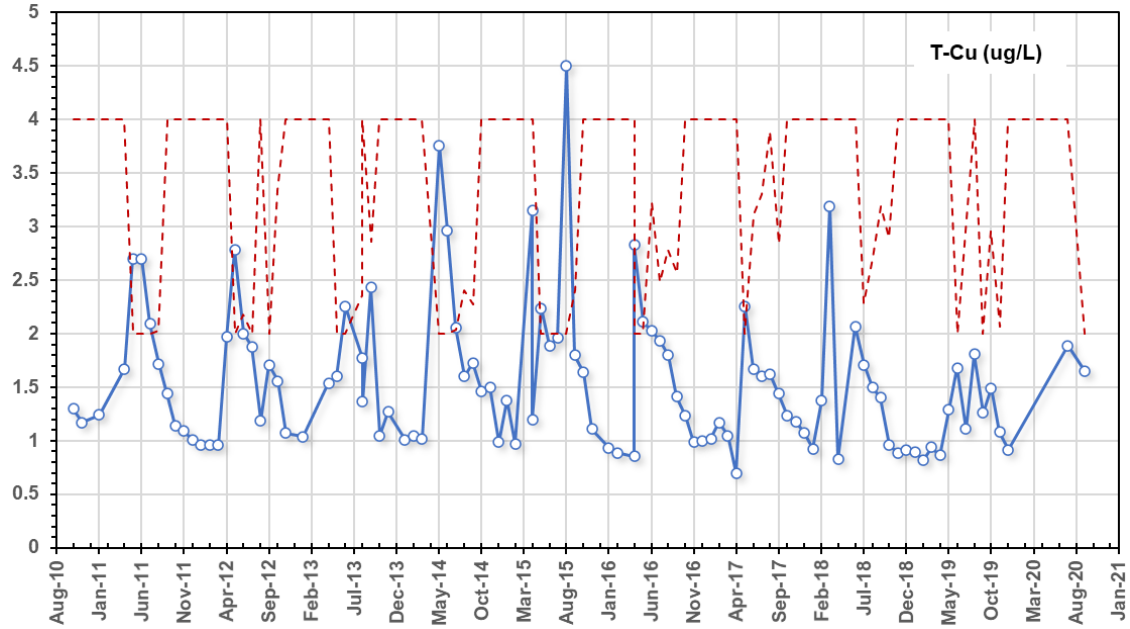

Figure 3.1-13: Total copper (T-Cu) in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness dependent water quality guidelines (red dashed line) for the protection of aquatic life.

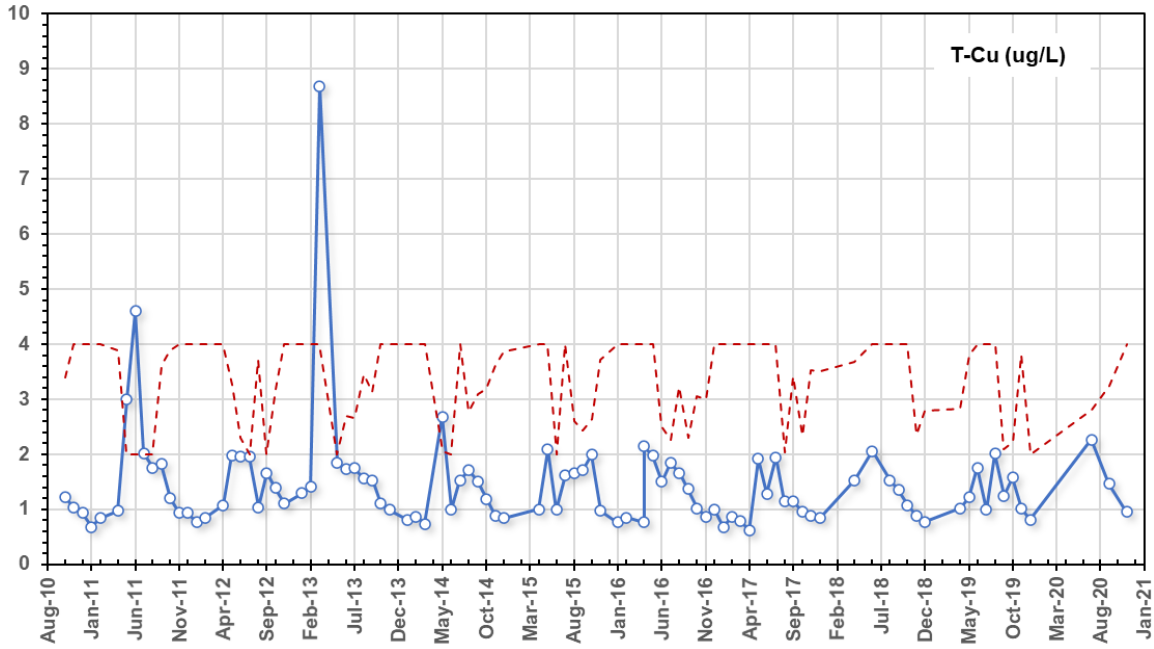

Figure 3.1-14: Total Cu in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness dependent water quality guidelines (red dashed line) for the protection of aquatic life.

With the exception of one instance in May 2016, mid (LC-11.4) and lower (LC-0.2) Latte Creek, total Cd concentrations do not exceed the chronic or acute CCME hardness-dependent guidelines for protection of aquatic life (Figure 3.1-15 and Figure 3.1-16).

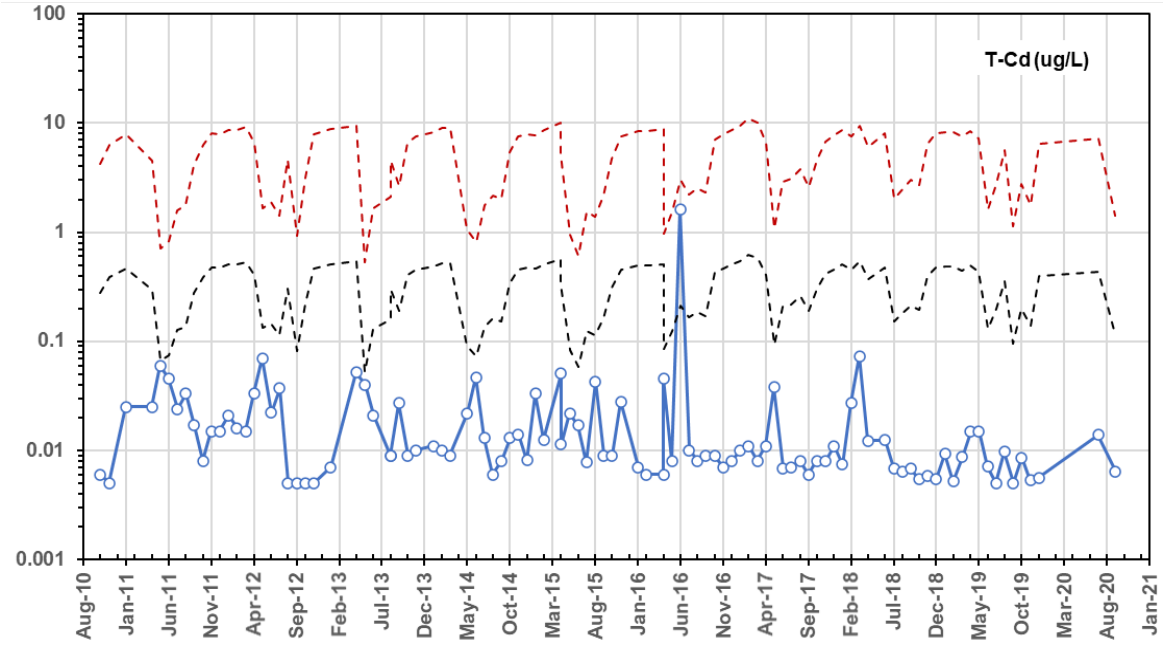

Figure 3.1-15: Total cadmium (T-Cd) concentrations in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness dependent water quality guidelines for the protection of aquatic life.

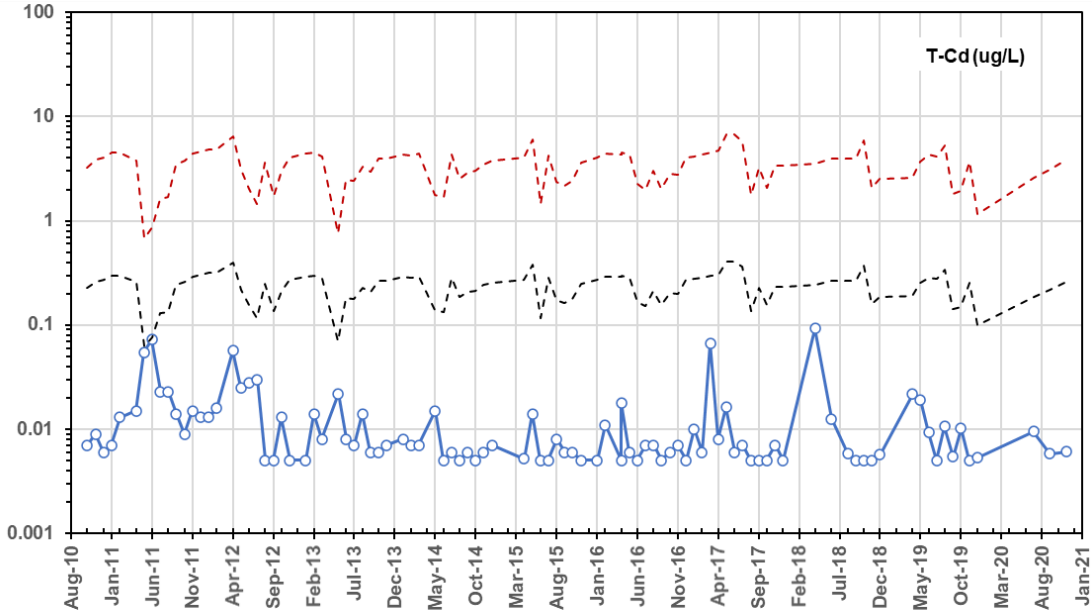

Figure 3.1-16: Total cadmium (T-Cd) concentrations in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness dependent water quality guidelines for the protection of aquatic life.

The most notable parameter of interest in mid and lower Latte Creek is U. Total and dissolved U concentrations in mid Latte Creek at station LC-11.4 show a distinct seasonal signature with maxima observed during winter low flow periods and coinciding with baseflow conditions. Concentrations during low flow periods can reach 35 µg/L and are often well above the CCME water quality guideline of 15 µg/L for the protection of aquatic life (Figure 3.1-17).

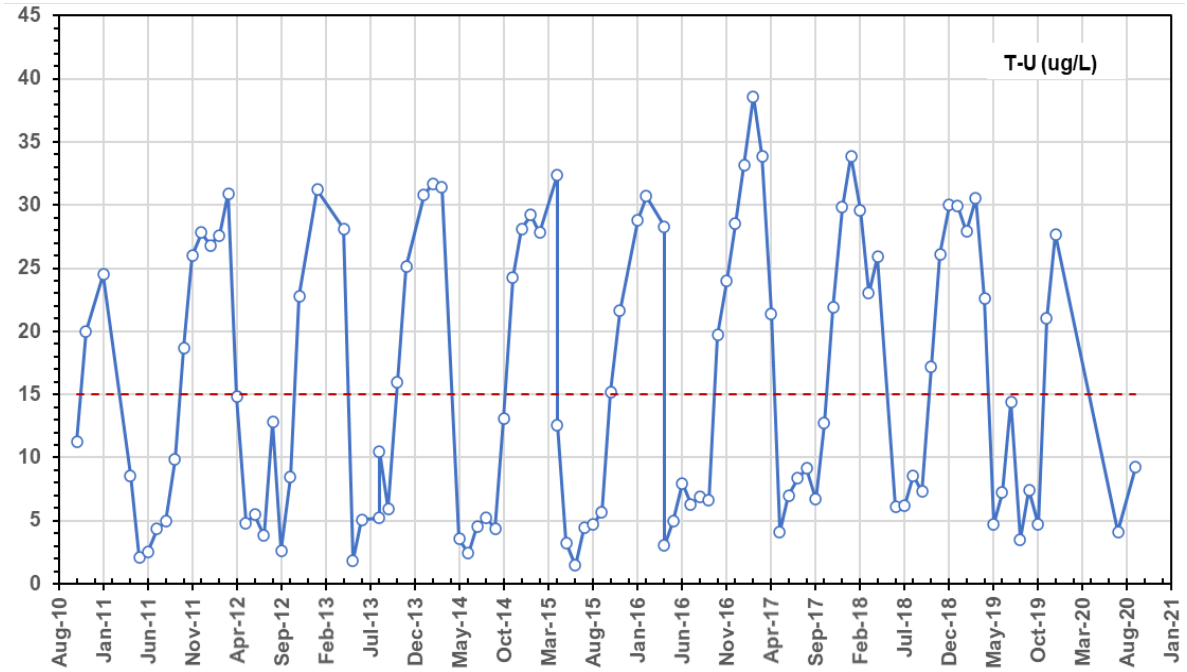

Figure 3.1-17: Total uranium (T-U) in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guideline (red dashed line) for the protection of aquatic life.

A strong inverse relationship ($r^2 = 0.86$) between total U and flow exists in mid Latte Creek at station LC-11.4 and is illustrated in Figure 3.1-18.

Graphical representation of monthly mean total U data at LC-11.4 illustrates concentrations in excess of the CCME guideline of 15 µg/L for U typically occurs from November to April (Figure 3.1-19).

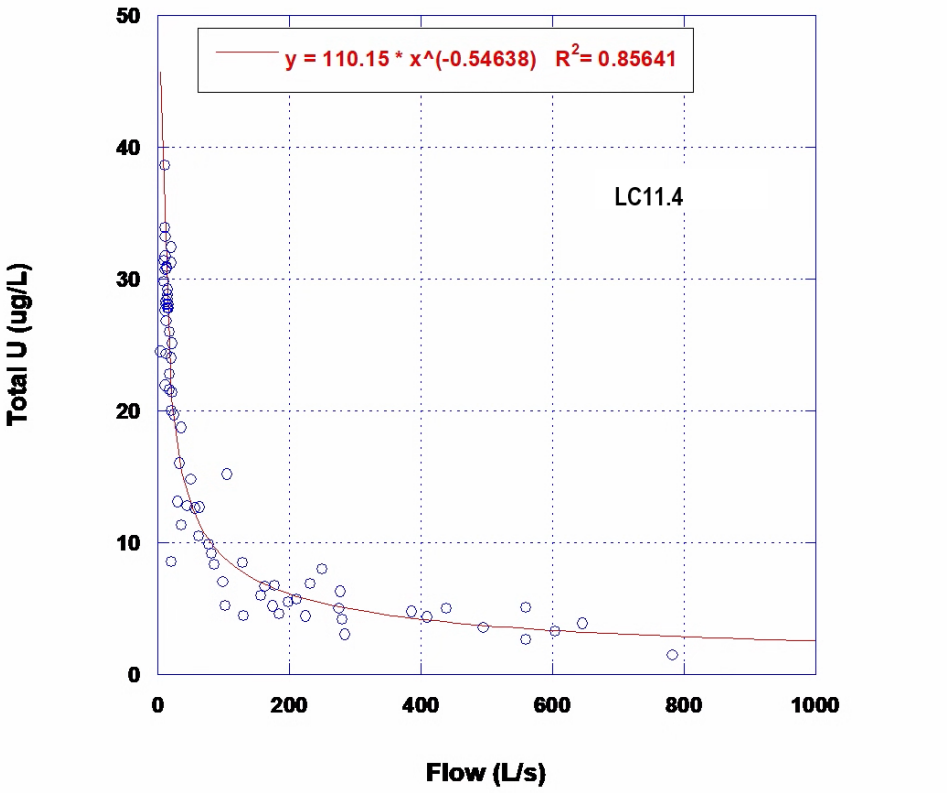

Figure 3.1-18: Relationship between total U and flow in mid Latte Creek (LC-11.4) for the period October 2010 to December 2020

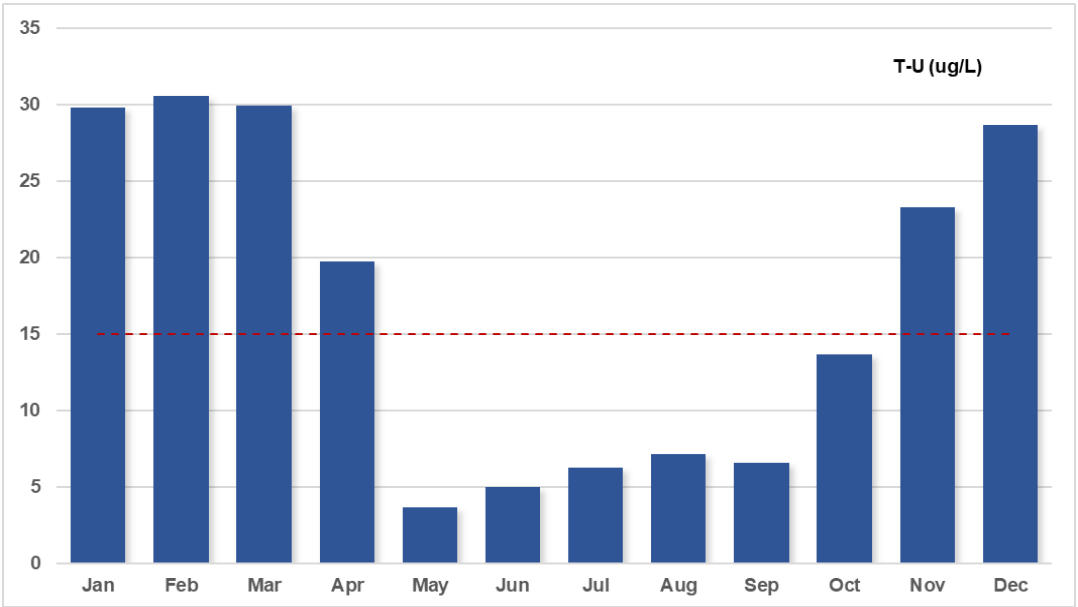

Figure 3.1-19: Mean monthly total uranium (T-U) concentrations at LC-11.4 mid Latte Creek for the period October 2010 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (dashed red line) for protection of aquatic life.

A similar, yet less pronounced seasonal trend of total U concentrations is observed in lower Latte Creek at station LC-0.2. Peak concentrations generally between 30 µg/L to 35 µg/L occur in late winter low flow periods; observed concentrations in most other months are less than the CCME guideline of 15 µg/L for the protection of aquatic life (Figure 3.1-20 and Figure 3.1-21). The highest U concentration is recorded in February of 2018, with values up to 75 µg/L (Figure 3.1-20).

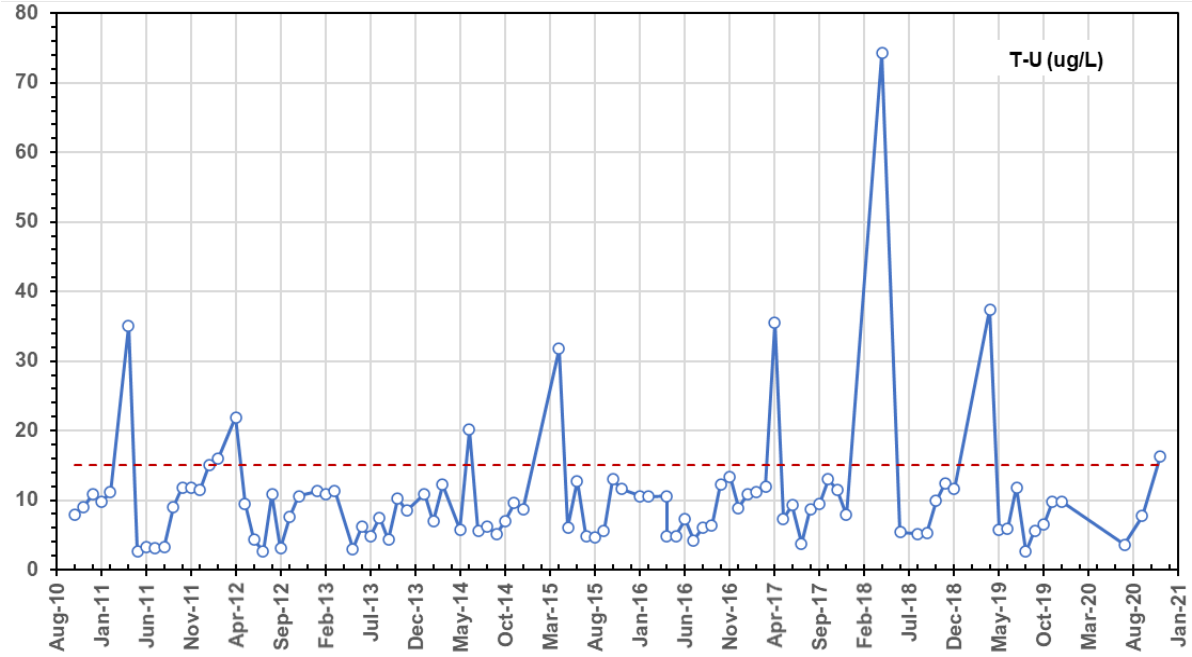

Figure 3.1-20: Total uranium (T-U) in lower Latte Creek (LC-0.2) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (red dashed line) for the protection of aquatic life.

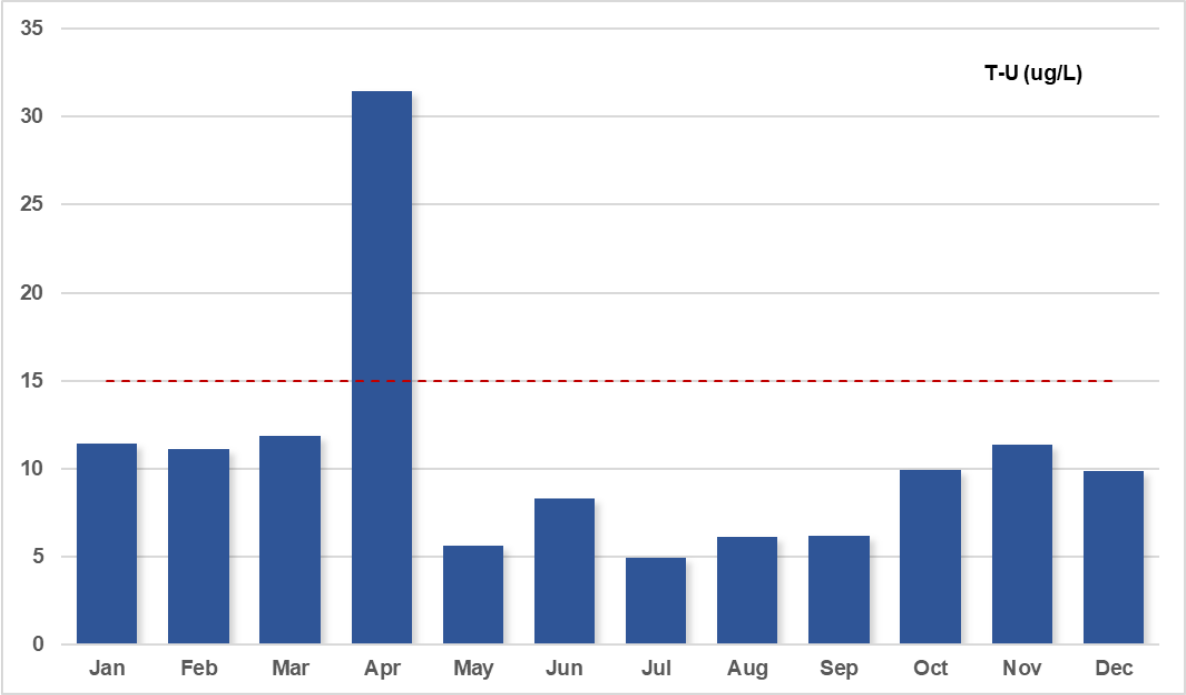

Figure 3.1-21: Mean monthly total uranium (T-U) concentrations at LC-0.2 in lower Latte Creek for the period October 2010 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (dashed red line) for protection of aquatic life.

3.1.2.5 5 in 30 Sampling Results Station LC-11.4

Weekly sampling occurred at LC-11.4 during the period of October 4 to October 28, 2017 to assess short-term variability in water quality and results are presented in Table 3.1-4; full results are presented in Appendix A.

Table 3.1-4:

Data for those parameters whose concentrations in Latte Creek are inversely related to flow conditions, including conductivity, hardness, alkalinity, sulphate and U show an increasing concentration trend over the sampling period. This can be readily explained by decreasing flow in Latte Creek through the sampling period (Figure 3.1-22). Flow data collected at LC-11.4 indicates decreasing flow from October 4, 2017 (~80 L/s) to October 19, 2017 (~20 L/s); flow after that date required extrapolation owing to freezing conditions occurring at the station and erroneous pressure transducer data.

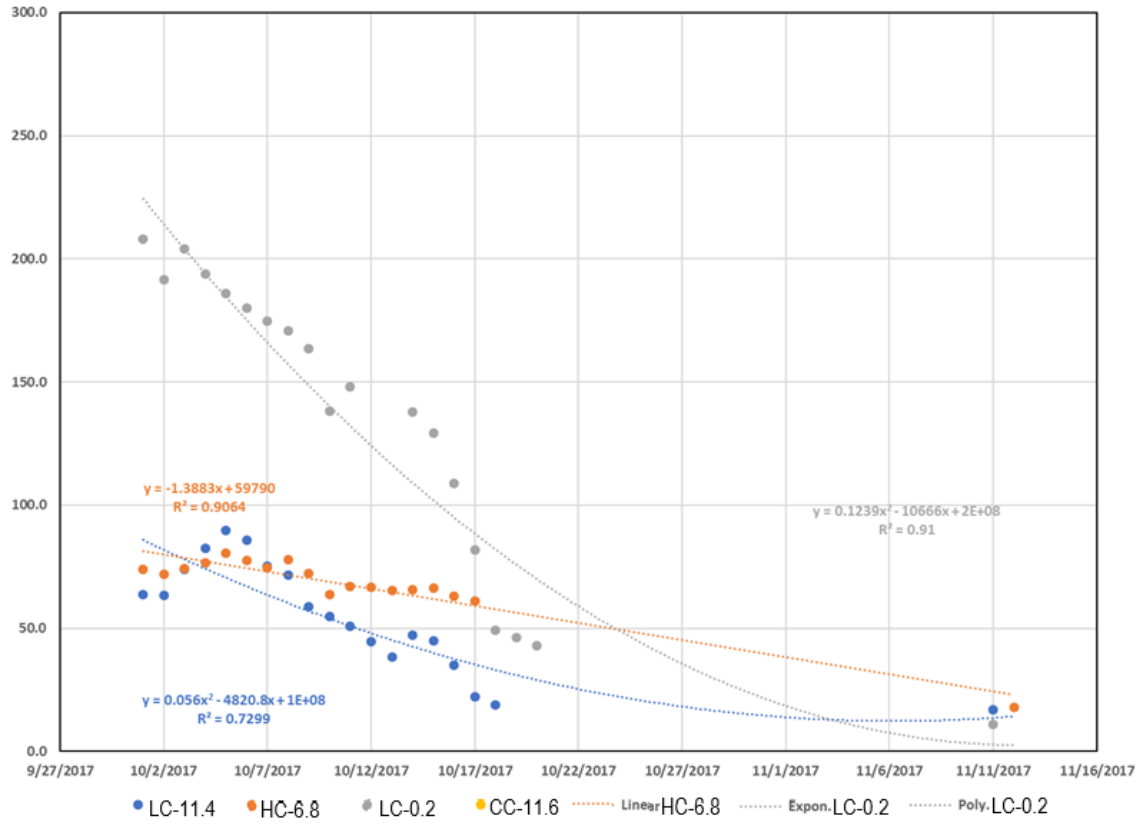

Figure 3.1-22: Flow measurements and extrapolations for LC-11.4 and LC-0.2 in Latte Creek and HC-6.8 in Halfway Creek for the period covering the 5 in 30 sampling from October 4 to October 28, 2017

For example, total U concentrations increased roughly 2-fold throughout the sampling period from a concentration of approximately 9.5 µg/L on October 4, 2017 to 17 µg/L on October 28, 2017.

By contrast, parameters that are positively correlated to flow, such as dissolved Al, show a roughly 2-fold decrease in concentration over the 5 in 30 sampling period. Parameters that have been shown to have very little correlation to flow, including As and Cu, were present at similar concentrations throughout the sampling period.

3.2 Coffee Creek

Background water chemistry in Coffee Creek can be divided between upper Coffee Creek (*e.g.,* above the confluence with Latte Creek) and lower Coffee Creek (Figure 3.1-21). Upper Coffee Creek is represented by data collected from CC-11.6 and lower Coffee Creek is represented by data collected at station CC-3.2. Station CC-10.9 located immediately downstream of the confluence with Latte Creek was added in 2017 to evaluate mixing with

Coffee Creek. Monthly water quality monitoring at both stations commenced in October 2010 and continue to present.

3.2.1 Upper Coffee Creek – Station CC-11.6

Upper Coffee Creek is characterized by water quality measured at Station CC-11.6 (Figure 3.2-1) which reflects contributions from a large watershed of approximately 385 km^2. This compares to the Latte Creek watershed area at LC-0.2 of approximately 70 km^2 described in Section 3.1.

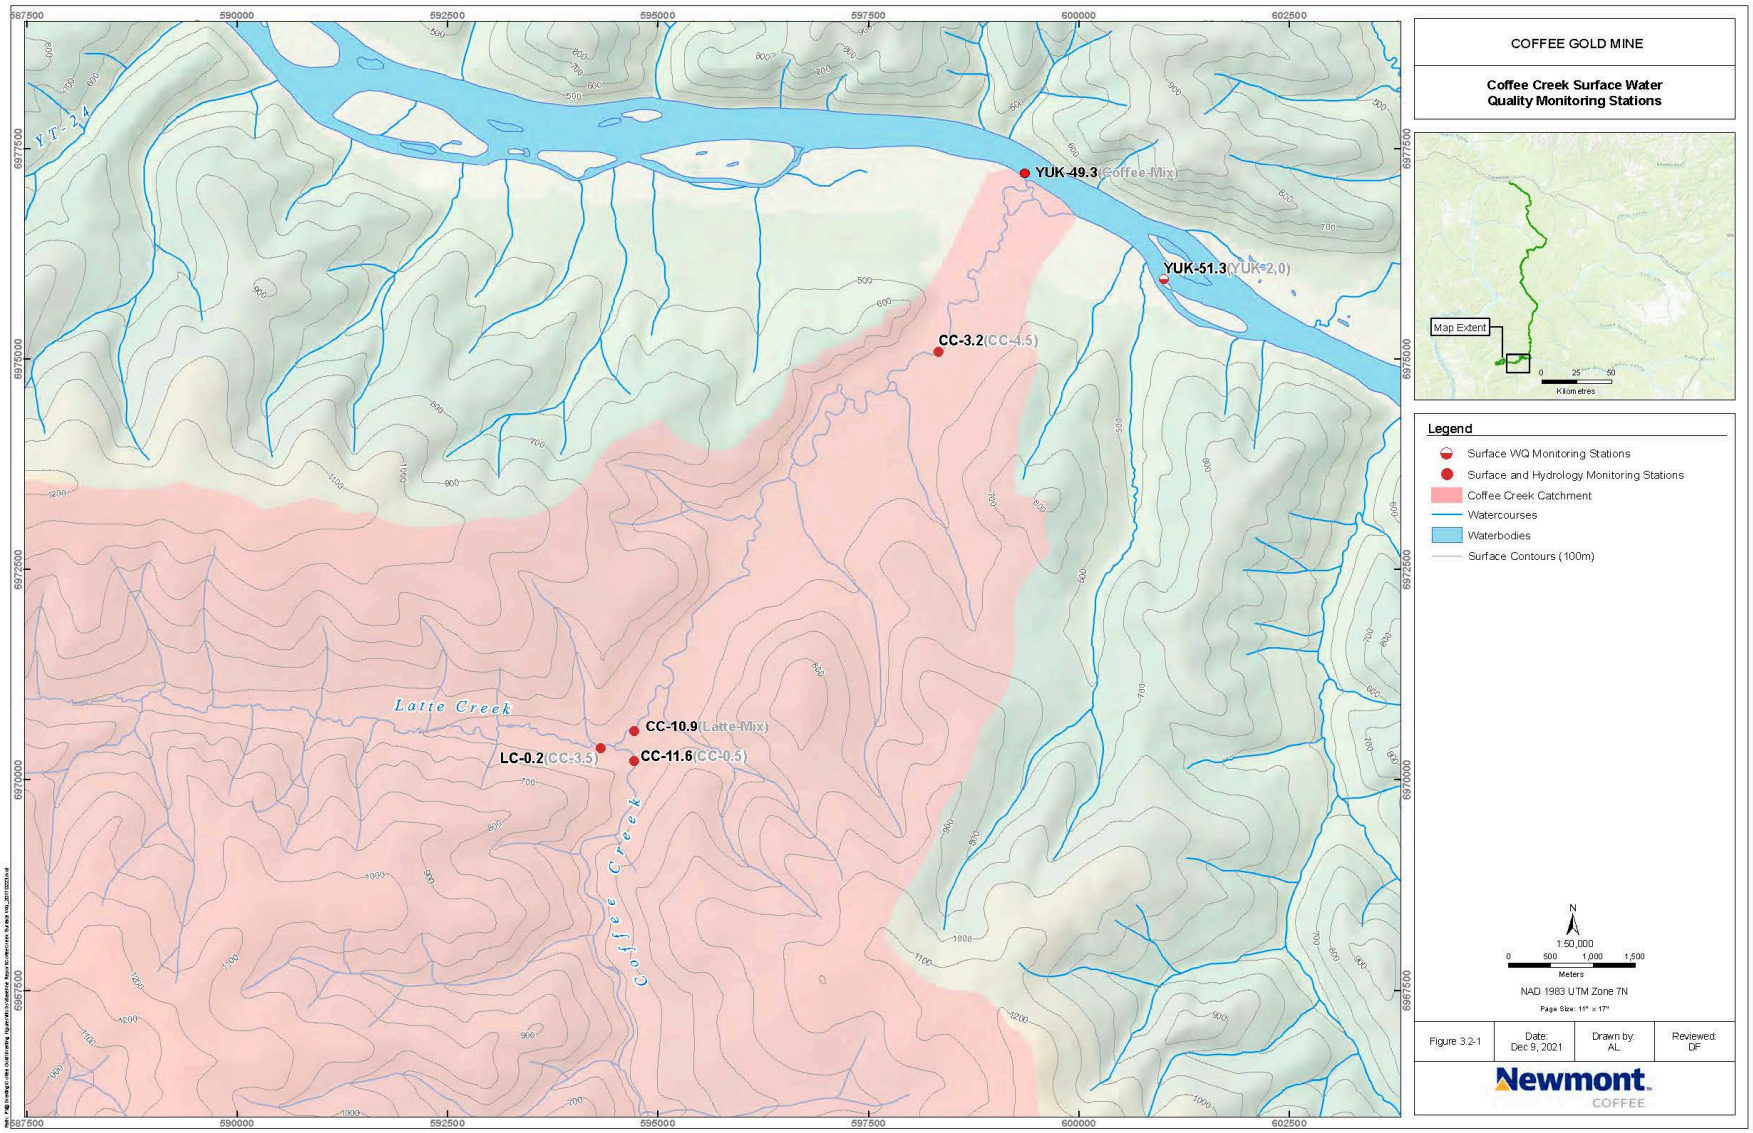

Figure 3.2-1: Detail of Coffee Creek drainage illustrating key monitoring station locations upstream and downstream of Latte Creek confluence

3.2.1.1 Summary Statistics

Table 3.2-1 summarizes the mean monthly values for a suite of the key parameters for station CC-11.6 in Coffee Creek.

3.2.1.2 Major Ions

The major ion chemistry of upper Coffee Creek is assessed with respect to conductivity, hardness, alkalinity, sulphate and pH. Station CC-11.6 is characterized by seasonally comparatively soft to moderately soft waters (approximately between 50 mg/L and 70 mg/L [as $CaCO_3$] during open water periods of May to September) and hard to very hard waters (ranging from approximately 91 mg/L to 280 mg/L [as $CaCO_3$]) during lower flow periods and winter low flows (Table 3.2-1; Figure 3.2-2.).

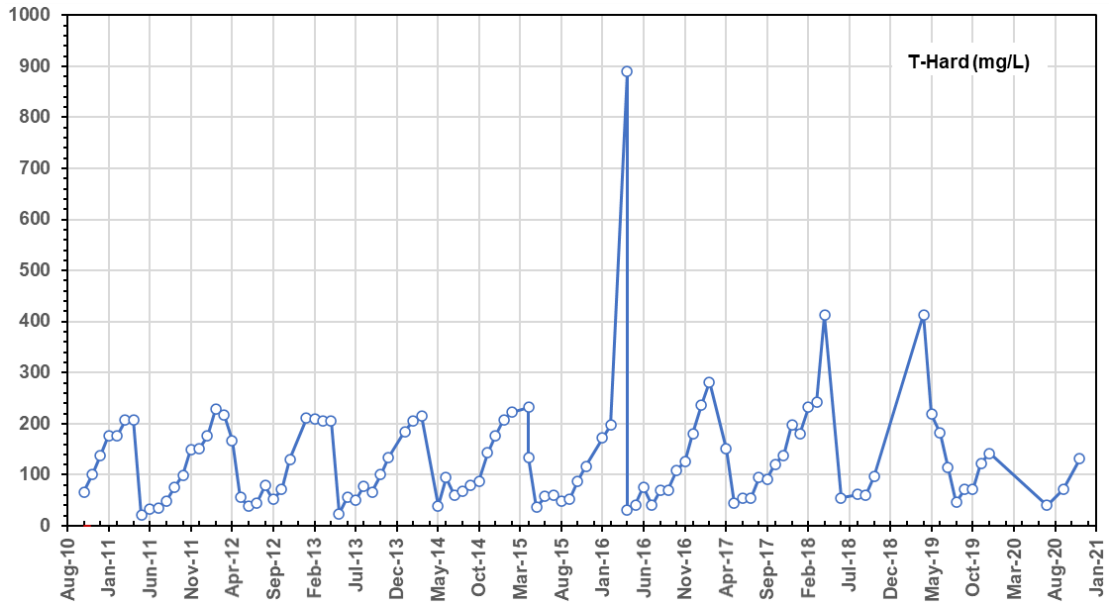

Figure 3.2-2: Total Hardness (T-Hard., as mg/L $CaCO_3$) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020.

The pH in upper Coffee Creek remains relatively uniform throughout the year with values generally ranging between 7.2 and 7.9. All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in upper Coffee Creek also exhibit a strong seasonal signature with lowest concentrations occurring during peak runoff conditions. During low flow periods, mean sulphate concentrations at CC-11.6 range from 48 mg/L to 180 mg/L (Table 3.2-1). As described previously, sulphate minima during high flow can be attributed to the influence of low ionic strength melt waters, while higher values during the low-flow periods reflect an increased proportion of groundwater inputs.

Unlike the dissolved ions, higher TSS concentrations in upper Coffee Creek generally coincide with the peak snowmelt months or during intense rainfall events (Table 3.2-1). At most other flow periods of the year, TSS values in upper Coffee Creek at CC-11.6 were generally below 3.0 mg/L.

3.2.1.3 Nutrients

Nutrient parameters have been observed at low concentrations in Coffee Creek at station CC-11.6. Ammonia-N concentrations are low with mean monthly values typically below 0.04 mg/L (Table 3.2-1). Nitrate-N monthly mean concentrations in upper Coffee Creek ranged from 0.02 mg/L to 0.4 mg/L with higher nitrate-N associated with winter low flows. Monthly mean dissolved phosphorus concentrations at CC-11.6 range between 0.002 mg/L to 0.01 mg/L and are indicative of oligotrophic to ultra-oligotrophic conditions.

The TOC and DOC concentrations exhibit a marked seasonal signature with highest values observed during peak runoff periods in Coffee Creek at station CC-11.6. Observed DOC concentrations are generally < 7 mg/L during baseflow periods when groundwater inputs dominate the flow regime. During the open water period, DOC values typically range between 12 mg/L and 20 mg/L during higher flow periods reflecting carbon inputs from terrestrial runoff (Figure 3.2-3).

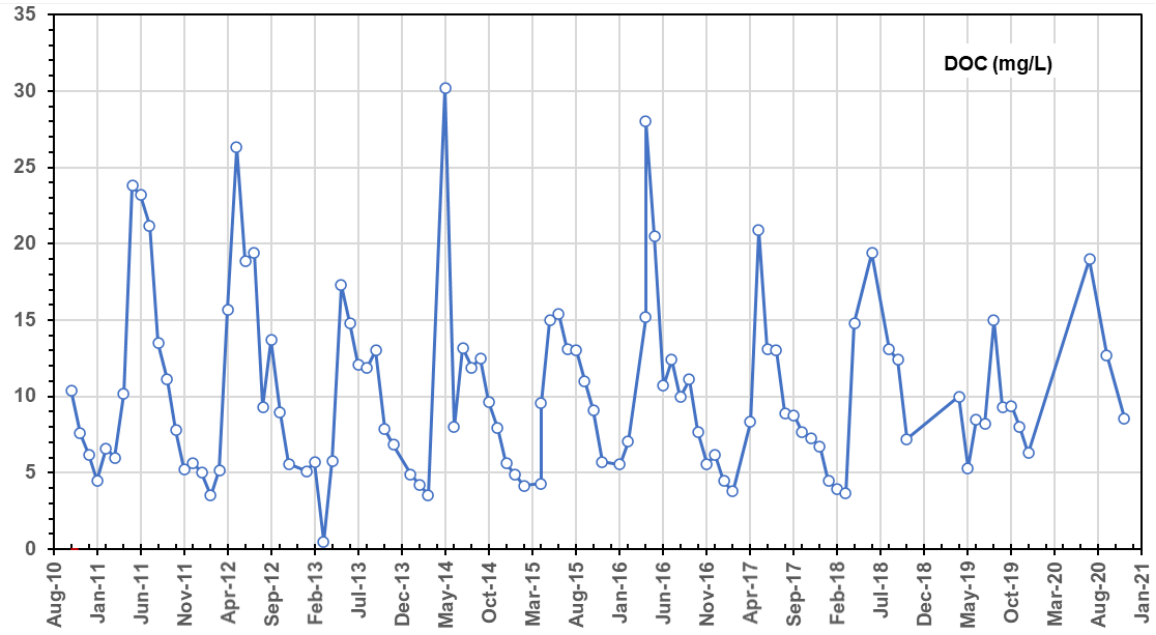

Figure 3.2-3: Dissolved organic carbon (DOC) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020.

3.2.1.4 Trace Elements

Baseline trace element concentrations in upper Coffee Creek were derived from data collected from October 2010 to December 2020 at CC-11.6. For most parameters, mean monthly concentrations of total and dissolved trace elements are low (*e.g.*, As, Sb, Co, Cr, Pb, Hg, Ni, Se, and Zn). Mean monthly total As concentrations in upper Coffee Creek at CC-11.6 are generally below 1.0 µg/L (Figure 3.2-4).

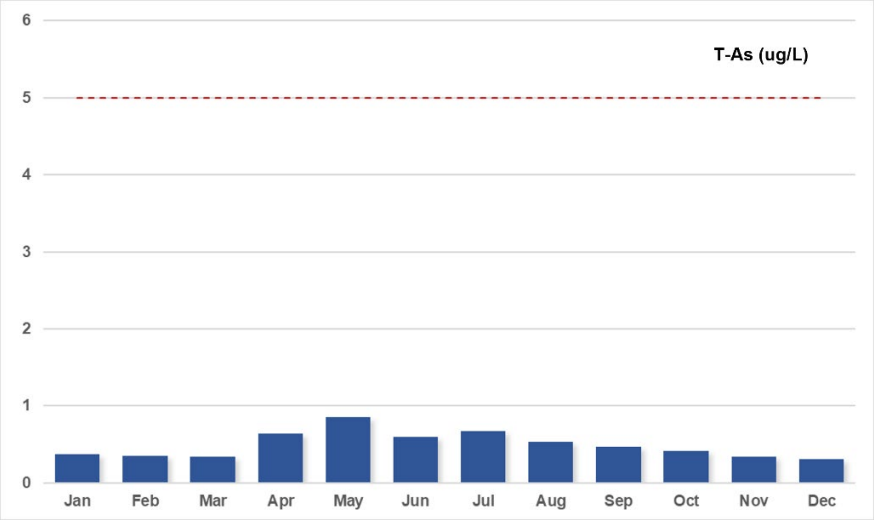

Figure 3.2-4: Mean monthly total arsenic (T-As) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed line) for protection of aquatic life.

Mean monthly total Se concentrations in upper Coffee Creek are typically less than 0.10 µg/L (Table 3.2-1).

Dissolved Al is seasonally elevated in upper Coffee Creek and consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L during peak runoff periods (Figure 3.2-5).

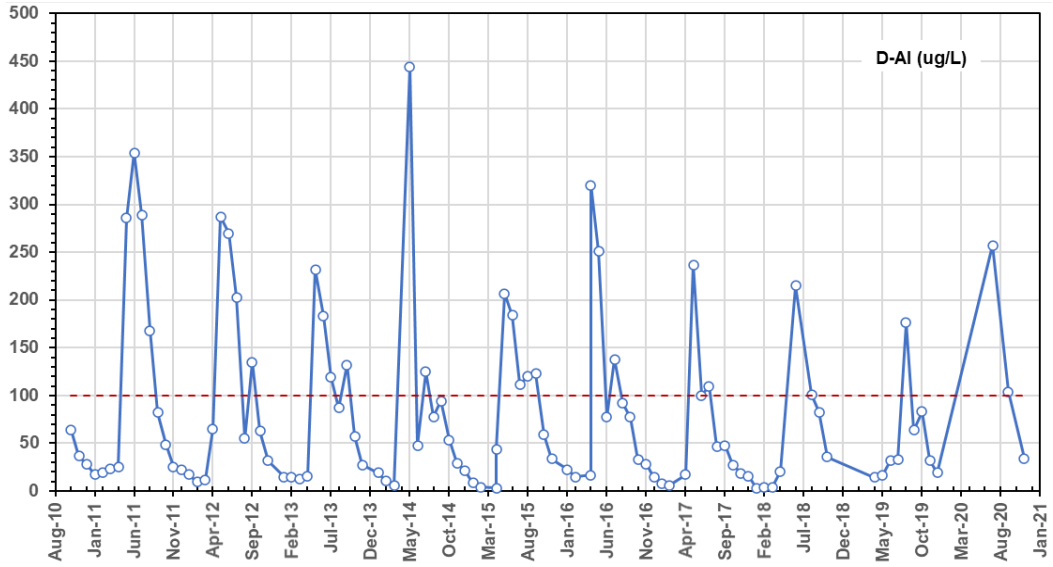

Figure 3.2-5: Dissolved Aluminum (D-Al) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020 compared to the British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

During baseflow periods, dissolved Al concentrations in upper Coffee Creek are typically between 10 and 90 µg/L (Table 3.2-1).

Concentrations of total Cu in upper Coffee Creek exhibit a strong seasonal signature with maxima associated with peak runoff periods that exceed the CCME hardness-dependent Cu guideline for the protection of aquatic life (Figure 3.2-6 and Figure 3.2-7). During most months of the open water period (*e.g.*, May to September), mean monthly total Cu concentrations are naturally elevated above the CCME guideline for Cu (Figure 3.2-7).

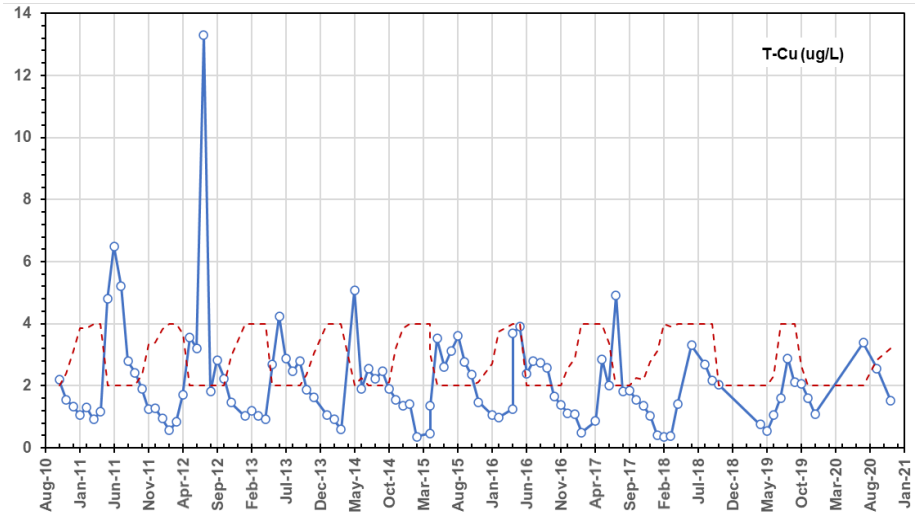

Figure 3.2-6: Total copper (T-Cu) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness dependent water quality guidelines (red dashed line) for the protection of aquatic life.

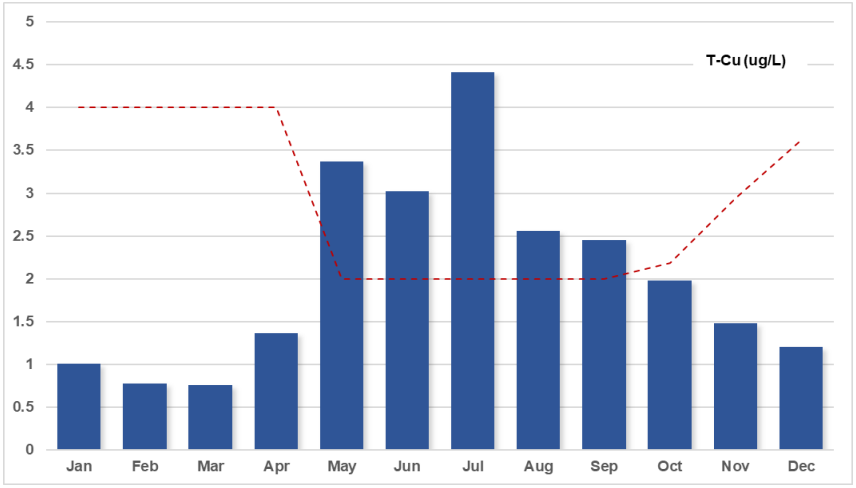

Figure 3.2-7: Monthly mean total copper (T-Cu) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness dependent water quality guidelines (red dashed line) for the protection of aquatic life.

In upper Coffee Creek, total Cd concentrations generally do not exceed the chronic or acute CCME hardness-dependent guidelines for protection of aquatic life (Figure 3.2-8).

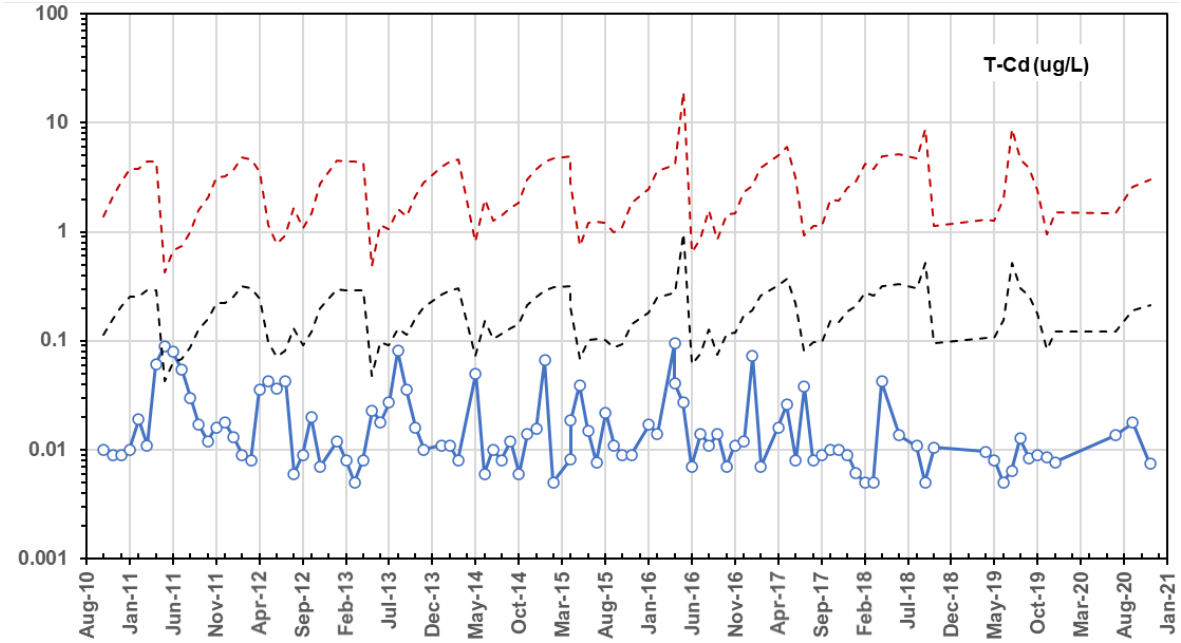

Figure 3.2-8: Total cadmium (T-Cd) concentrations in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness dependent water quality guidelines for the protection of aquatic life.

Similar to the monitoring observations in Latte Creek, total U concentrations in Coffee Creek at CC-11.6 show a distinct seasonal signature with maxima observed during winter low flow periods and coinciding with baseflow conditions. Concentrations during low flow periods often exceed the CCME chronic water quality guideline of 15 µg/L with peak concentrations of 45 µg/L (January 2013), 40 µg/L (February 2016), 178 µg/L (April 2018) and 61 µg/L observed in April 2019 (Figure 3.2-9). While the April 2018 total U value of 178 µg/L is the highest recorded for this station, the measured concentration was not associated with TSS as dissolved U for that sample was 176 µg/L (Appendix A).

Graphical representation of monthly mean total U data at CC-11.6 illustrates that concentrations exceeding the CCME water quality guideline of 15 µg/L typically occur from November to January (Figure 3.2-10) although specific sampling events have also measured concentrations well above CCME guidelines in February and March (Figure 3.2-9).

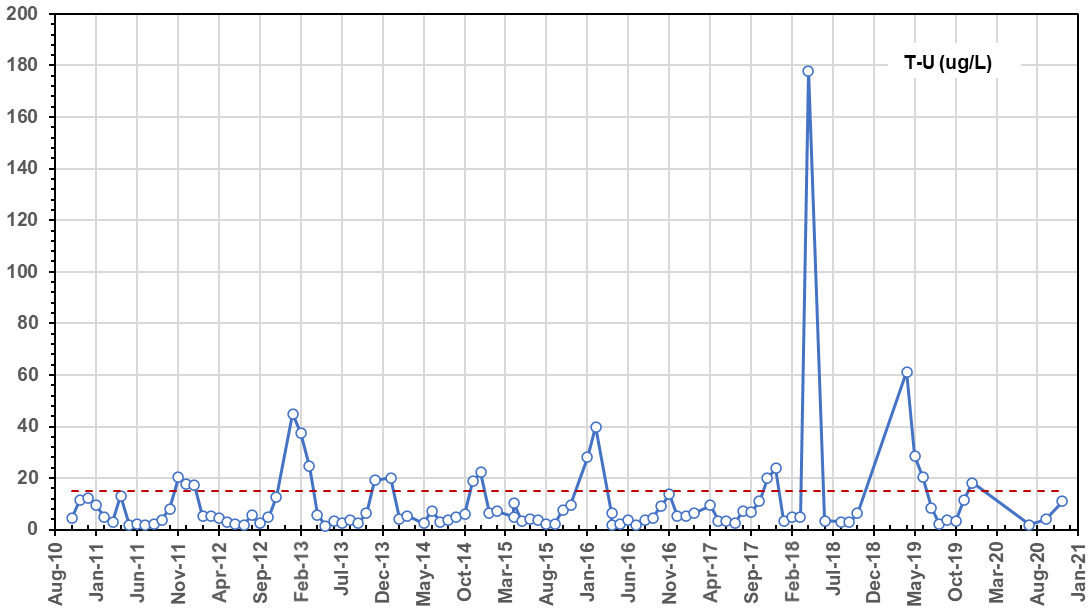

Figure 3.2-9: Total uranium (T-U) in upper Coffee Creek (CC-11.6) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (red dashed line) for the protection of aquatic life.

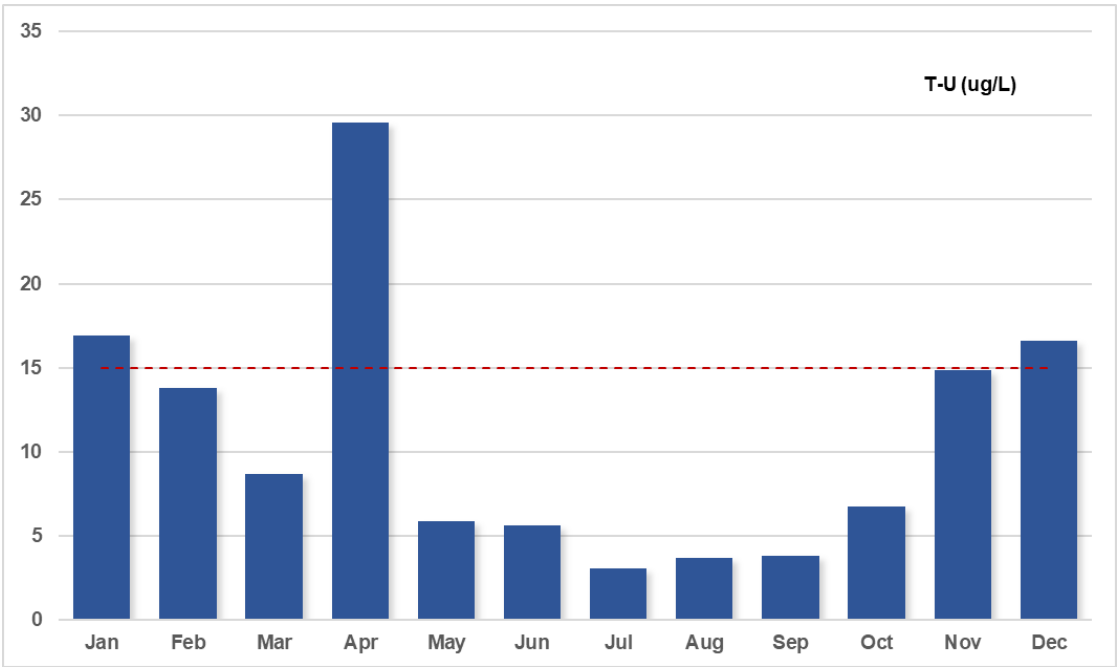

Figure 3.2-10: Mean monthly total uranium (T-U) concentrations at CC-11.6 in upper Coffee Creek for the period October 2010 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (dashed red line) for protection of aquatic life.

3.2.2 Lower Coffee Creek – Station CC-3.2

Lower Coffee Creek is characterized by water quality measured at Station CC-3.2 (Figure 3.2-1) which reflects contributions from Latte Creek that enters Coffee Creek immediately downstream of previously described station CC-11.6 on upper Coffee Creek.

3.2.2.1 Summary Statistics

Table 3.2 summarizes the mean monthly values for a suite of the key parameters for station CC-3.2 in Coffee Creek.

3.2.2.2 Major Ions

The major ion chemistry of lower Coffee Creek is assessed with respect to hardness, sulphate and pH. Station CC-3.2 is characterized by seasonally comparatively soft waters (approximately between 40 mg/L and 80 mg/L [as $CaCO_3$] during open water periods [May to September]) and hard waters (ranging from approximately 90 mg/L to 140 mg/L [as $CaCO_3$]) during low flow periods such as winter (Table 3.2-2; Figure 3.2-11).

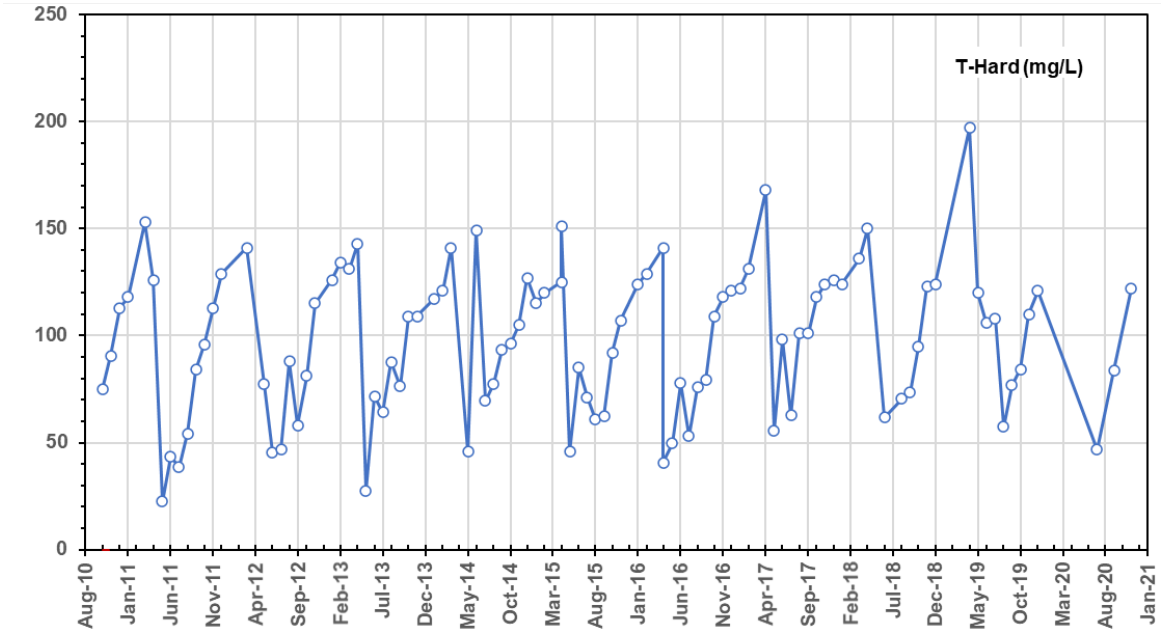

Figure 3.2-11: Total Hardness (T-Hard., as mg/L of $CaCO_3$) in lower Coffee Creek (CC-3.2) for the period October 2010 to December 2020.

The pH in lower Coffee Creek remains relatively uniform throughout the year with values generally ranging between 7.2 and 7.8 (Table 3.2-2). All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in lower Coffee Creek also exhibit a strong seasonal signature with lowest concentrations occurring during peak runoff conditions. During low flow periods, mean sulphate concentrations at CC-3.2 range from 45 mg/L to 72 mg/L (October to February; Table 3.2-2). Sulphate concentrations during freshet (March to June) and the open water (July to September) period range from roughly 20 mg/L to 80 mg/L.

As with the other stations monitored, TSS concentrations in lower Coffee Creek exhibit maxima coincident with the peak snowmelt months (Table 3.2-2). At most other flow periods of the year, TSS values in lower Coffee Creek at CC-3.2were generally below 3.0 mg/L.

3.2.2.3 Nutrients

As with upper Coffee Creek, nutrient parameters are found in low concentrations in lower Coffee Creek at station CC-3.2. Ammonia-N concentrations are low with mean monthly values typically less than 0.04 mg/L (Table 3.2-2). Mean monthly nitrate-N concentrations in lower Coffee Creek are higher than observed in upper Coffee Creek. Mean monthly nitrate-N at CC-3.2 ranged approximately an order of magnitude, with peak flow minima of 0.06 mg/L and winter low flow maxima of 0.7 mg/L. Lower Coffee Creek waters are oligotrophic to ultra-oligotrophic with monthly mean dissolved phosphorus concentrations at CC-3.2 ranging between 0.003 mg/L to 0.01 mg/L (Table 3.2-2).

As with upper Coffee Creek, TOC and DOC exhibit a marked seasonal signature with highest values observed during peak runoff periods at station CC-3.2. DOC accounts for virtually all of the TOC. Mean monthly DOC concentrations range from approximately 7.0 mg/L during baseflow periods to up to 20 mg/L during higher flow periods (Figure 3.2-12).

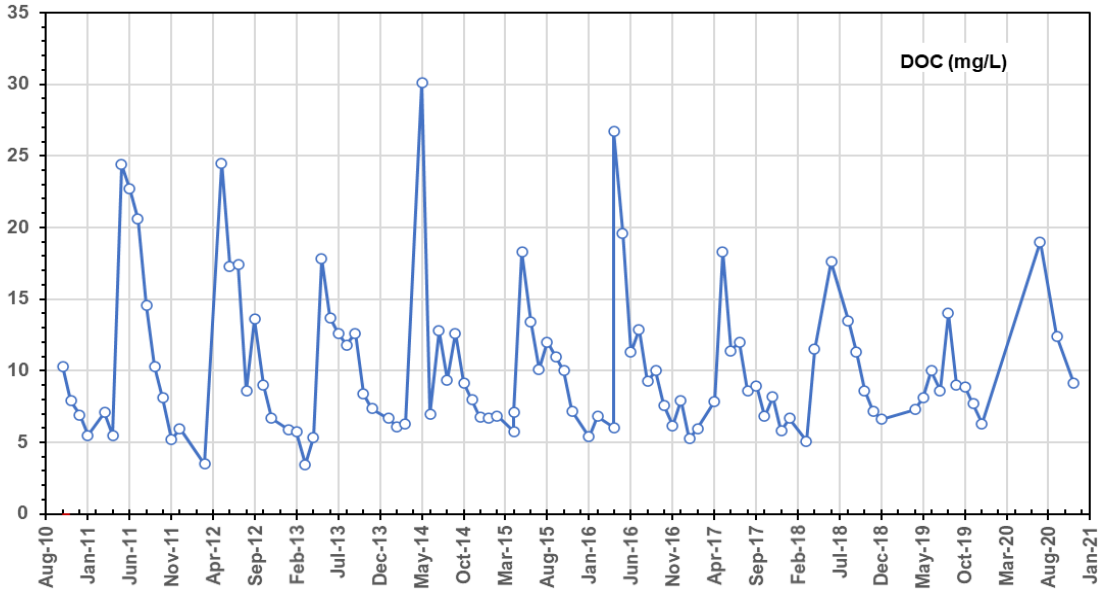

Figure 3.2-12: Dissolved organic carbon (DOC) in lower Coffee Creek CC-3.2 for the period October 2010 to December 2020.

3.2.2.4 Trace Elements

Baseline trace element concentrations in lower Coffee Creek were derived from data collected from October 2010 to December 2020 at CC-3.2 (Figure 3.2-1). For most parameters monitored, mean monthly concentrations of total and dissolved trace elements are low; the sole exceptions to this observation are for dissolved Al and total Cu. Of particular note is the absence of elevated total U in lower Coffee Creek and this result marks a departure of the trend observed at the other stations monitored in the immediate project area (Table 3.2-2).

Dissolved Al at CC-3.2 is seasonally elevated in lower Coffee Creek and consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L during peak runoff periods (Figure 3.2-13).

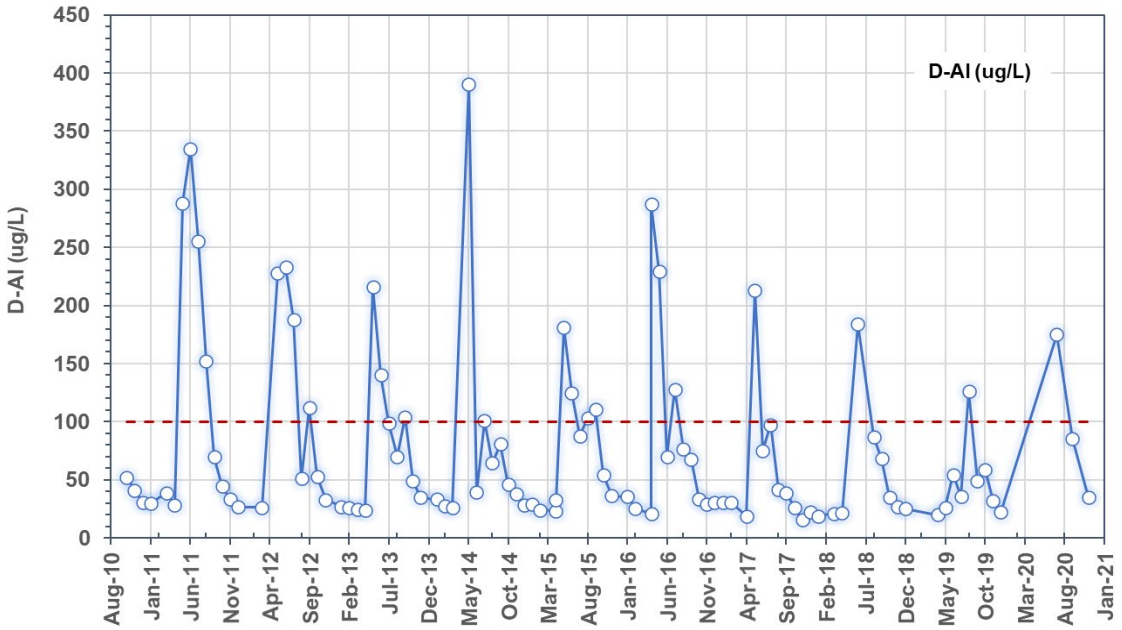

Figure 3.2-13: Dissolved aluminum (D-Al) in lower Coffee Creek (CC-3.2) for the period October 2010 to December 2020 compared to the British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

During baseflow periods, dissolved Al concentrations in lower Coffee Creek are typically roughly between 30 and 90 µg/L (Table 3.2-2).

Concentrations of total Cu in lower Coffee Creek exhibit the same strong seasonal signature observed at CC-11.6, with maxima associated with peak runoff periods that exceed the CCME hardness-dependent Cu guideline for the protection of aquatic life (Figure 3.2-14 and Figure 3.2-15). During most months of the open water period including May to September, mean monthly total Cu concentrations are naturally elevated above the CCME guideline for copper (Figure 3.2-15).

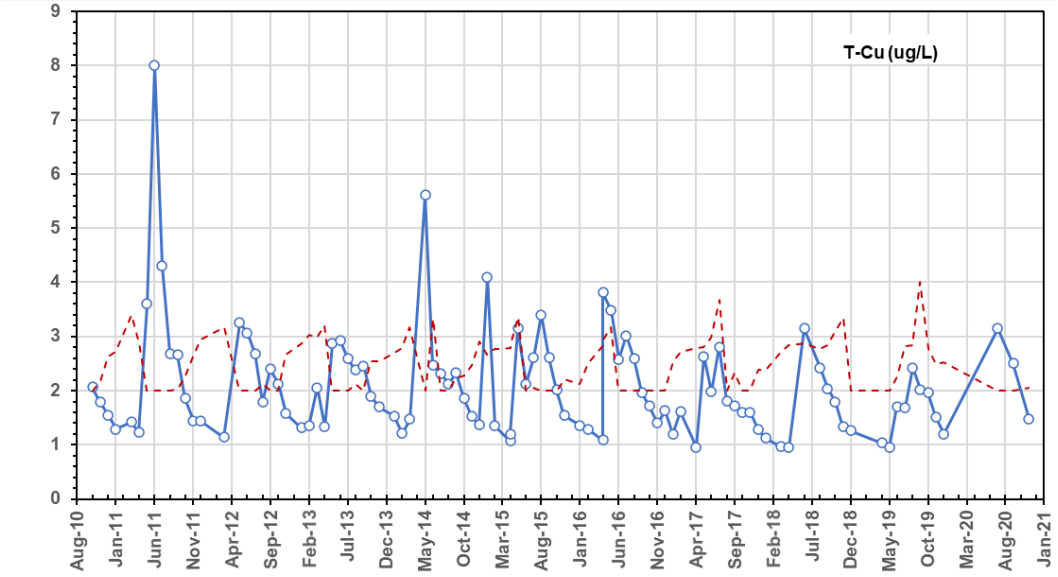

Figure 3.2-14: Total copper (T-Cu) in lower Coffee Creek (CC-3.2) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent water quality guidelines (red dashed line) for the protection of aquatic life.

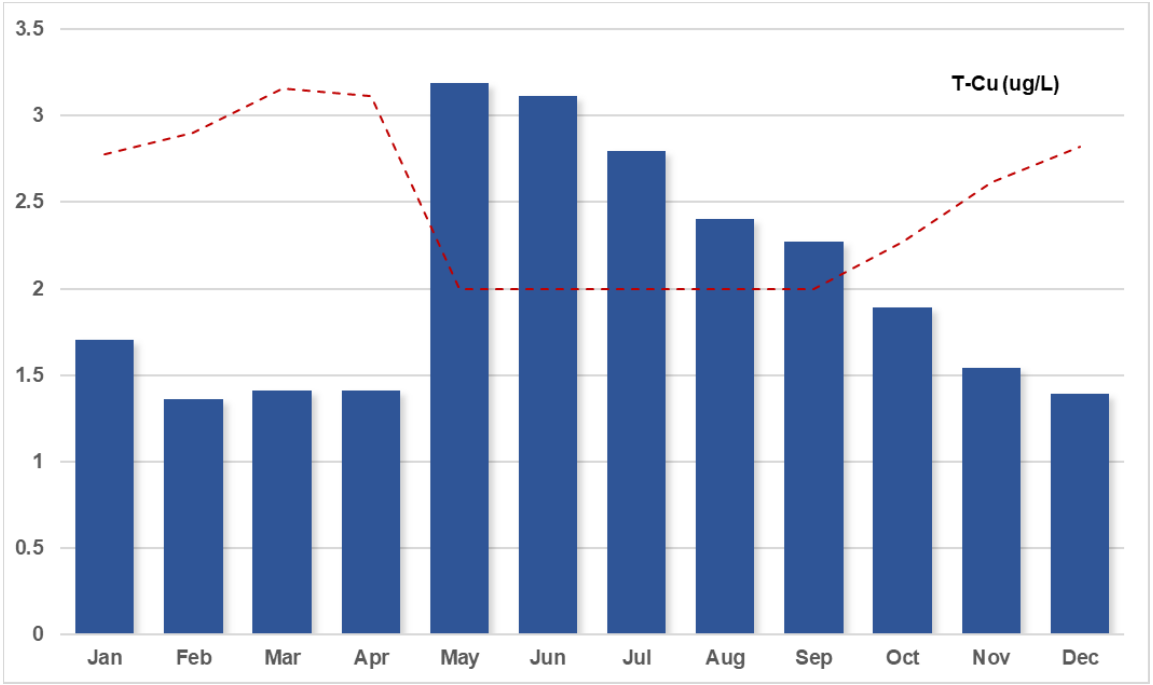

Figure 3.2-15: Monthly mean total copper (T-Cu) in lower Coffee Creek for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent water quality guidelines (red dashed line) for the protection of aquatic life.

Similar to that observed in upper Coffee Creek, total Cd concentrations in lower Coffee Creek at CC-3.2 generally do not exceed the chronic or acute CCME hardness-dependent guidelines for protection of aquatic life for Cd (Figure 3.2-16).

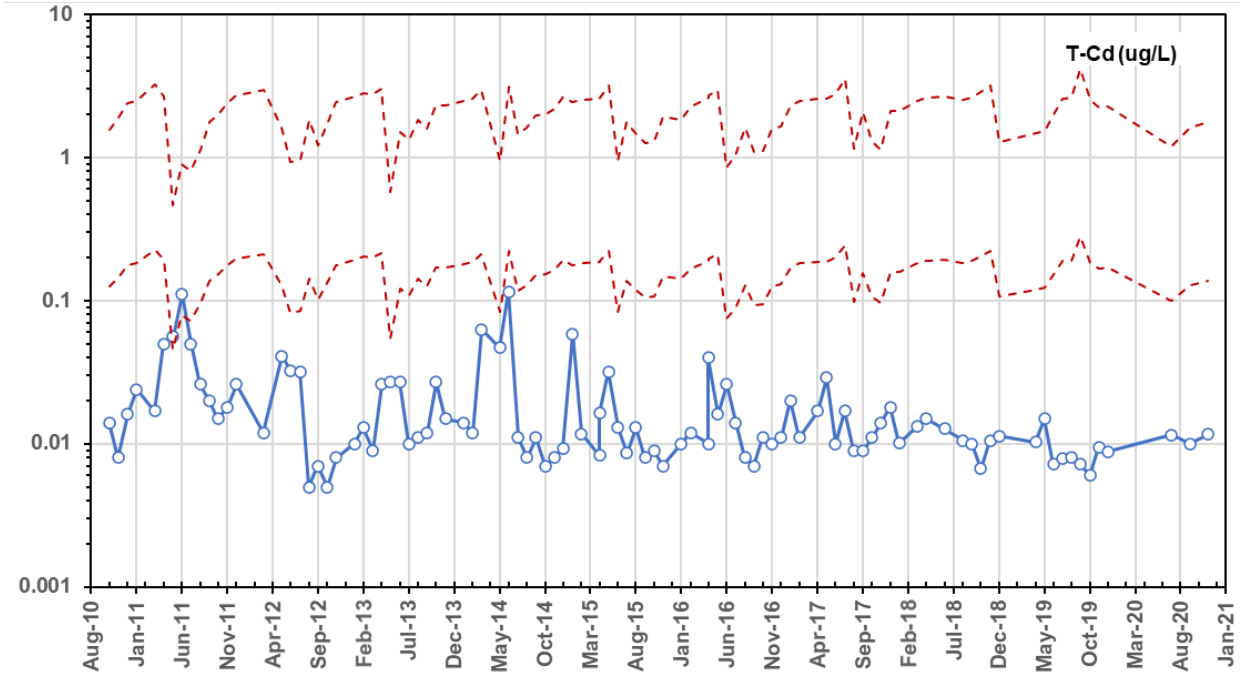

Figure 3.2-16: Total cadmium (T-Cd) concentrations in lower Coffee Creek (CC-3.2) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent water quality guideline for the protection of aquatic life.

As previously introduced, total U concentrations in lower Coffee Creek do not exhibit the same pronounced seasonal signature observed in upper Coffee Creek or Latte Creek. Total U concentrations at CC-3.2 have never exceeded the CCME guideline of 15 µg/L for the protection of aquatic life since the inception of monitoring in October 2010 (Figure 3.2-17). Interestingly, the lowest mean monthly total U concentrations at CC-3.2 occur during winter low flows, a notable departure from observations in upper Coffee Creek and may indicate a different groundwater source or input into lower Coffee Creek that is comparatively deplete in U. Mean monthly total U concentrations at CC-3.2typically are on the order of only 1.0 to 4.0 µg/L (Figure 3.2-18).

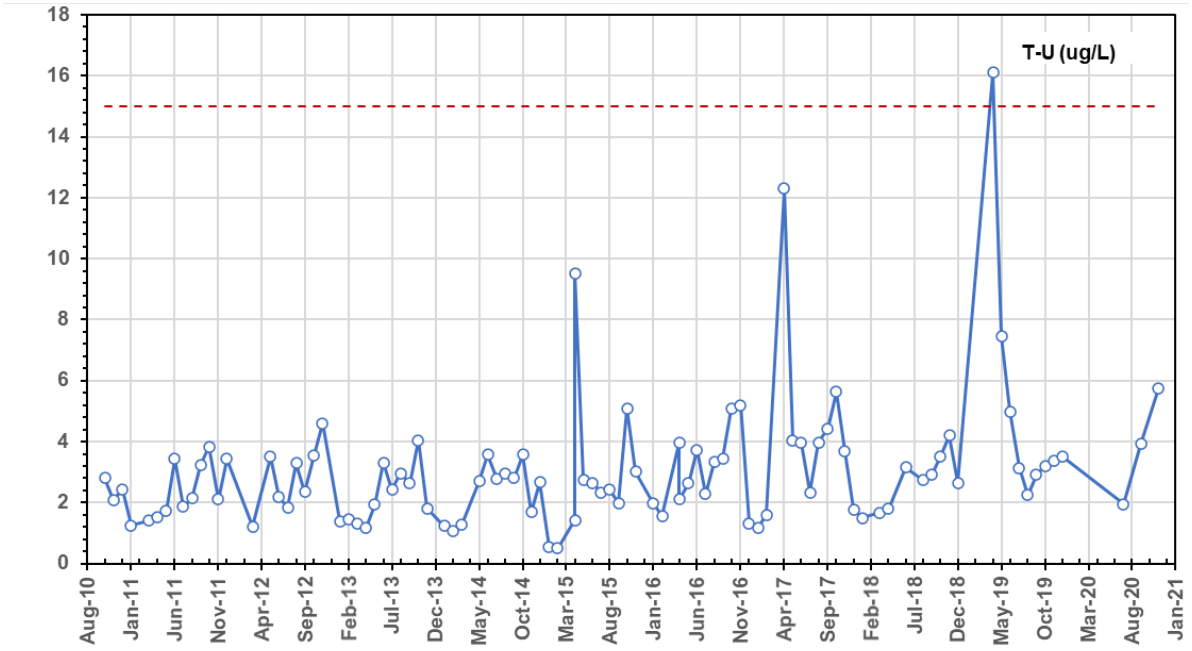

Figure 3.2-17: Total uranium (T-U) in lower Coffee Creek (CC-3.2) for the period October 2010 to December 2020 compared to Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (red dashed line) for the protection of aquatic life.

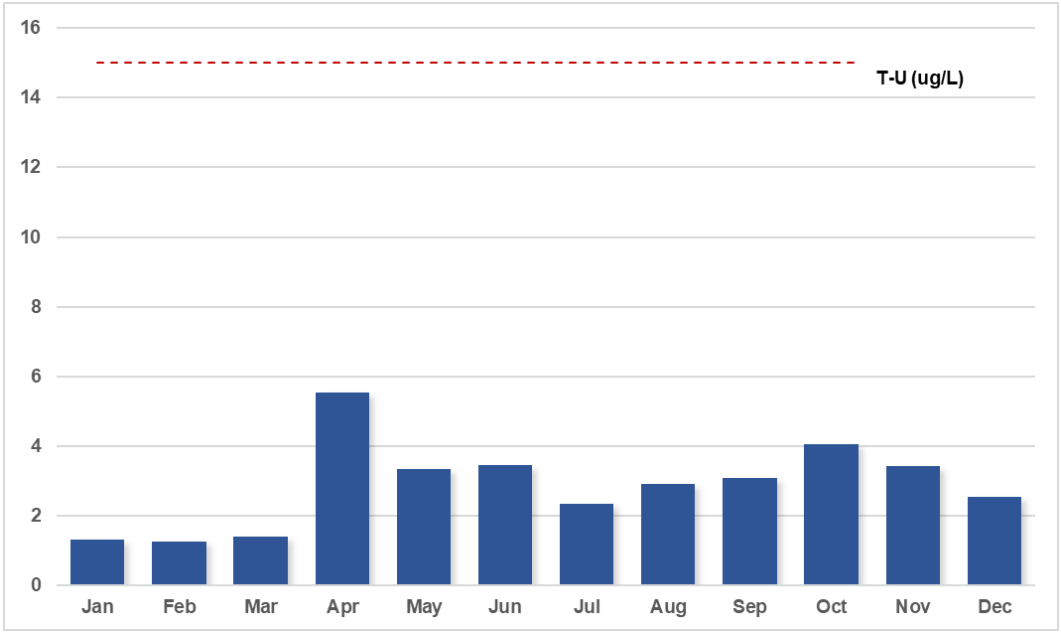

Figure 3.2-18: Mean monthly total uranium (T-U) concentrations at CC-3.2 in lower Coffee Creek for the period October 2010 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guideline (dashed red line) for protection of aquatic life.

3.2.2.5 5 in 30 Sampling at CC-3.2

Weekly sampling occurred at CC-3.2 during the period of October 4 to October 28, 2017 to assess short-term variability in water quality and results are presented in Table 3.2-3; full results are presented in Appendix A.

Table 3.2-3:

3.2.3 CC-10.9 Coffee Creek

This station reflects the contributions from Latte Creek that enters Coffee Creek immediately upstream of this station (Figure 3.2-1).

3.2.3.1 Summary Statistics

Table 3.2-4 summarizes the mean monthly values for a suite of the key parameters for station CC-10.9 in Coffee Creek.

3.2.3.2 Major Ions

Station CC-10.9 is characterized by moderately hard waters (~ 100 mg/L [as $CaCO_3$]) during open water periods (May to September) and hard waters (up to 358 mg/L [as $CaCO_3$]) during low flow periods, such as winter (Table 3.2-4; Figure 3.2-19).

The pH in CC-10.9 remains relatively uniform throughout the year with values roughly around 8 (Table 3.2-4). All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in lower Coffee Creek shows signature highest concentrations during peak runoff conditions in April, with mean sulphate concentrations ranging from 50 mg/L to 90 mg/L for the remaining months (Table 3.2-4). As with the other stations monitored, TSS concentrations in this station exhibit maxima coincident with the peak snowmelt months (May-July; Table 3.2-4). At most other flow periods of the year, TSS values in lower Coffee Creek at CC-10.9 were generally below 3.0 mg/L.

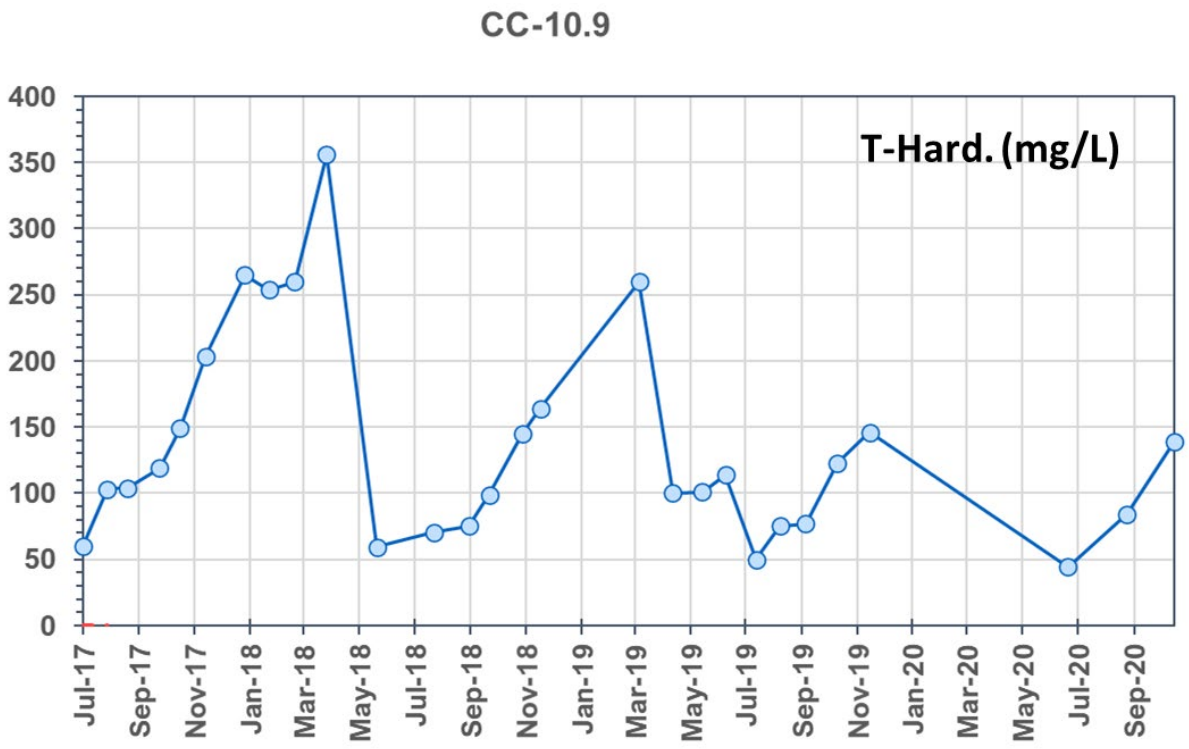

Figure 3.2-19: Total Hardness (T-Hard., as mg/L of $CaCO_3$) in CC-10.9 located in Coffee Creek for the period October 2017 to December 2020.

3.2.3.3 Nutrients

Nutrient parameters are found in low concentrations in Coffee Creek at station CC-10.9. Ammonia-N and nitrate-N concentrations are low with mean monthly values typically around 0.04 mg/L and 0.3 mg/L, respectively (Table 3.2-4). In regards to trophic status, waters at this station are oligotrophic to ultra-oligotrophic with monthly mean dissolved phosphorus concentrations at CC-10.9 ranging between 0.003 mg/L to 0.03 mg/L (Table 3.2-4). As with other stations in Coffee Creek, TOC and DOC exhibit a marked seasonal signature with highest values observed during peak runoff periods at station CC-10.9. Mean monthly DOC concentrations remain < 9.0 mg/L during baseflow periods to up to 20 mg/L during higher flow periods (Figure 3.2-20).

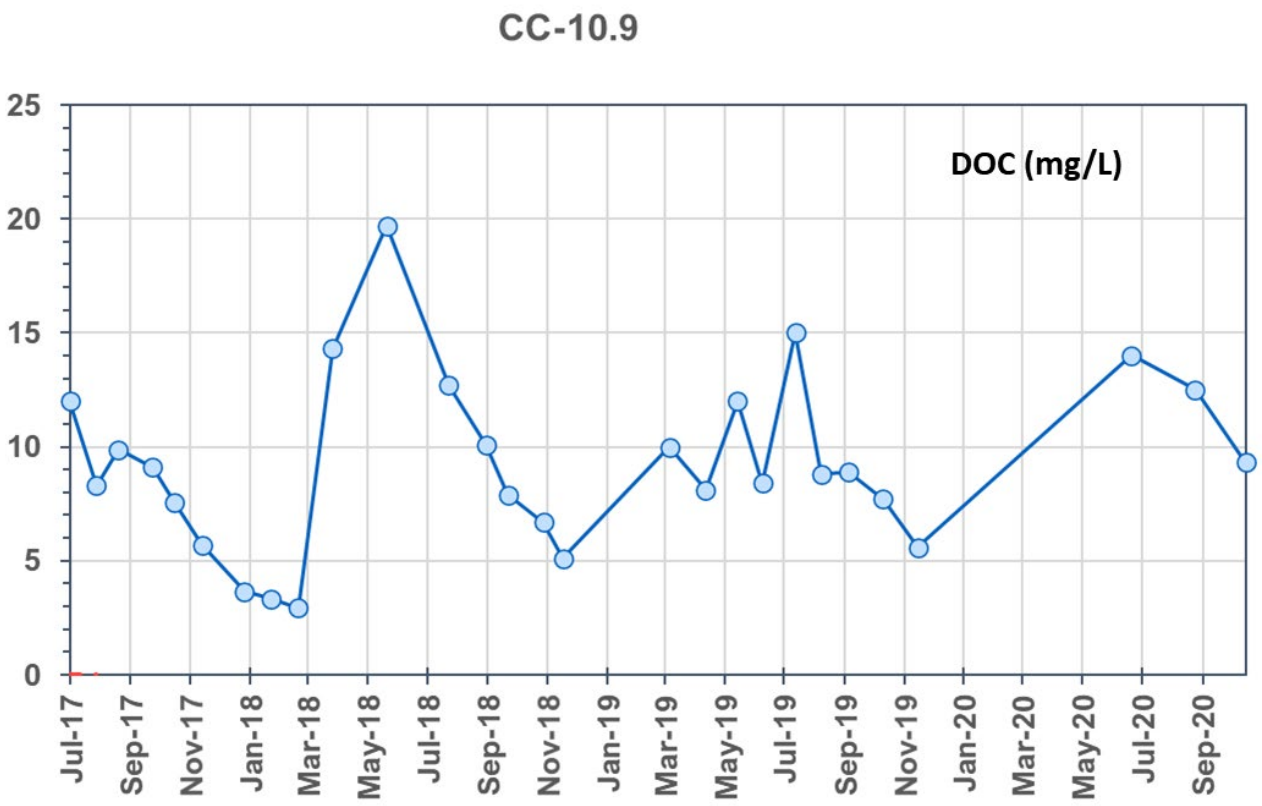

Figure 3.2-20: Dissolved organic carbon (DOC) in Coffee Creek CC-10.9 for the period October 2017 to December 2020.

3.2.3.4 Trace Elements

Baseline trace element concentrations in CC-10.9 were derived from data collected from October 2017 to December 2020. For most parameters monitored, mean monthly concentrations of total and dissolved trace elements are low (Table 3.2-4). Total arsenic in this station remained well below the applicable WQG for the protection of aquatic life (Figure 3.2-21).

Dissolved Al at CC-10.9 is seasonally elevated and observed to exceed the BC ENV guideline for the protection of aquatic life of 100 µg/L during peak runoff periods (Figure 3.2-22).

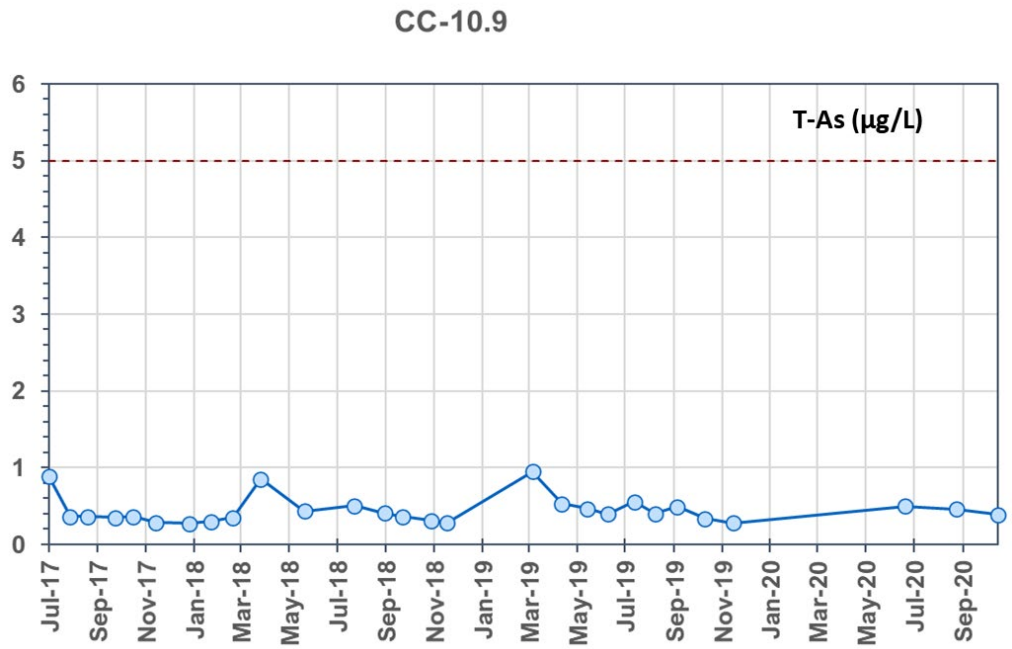

Figure 3.2-21: Total arsenic (T-As) in Coffee Creek (CC-10.9) for the period October 2017 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed line) for protection of aquatic life.

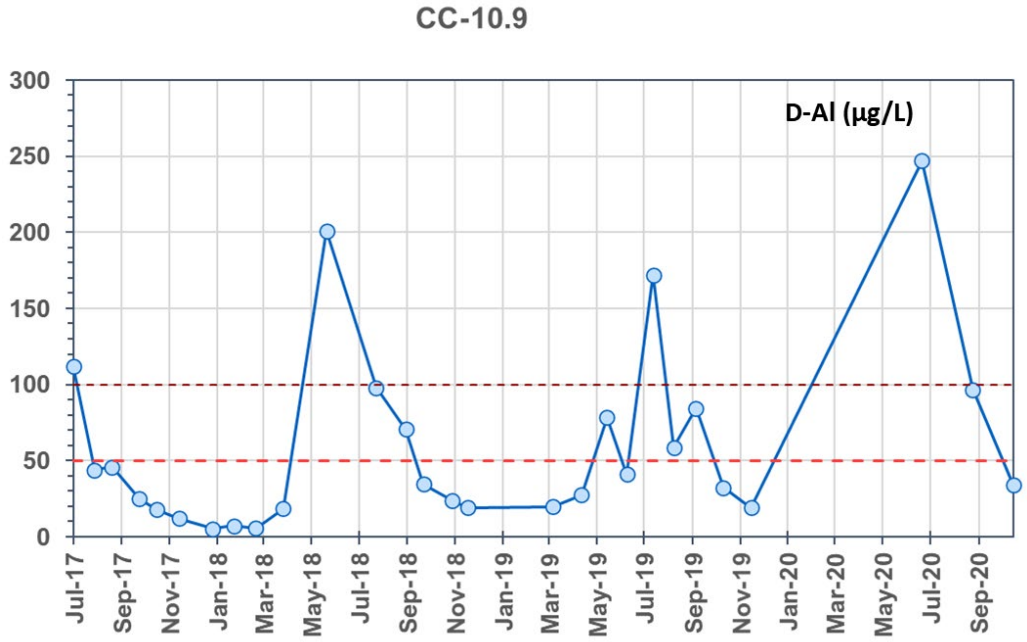

Figure 3.2-22: Dissolved aluminum (D-Al) concentrations at CC-10.9 for the period October 2017 to December 2020 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

Total Se concentrations in CC-10.9 are very low and typically less than 0.2 µg/L (Table 3.2-4). Concentrations of total Cu in CC-10.4 exceeds the CCME hardness-dependent Cu guideline for the protection of aquatic life during most months of the open water period (*e.g.*, May to September; Figure 3.2-23).

Concentrations of total cadmium in CC-10.9 remained well below acute and chronic WQG for the protection of aquatic life (Figure 3.2-24).

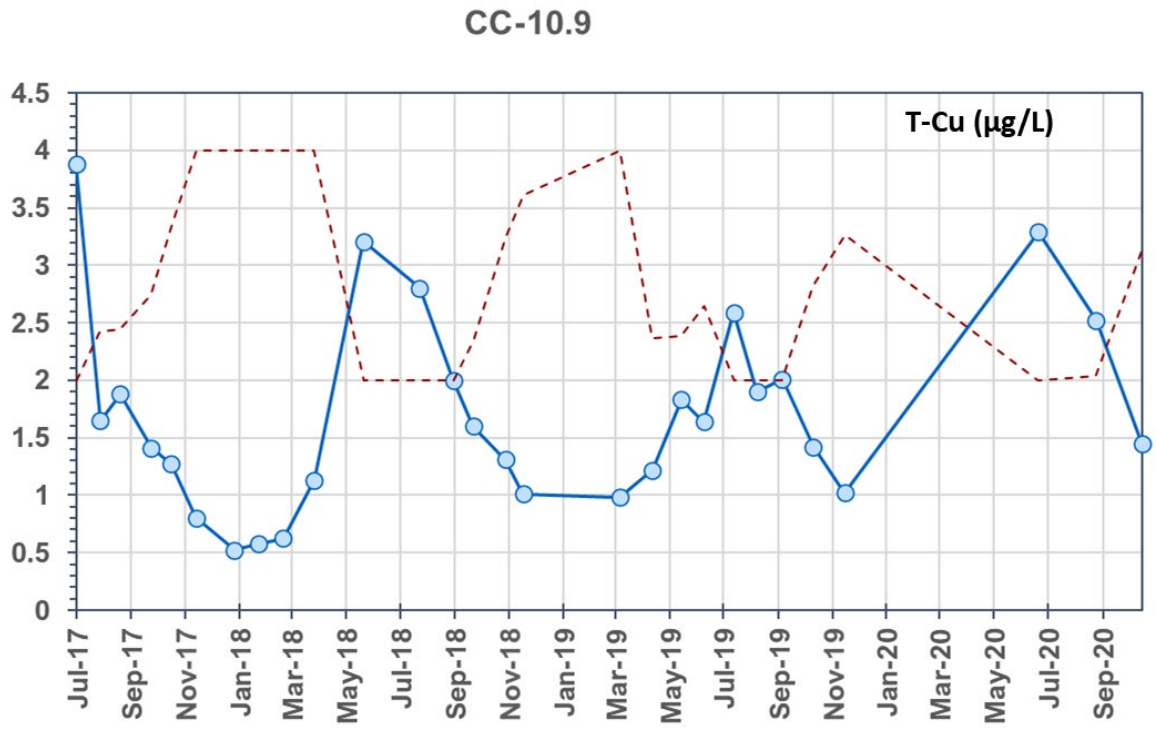

Figure 3.2-23: Total copper (T-Cu) in CC-10.9 located in Coffee Creek for the period October 2017 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness dependent water quality guidelines (red dashed line) for the protection of aquatic life.

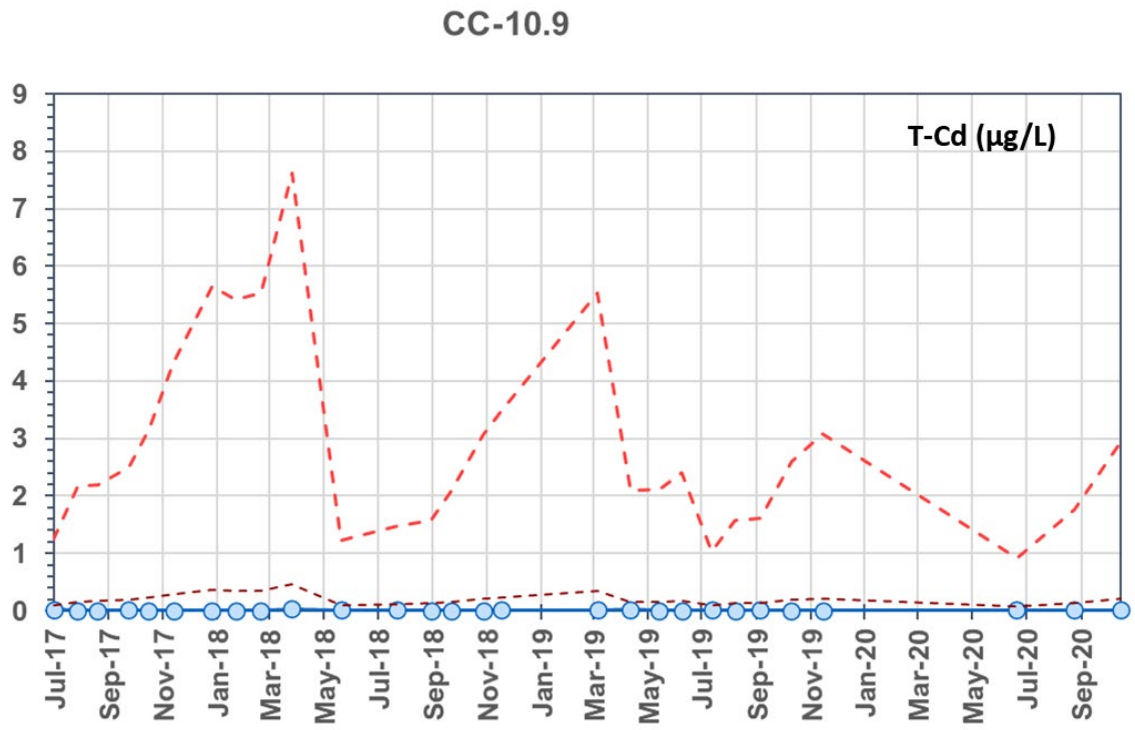

Figure 3.2-24: Total cadmium (T-Cd) concentrations in CC-10.9 located in Coffee Creek for the period October 2017 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness dependent water quality guidelines for the protection of aquatic life.

Similar to other observations in Coffee Creek, total U concentrations in CC-10.9 show a distinct seasonal signature with maxima observed during winter low flow periods and coinciding with baseflow conditions. Concentrations during low flow periods often exceed the CCME chronic water quality guideline of 15 µg/L with concentrations ranging from 30 to 80 µg/L (Figure 3.2-25).

Graphical representation of monthly mean total U data at CC-10.9 illustrates that concentrations exceeding the CCME water quality guideline of 15 µg/L typically occur from November to January (Figure 3.2-26).

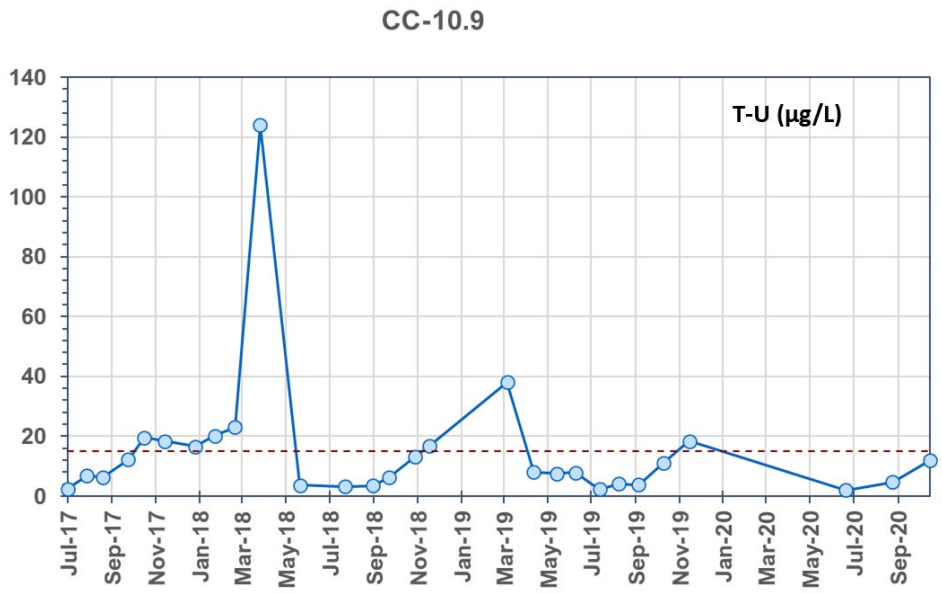

Figure 3.2-25: Total uranium (T-U) in CC-10.9 located in Coffee Creek for the period October 2017 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (red dashed line) for the protection of aquatic life.

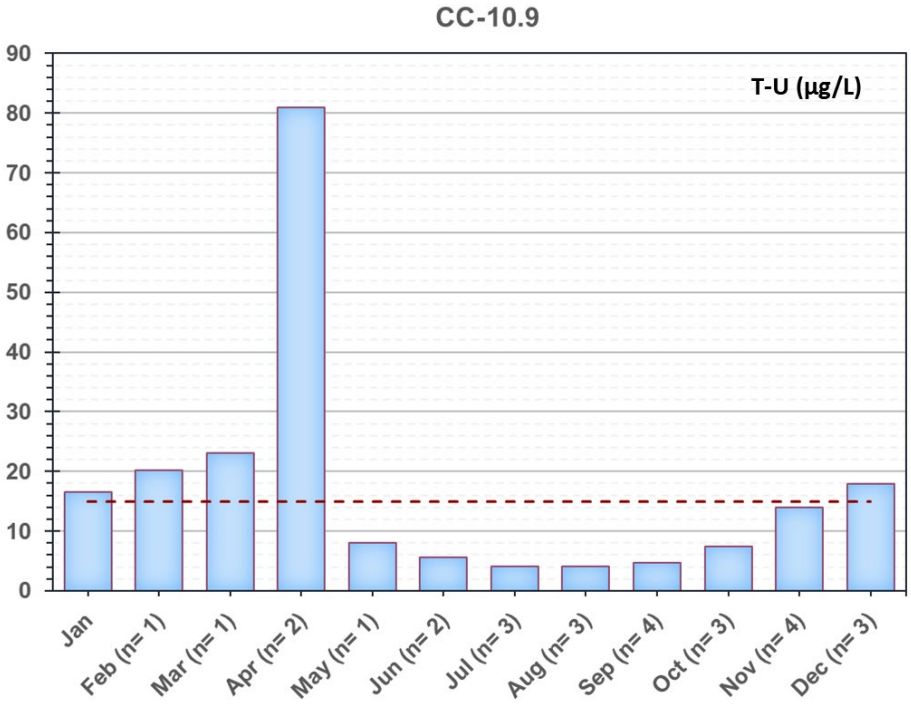

Figure 3.2-26: Mean monthly total uranium (T-U) concentrations at CC-10.9 in Coffee Creek for the period October 2017 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (dashed red line) for protection of aquatic life.

3.2.3.5 5 in 30 Sampling of CC-10.9

Weekly sampling occurred at CC-10.9 during the period of October 4 to October 28, 2017 to assess short-term variability in water quality and results are presented in Table 3.2-5; full results are presented in Appendix A.

Table 3.2-5:

Less variability occurred throughout the 5 in 30 sampling period at CC-10.9 as compared to LC-11.4 described previously and likely reflects the well mixed conditions within Coffee Creek. Sulphate, a conservative parameter (*e.g.*, changes in concentration would only arise from dilution and not geochemical adsorption or precipitation reactions), was present at CC-10.9 on October 19, 2017 at concentrations of approximately 70 mg/L (Table 3.2-5) which corresponded to sulphate concentrations at CC-11.6, immediately upstream of the confluence of Latte Creek and Coffee Creek of 69 mg/L for the same date (Appendix A). Sulphate concentrations in lower Latte Creek at LC-0.2, immediately before entering Coffee Creek, on the same date was approximately 100 mg/L, suggesting that station CC-10.9 indeed represents a well-mixed condition of Latte Creek water with Coffee Creek waters.

A slight increasing trend in concentration was observed for those parameters inversely related to flow, most notably conductivity, hardness, sulphate and uranium.

3.3 Halfway Creek and YT-24

The following section describes baseline water quality results for Halfway Creek and the small, ephemeral creek named YT-24.

Halfway Creek contains two water quality monitoring stations at HC-6.8, approximately mid-way down the watershed, and at station HC-1.0, at the mouth of Halfway Creek prior to entering the Yukon River (Figure 3.3-1).

Water quality in YT-24 is characterized by data collected at YT24-0.1 at the mouth of the creek prior to entering the Yukon River (Figure 3.3-1).

3.3.1 Halfway Creek – Stations HC-6.8 and HC-1.0

3.3.1.1 Summary Statistics

Water quality at stations HC-6.8 and HC-1.0 has been collected since October 2010 and continues to present. Data for HC-6.8 represents a nearly continuous monthly record for the period of October 2010 to December 2020. For station HC-1.0, monthly sampling in the winter period has proved sporadic as a result of freezing conditions and during the low-low flow periods, the lower reaches of Halfway Creek do not contain flow.

Table 3.3-1 and Table 3.3-2 summarize monthly mean concentrations for a suite of key parameters at station HC-6.8 and HC-1.0, respectively.

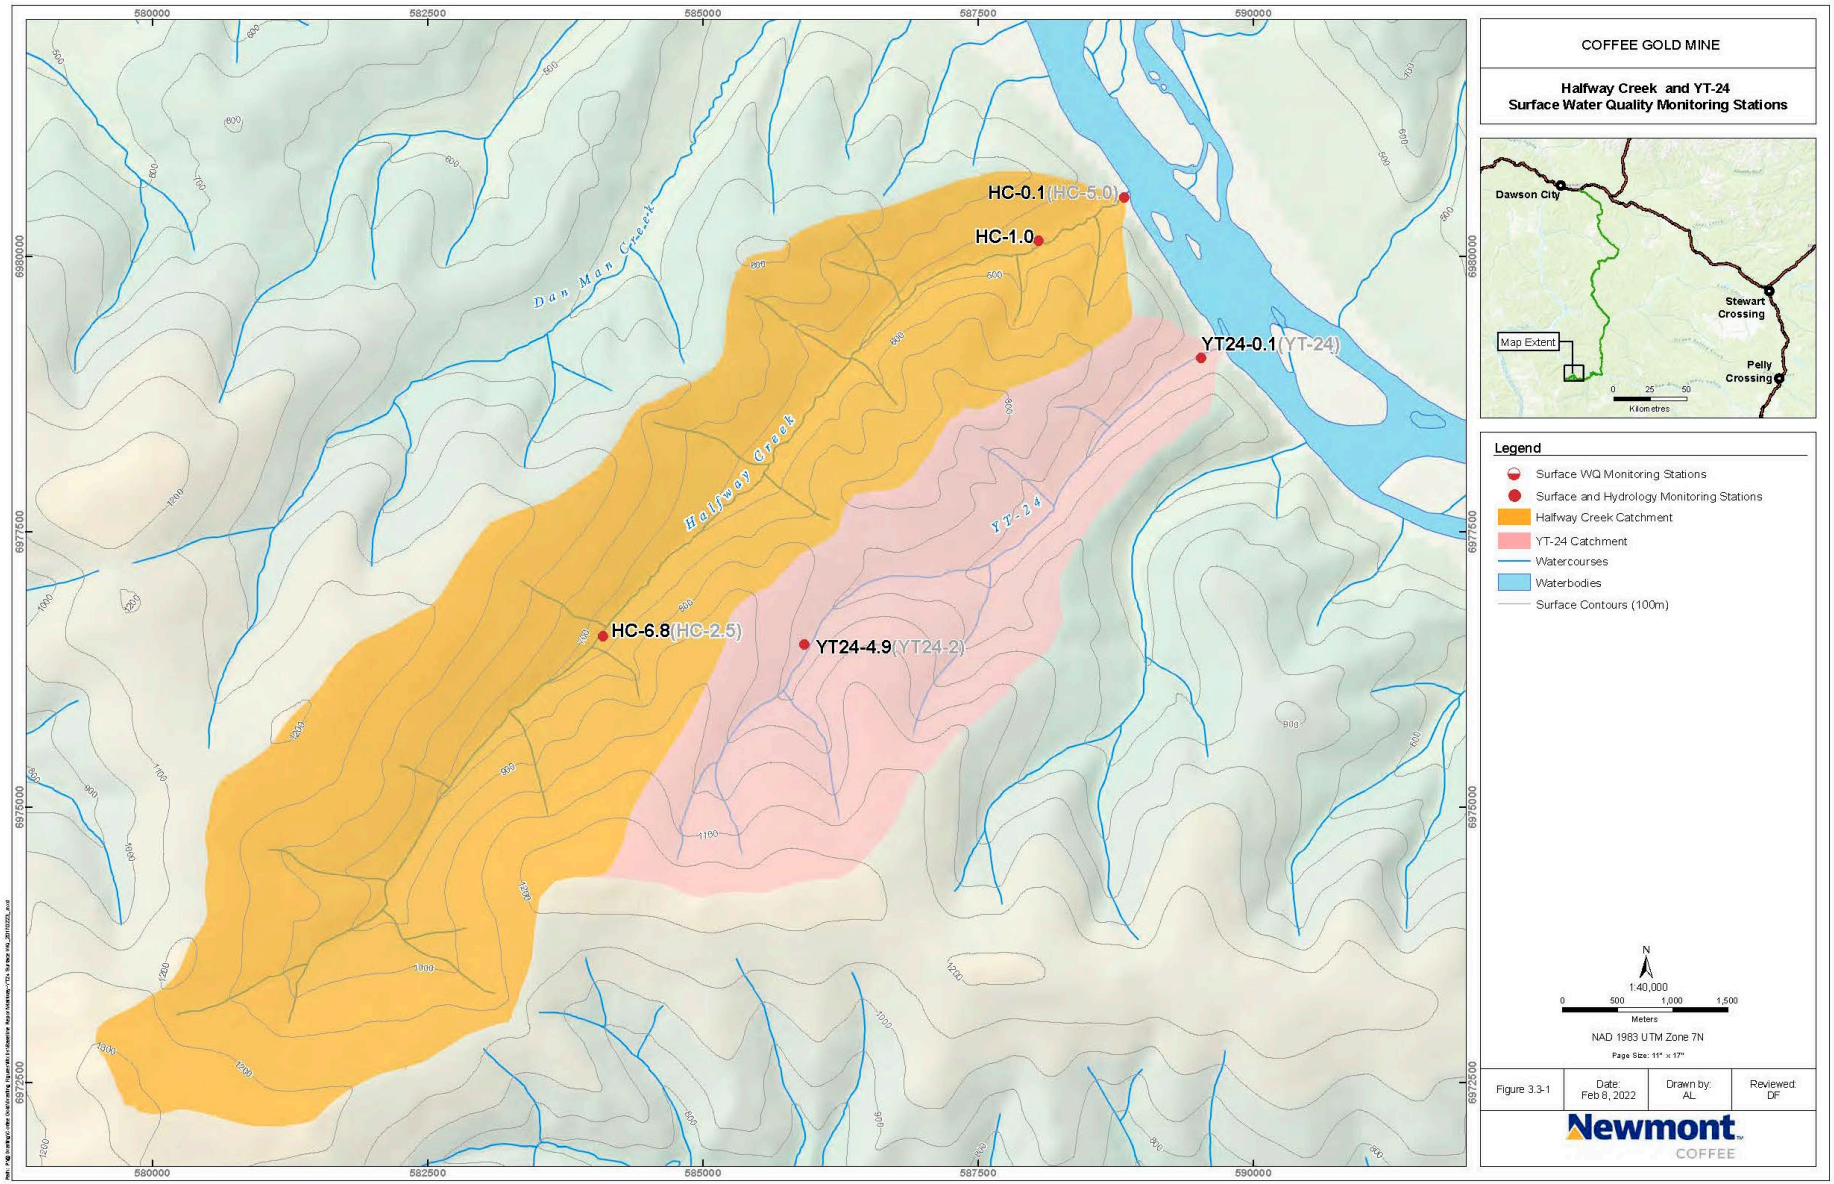

Figure 3.3-1: Detail of Halfway Creek and YT-24 drainages illustrating key monitoring station locations

3.3.1.1 Major Ions

The major ion chemistry of mid-reach and lower-reach Halfway Creek is assessed with respect to hardness, sulphate and pH. Station HC-6.8 is characterized by seasonally soft waters (~50 mg/L [as $CaCO_3$]) during freshet periods (May-June) and moderately hard to hard waters (ranging from 70 mg/L to ~200 mg/L [as $CaCO_3$]) during low flow periods such as winter (Table 3.3-1; Figure 3.3-2).

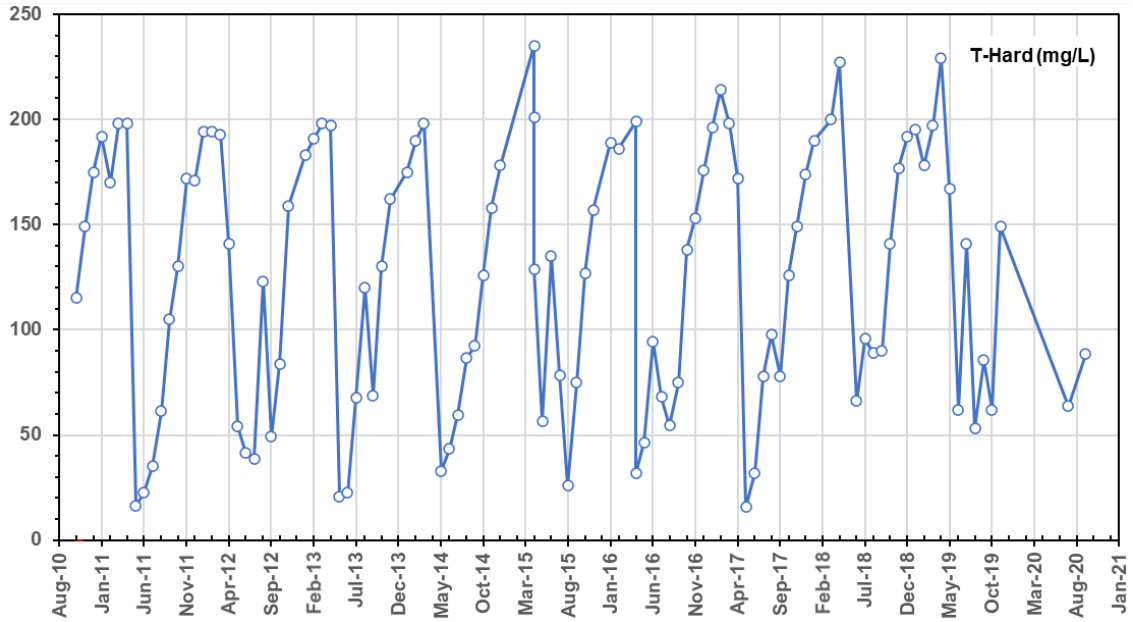

Figure 3.3-2: Total hardness (T-Hard., as mg/L $CaCO_3$) in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020

In lower Halfway Creek, hardness values range typically between roughly 66 mg/L to 175 mg/L (as $CaCO_3$) (Table 3.3-2.; Figure 3.3-3).

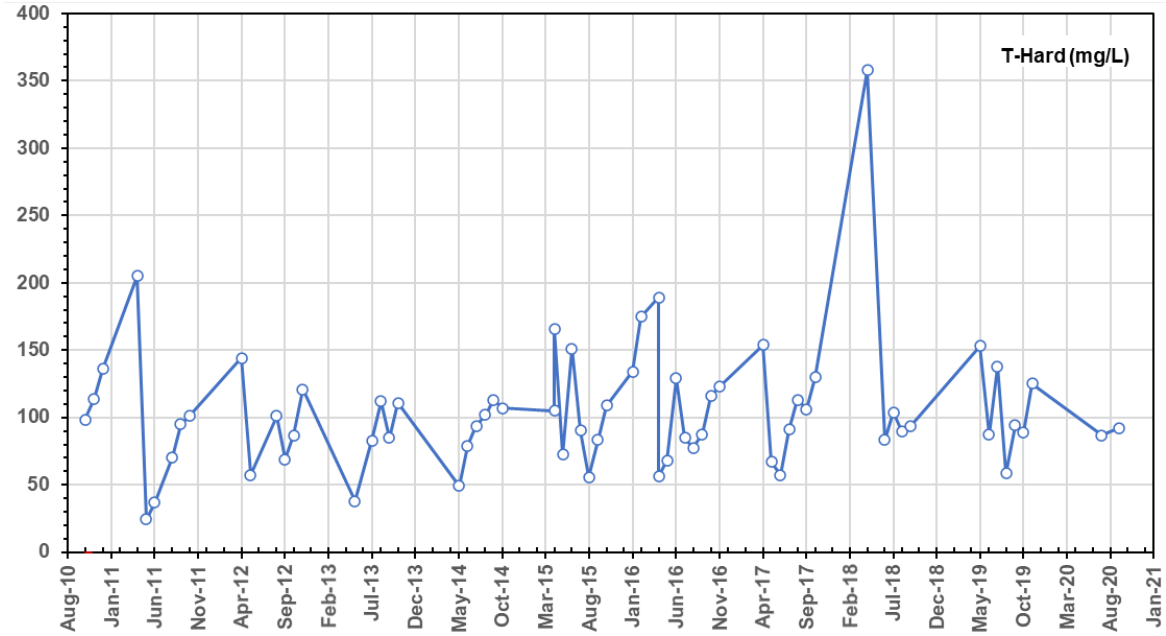

Figure 3.3-3: Total hardness (T-Hard., as mg/L $CaCO_3$)in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020.

Similar trends for conductivity and alkalinity are also observed at stations HC-6.8 and HC-1.0 with pronounced seasonal fluctuations, with minima coinciding with freshet periods in May and June (Table 3.3-1 and Table 3.3-2). As observed in the other drainages at the project site, these trends in stream salinity reflect varying proportions of low ionic strength snow-melt driven surface runoff and groundwater inputs (higher ionic strength). The stronger seasonal signature observed in mid Halfway Creek at HC-6.8 reflects a more pronounced groundwater influence in the winter low flow periods as compared to HC-1.0.

The pH in mid and lower Halfway Creek remains relatively uniform throughout the year with values generally ranging between 7.0 and 8.0 with the lower pH occurring during peak snow-melt periods. All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in mid and lower Halfway Creek exhibit similar trends and concentrations with lower values occurring in peak freshet periods (12 to 28 mg/L; May to June) and high values during lower flow conditions (22 to 76 mg/L; October to February) (Table 3.3-1 and Table 3.3-2).

Unlike the dissolved ions, higher TSS concentrations in mid and lower Halfway Creek coincide with the peak snowmelt months or during intense summer rainfall events (Table 3.3-1 and Table 3.3-2). At most other flow periods of the year, TSS values in Halfway Creek were generally below 2.0 mg/L.

3.3.1.2 Nutrients

As with other Project catchments, nutrient parameters are found in low concentrations in mid and lower Halfway Creek. Ammonia-N concentrations are low with mean monthly values typically below 0.03 mg/L for HC-6.8 and HC-1.0 (Table 3.3-1 and Table 3.3-2). Baseline mean nitrate-N concentrations in mid Halfway Creek ranged from 0.09 to 0.5 mg/L, with highest monthly means observed during late fall-early winter low flows. Similarly, mean nitrate-N concentrations in lower Halfway Creek ranged from 0.03 to 0.5 mg/L, again with highest monthly means observed during late fall-early winter low flow conditions. Dissolved phosphorus concentrations at both stations were low with values ranging from 0.004 to < 0.01 mg/L, indicative of ultra-oligotrophic and oligotrophic conditions (Table 3.3-1 and Table 3.3-2).

As with other streams monitored for the project, TOC and DOC exhibit a marked seasonal signature with highest values observed during peak runoff periods. For HC-6.8, DOC concentrations range from less than 5.0 mg/L during baseflow periods, dominated by groundwater inputs, to upwards of 12 to 23 mg/L during higher flow periods reflecting carbon contributions associated with terrestrial runoff (Figure 3.3-4). For HC-1.0, DOC values ranged from < 10 mg/L during baseflow periods up to 20 mg/L during higher flow periods (Figure 3.3-5).

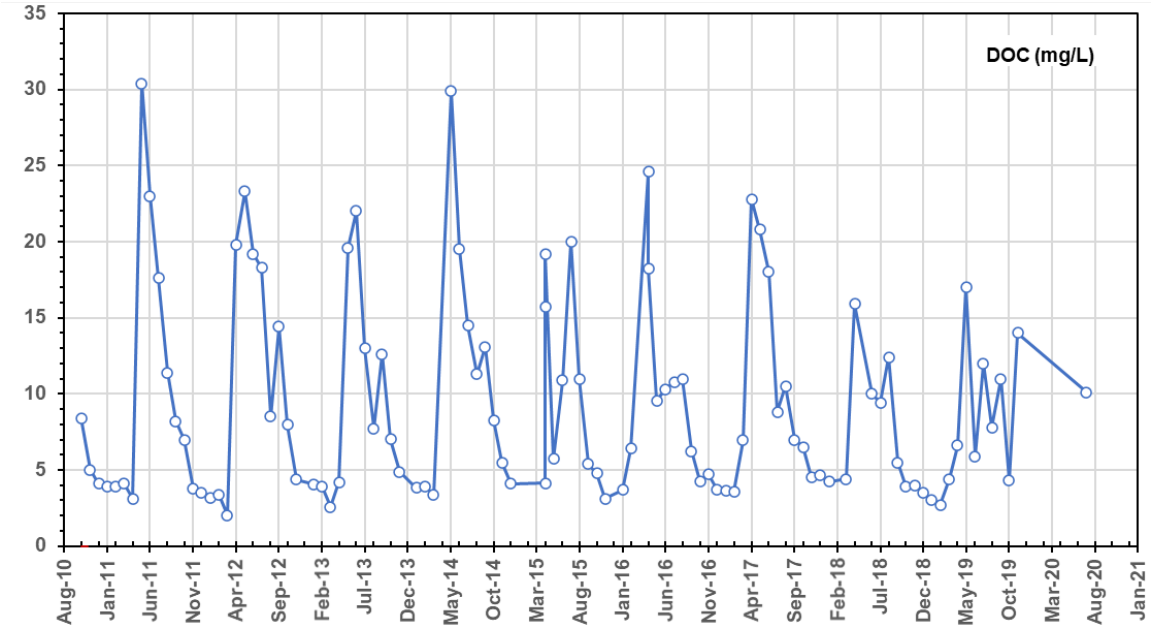

Figure 3.3-4: Dissolved organic carbon (DOC) in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020.

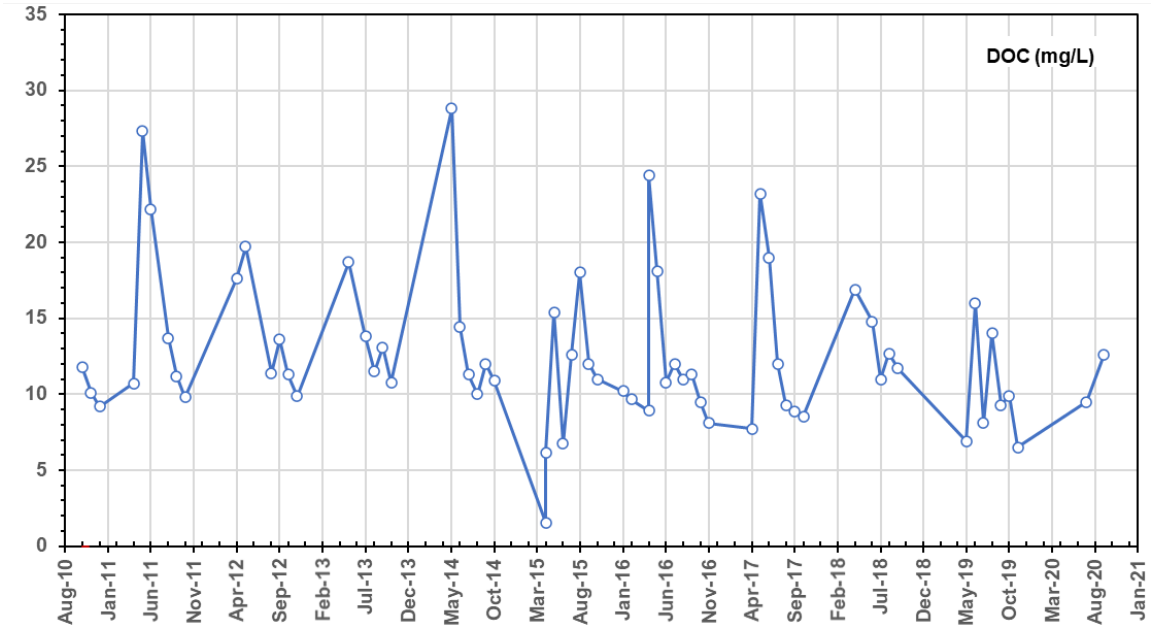

Figure 3.3-5: Dissolved organic carbon (DOC) in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020

3.3.1.3 Trace Elements

Characterization of baseline trace element concentrations in mid and lower Halfway Creek was developed from data collected from October 2010 to December 2020 at HC-6.8 and HC-1.0. For most parameters, mean monthly concentrations of total and dissolved trace elements are low (*e.g.*, As, Sb, Co, Cr, Pb, Hg, Ni, Se, and Zn). Total As concentrations in mid Halfway Creek at HC-6.8 and HC-1.0 are roughly between 0.6 to 1.5 µg/L with maximum concentrations of total As observed coincident with high flow events and elevated TSS (Figure 3.3-6 and Figure 3.3-7; Appendix A).

Total As concentrations remained well below the CCME guideline of 5.0 µg/L for the protection of aquatic life at both sampling stations. However, precipitation events that produce elevated TSS in these stations also produce elevated total As concentrations (*e.g.*, August 2015 event; TSS = 333 mg/L; total As = 8.4 µg/L at HC-1.0; see Appendix A).

Total Se concentrations in mid and lower Halfway Creek are very low and typically less than 0.15 µg/L (Table 3.3-1 and Table 3.3-2).

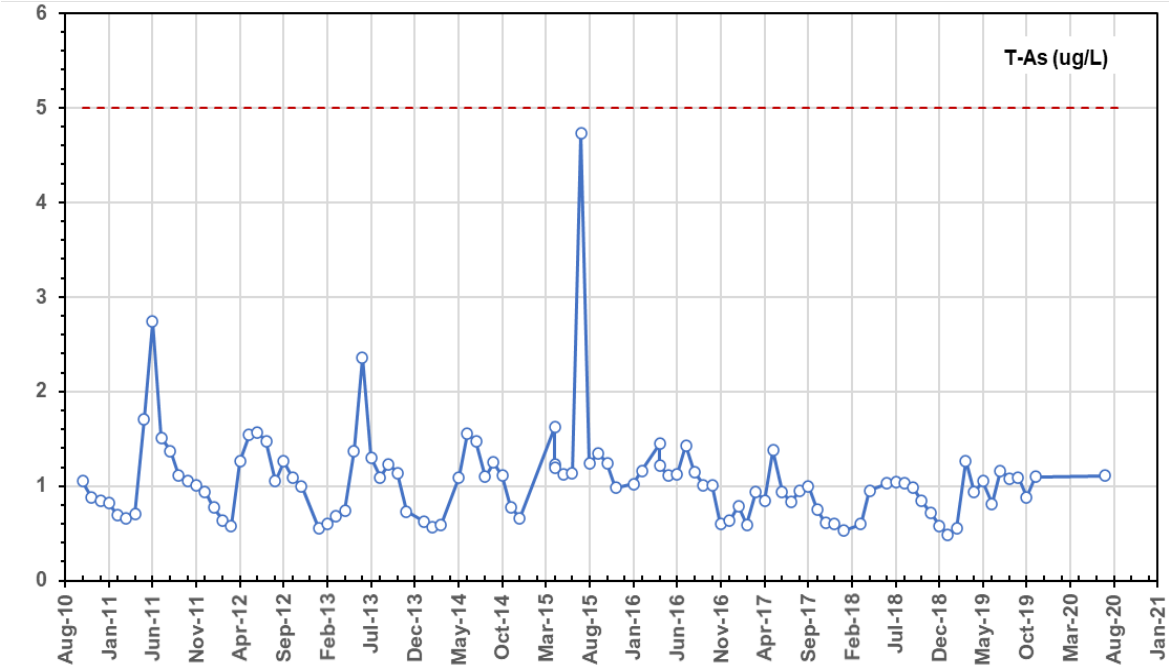

Figure 3.3-6: Total arsenic (T-As) in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed line) for protection of aquatic life.

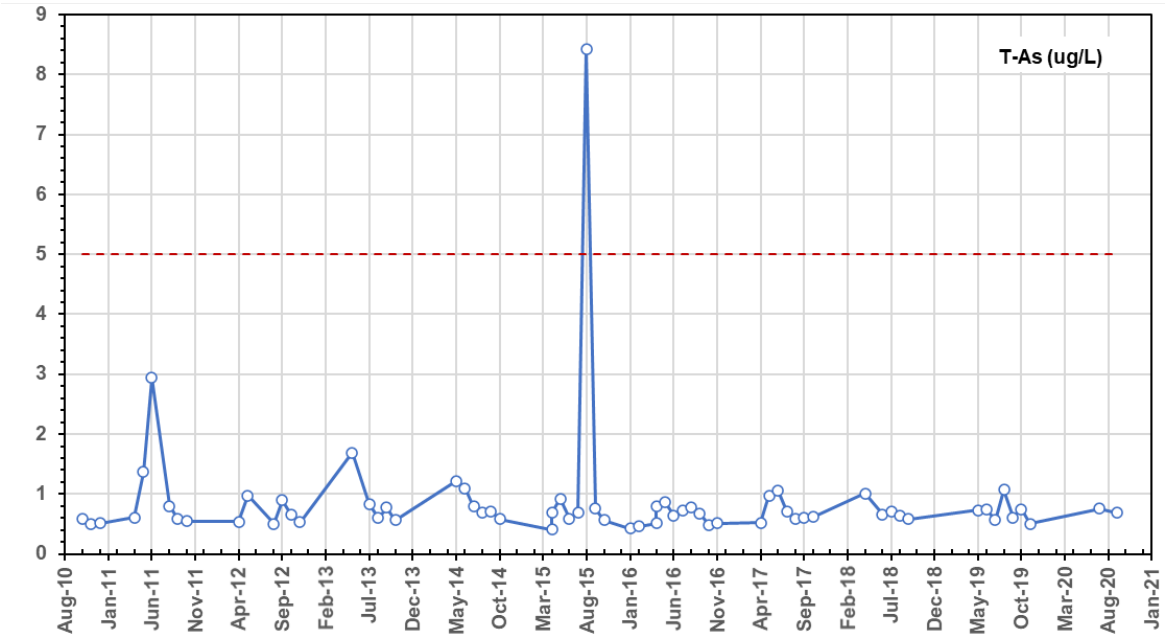

Figure 3.3-7: Total arsenic (T-As) in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed line) for protection of aquatic life.

Dissolved Al is consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L throughout Halfway Creek, with peak concentrations coinciding with higher flow conditions (Figure 3.3-8 and Figure 3.3-9). The highest dissolved Al values are observed at HC-6.8 with peak concentrations on the order of 300 µg/L (Figure 3.3-8). During baseflow periods, dissolved Al concentrations throughout Halfway Creek are generally below 30 µg/L (Figure 3.3-8 and Figure 3.3-9).

Concentrations of total Cu in mid and lower Halfway Creek show seasonal maxima associated with peak runoff periods that can slightly exceed the CCME hardness-dependent Cu guideline for the protection of aquatic life (Figure 3.3-10and Figure 3.3-11).

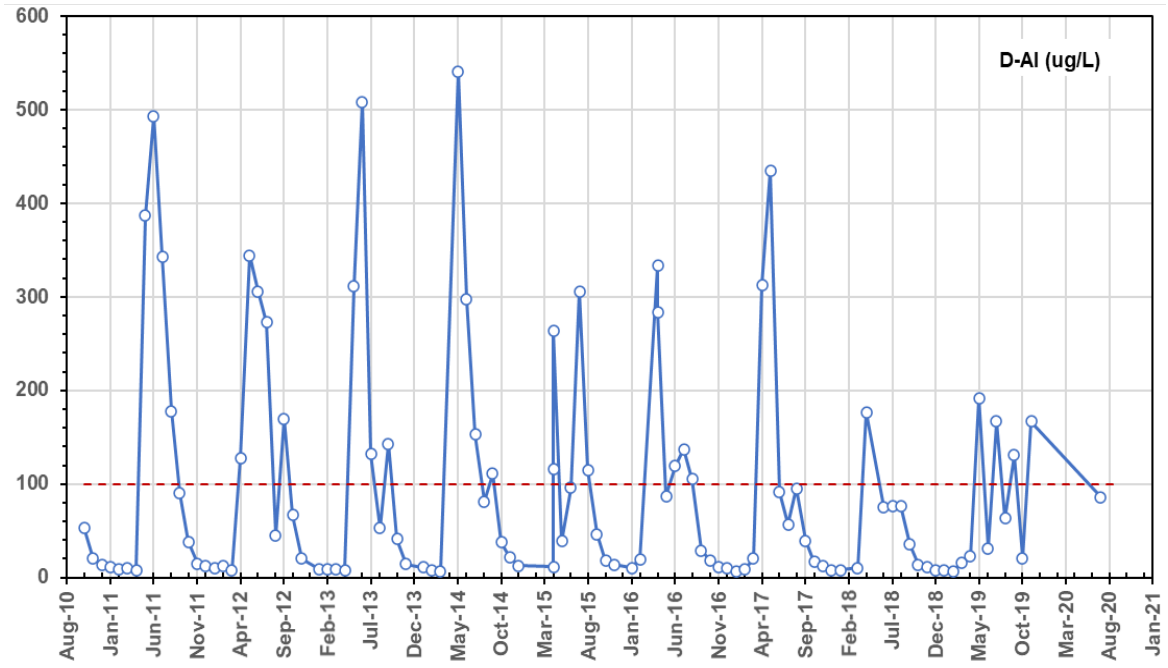

Figure 3.3-8: Dissolved aluminum (D-Al) in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020 compared to the British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

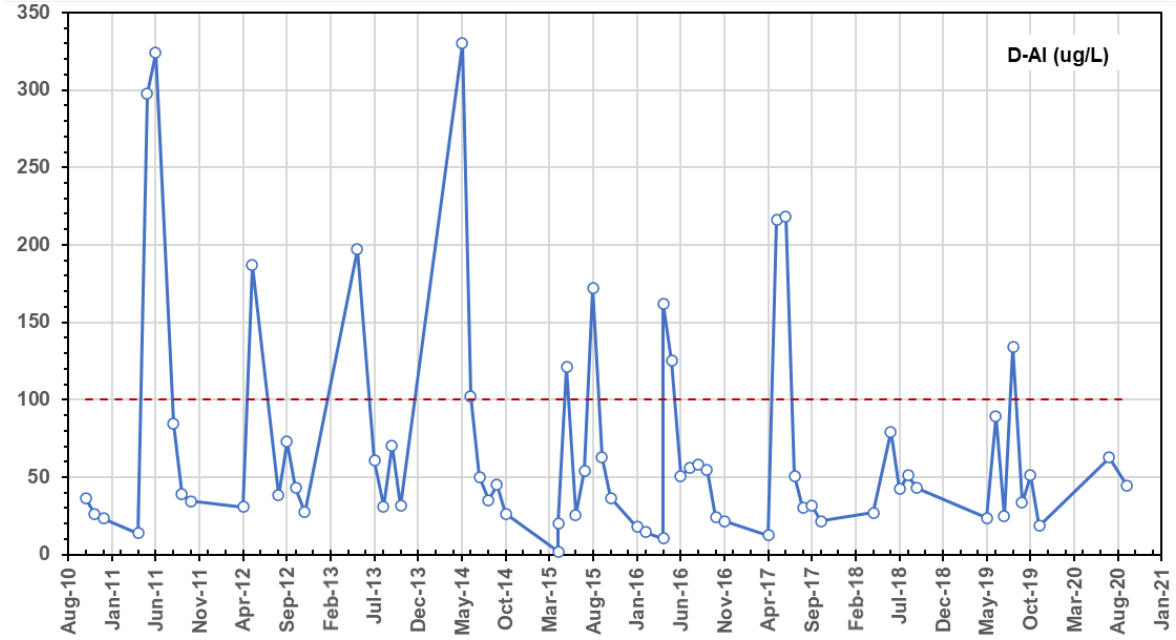

Figure 3.3-9: Dissolved aluminum (D-Al) in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

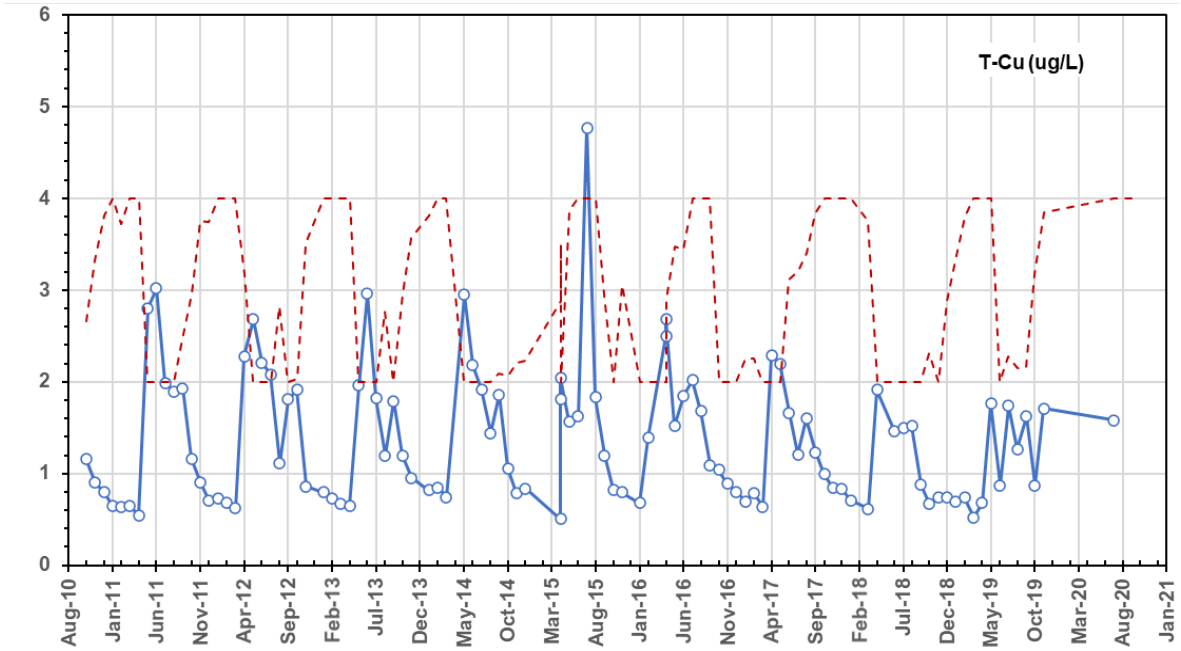

Figure 3.3-10: Total copper (T-Cu) in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness dependent water quality guidelines (red dashed line) for the protection of aquatic life.

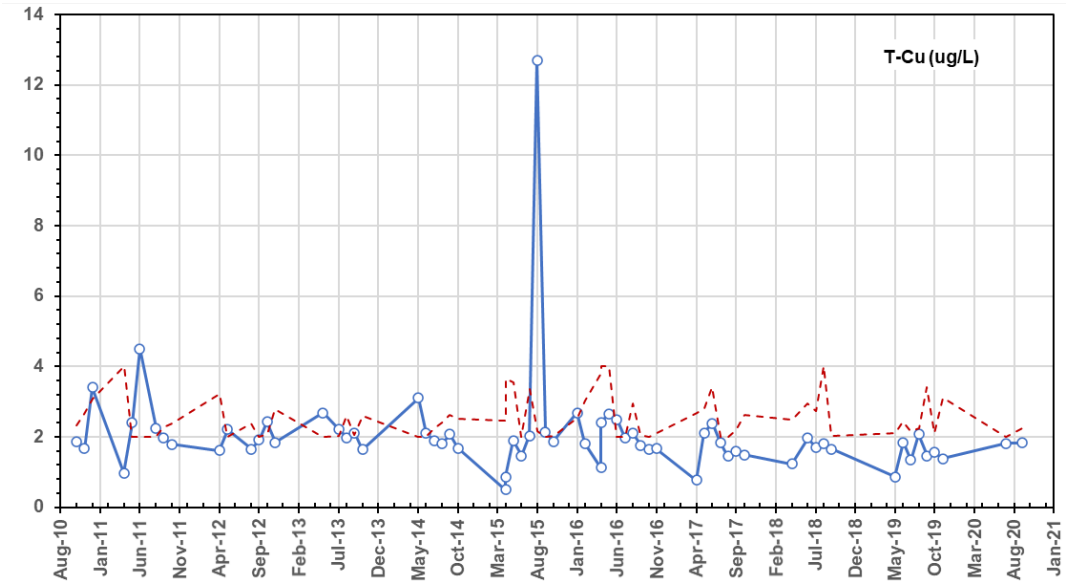

Figure 3.3-11: Total copper (T-Cu) in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent water quality guidelines (red dashed line) for the protection of aquatic life.

In mid and lower Halfway Creek, total Cd concentrations do not exceed the chronic or acute CCME hardness-dependent guidelines for protection of aquatic life (Figure 3.3-12 and Figure 3.3-13).

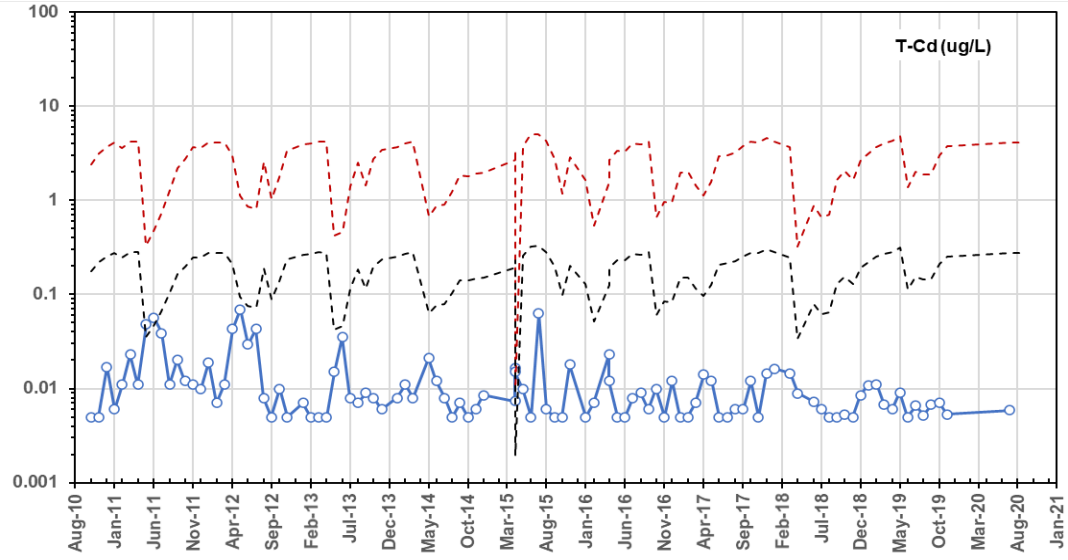

Figure 3.3-12: Total cadmium (T-Cd) concentrations in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent water quality guideline for the protection of aquatic life.

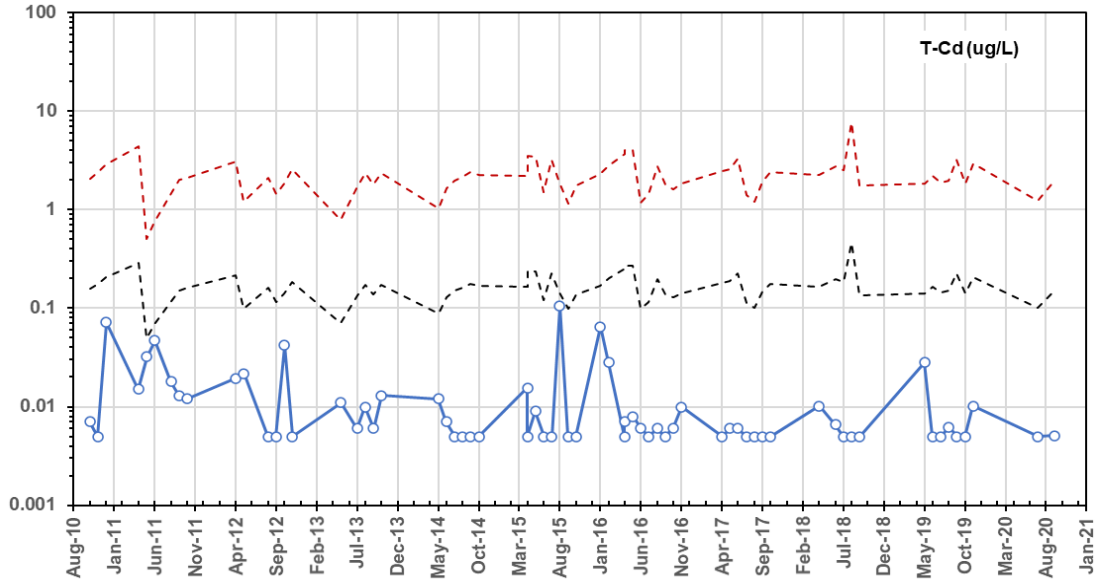

Figure 3.3-13: Total cadmium (T-Cd) concentrations in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent dashed line) water quality guideline for the protection of aquatic life.

Like Latte Creek and upper Coffee Creek, total U concentrations in Halfway Creek exhibit a distinct seasonality at station HC-6.8. Total U concentrations in mid Halfway Creek at station HC-6.8 were above the chronic CCME water quality guideline of 15 µg/L during fall and winter periods with mean monthly concentrations ranging from 37 to 84 µg/L (Table 3.3-1 and Figure 3.3-14). The high magnitude of the winter values can be attributed to the input of U-enriched groundwater which sustains baseflow conditions during the ice-up period. During the freshet and summer periods, the introduction of surface runoff dilutes the groundwater signature, resulting in considerably lower mean monthly U concentrations (roughly 15 to 20 µg/L; Table 3.3-1). The strong inverse relationship ($r^2 = 0.83$) between total U and flow in mid Halfway Creek at station HC-6.8 is illustrated in Figure 3.3-15.

Graphical representation of monthly mean total U data at HC-6.8 illustrates that monthly mean concentrations generally exceed the CCME guideline of 15 µg/L for U (Figure 3.3-16).

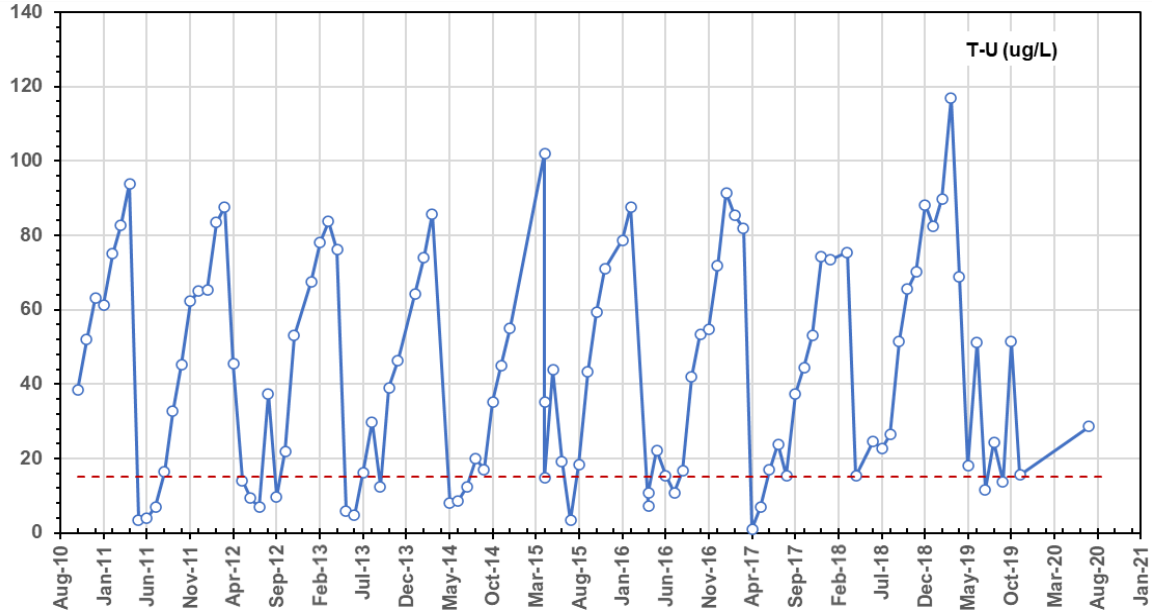

Figure 3.3-14: Total uranium (T-U) in mid Halfway Creek (HC-6.8) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guideline (red dashed line) for the protection of aquatic life.

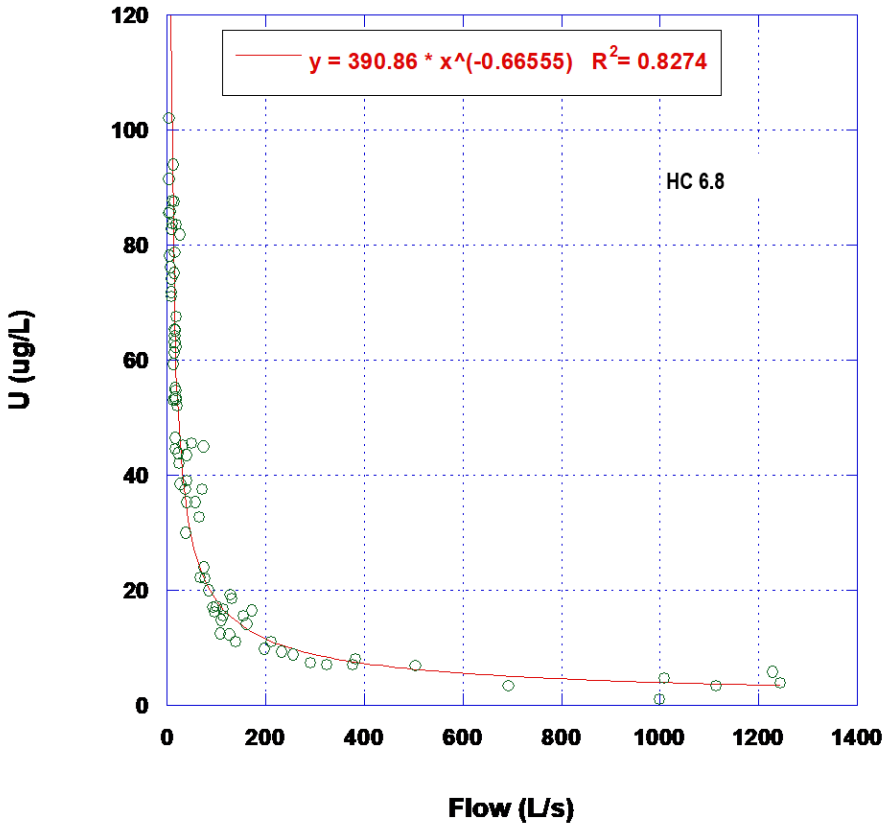

Figure 3.3-15: Relationship between total U and flow in mid Halfway Creek for the period October 2010 to December 2020

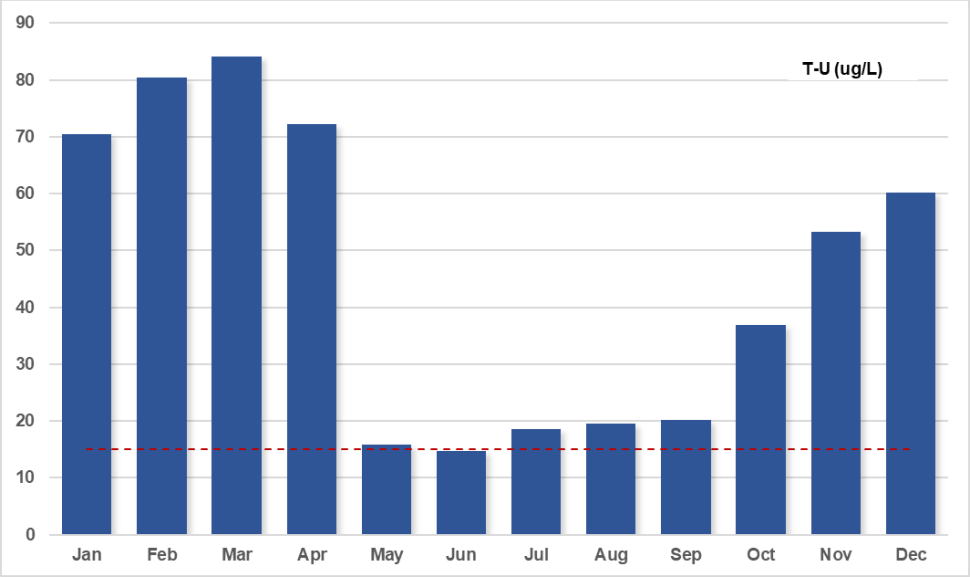

Figure 3.3-16: Mean monthly total uranium (T-U) concentrations at HC-6.8 in mid Halfway Creek for the period October 2010 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (dashed red line) for protection of aquatic life.

In lower Halfway Creek this same seasonal trend for total U is less prominent and may be an artifact of the dataset being biased to the open water period (*i.e.*, minimal baseflow representation due to absence of flow in lower Halfway Creek). However, low flow conditions were observed in Halfway Creek in June 2015, February 2016 and April 2017 that coincided with peak total U concentrations on the order of 30 µg/L at station HC-1.0. In 2018 and 2019, the lowest flows recorded in March and February also coincided with the highest U concentrations. However, it should be noted that flow regimes in HC-1.0 is highly variable. Measured concentrations in most other months are less than the CCME guideline of 15 µg/L for the protection of aquatic life (Figure 3.3-17and Figure 3.3-18).

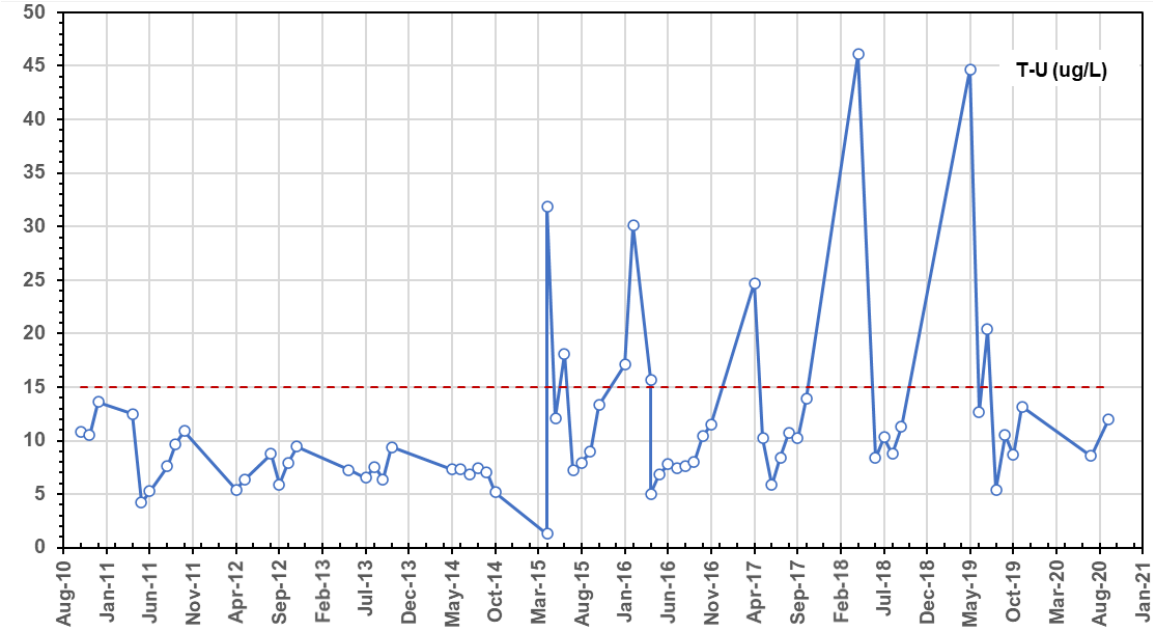

Figure 3.3-17: Total uranium (T-U) in lower Halfway Creek (HC-1.0) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (red dashed line) for the protection of aquatic life.

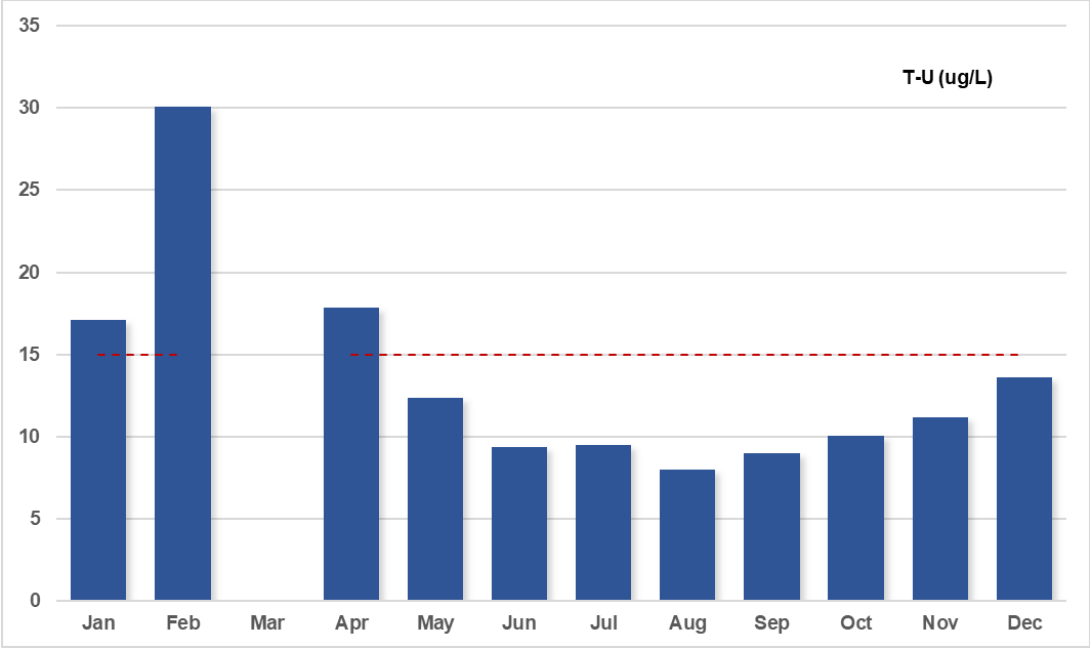

Figure 3.3-18: Mean monthly total uranium (T-U) concentrations at HC-1.0 in lower Halfway Creek for the period October 2010 to December 2020 and compared to the Canadian Council of Ministers of the Environment (CCME) chronic water quality guidelines (dashed red line) for protection of aquatic life.

3.3.1.4 5 in 30 Sampling Results Station HC-6.8

Weekly sampling occurred at HC-6.8 during the period of October 4 to October 28, 2017 to assess short-term variability in water quality and results are presented in Table 3.3-3; full results are presented in Appendix A.

Table 3.3-3:

Data for those parameters whose concentrations in Halfway Creek are inversely related to flow conditions, including conductivity, hardness, alkalinity, sulphate and uranium show an increasing concentration trend over the sampling period. This is likely the result of decreasing flow in Halfway Creek through the sampling period (Figure 3.3-22). Flow data collected at HC-6.8 indicates decreasing flow from October 4, 2017 (~72 L/s) to October 19, 2017 (~57 L/s); flow after that date required extrapolation owing to freezing conditions occurring at the station and erroneous pressure transducer data.

For example, total U concentrations increased roughly 2-fold throughout the sampling period from a concentration of approximately 27 µg/L on October 4, 2017 to 43 µg/L on October 28, 2017.

By contrast, parameters that are positively correlated to flow, such as dissolved Al, show a roughly 2-fold decrease in concentration over the 5 in 30 sampling period. Parameters that have been shown to have very little correlation to flow, including As and Cu, were present at similar concentrations throughout the sampling period.

3.3.2 YT-24 Stations

A relatively small, ephemeral drainage named YT-24, drains the northern slopes of the Coffee Project area and enters the Yukon River. Monitoring of this drainage occurs at two stations YT24-4.9 (mid-creek) and near the mouth at station at YT24-0.1 (Figure 3.3-1).

3.3.2.1 Summary Statistics

Table 3.3-4 summarizes the mean monthly values for a suite of the key parameters for stations YT24-0.1 and YT24-4.9; baseline monitoring at this station commenced in June 2014. Data is not available for the period of November to March owing to an absence of flow.

3.3.2.2 Major Ions

The major ion chemistry for these two stations in YT-24 is assessed with respect to conductivity, hardness, alkalinity, sulphate and pH. Hardness in YT-24 stations was different with values ranging from 77 to 310 mg/L ($CaCO_3$, moderately hard to very hard water) and from 18 to 32 mg/L ($CaCO_3$, soft water) for YT24-4.6 and YT24-0.1, respectively. Table 3.3-4 and Table 3.3-5; Appendix B). The pH in YT-24 is consistently circumneutral with pH values ranging from 6.3 to 7.8. Generally observed pH values have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0, however some exceedances were recorded for YT24-4.9 specifically in May. These exceedances are mainly related to the input of slightly acidic snowmelt water to the creek.

Baseline concentrations for sulphate in YT24-4.9 are low and remained < 3 mg/L (Table 3.3-4). Contrarily, YT24-0.1 showed sulphate concentrations ranging from 32 to 190 mg/L (Table 3.3-5). Measured TSS concentrations in both stations are generally low, however peak flow events are associated with elevated TSS above 10 mg/L occurred in some months (Table 3.3-4 and Table 3.3-5).

3.3.2.3 Nutrients

Nutrient concentrations quantified in YT-24 include those for nitrate, nitrite, ammonia, and dissolved phosphorus. Like all the other project drainages, nutrients are present at low concentrations in YT-24. Ammonia-N concentrations are low with mean monthly values typically between 0.025 and 0.06 mg/L (Table 3.3-4 and Table 3.3-5). Mean monthly nitrate-N values ranged from 0.25 mg/L to approximately 1.6 mg/L with higher values observed for YT24-0.1 compared to YT24-4.9 Table 3.3-4 and Table 3.3-5).

Baseline concentrations for dissolved phosphorus in YT-24 are low, ranging from approximately 0.004 to a maximum of 0.02 mg/L (Table 3.3-4 and Table 3.3-5) and indicative of indicative of oligotrophic to mesotrophic conditions. (Appendix C)

TOC and DOC values were relatively consistent throughout the open water period. Mean monthly TOC and DOC levels in YT-24 are relatively high, ranging between approximately 9.8 to 28 mg/L, with highest values observed during peak flow periods (Table 3.3-4 and Table 3.3-5).

3.3.2.4 Trace Elements

Baseline trace element concentrations were derived from data collected from June 2014 to December 2020 at YT24-0.1. In general, mean monthly concentrations of total and dissolved trace elements are low (*e.g.*, As, Sb, Co, Cr, Pb, Hg, Ni, Se, U and Zn). For example, total As concentrations at YT24-0.1 and YT24-4.9 are typically well below 2.0 µg/L (Table 3.3-4 and Table 3.3-5). Unlike nearby Halfway Creek, total U concentrations in YT24-0.1 and YT24-4.9 are generally much lower and are below 3.0 µg/L for most of the open water period. However, mean U concentrations in YT24-0.1 during freshet (April and May), exceed the CCME chronic water quality guideline of 15 µg U/L.

Dissolved Al in YT24-0.1 is episodically observed to be elevated above BC ENV guideline for the protection of aquatic life of 100 µg/L and appears to coincide with peak flow periods and elevated TSS (Figure 3.3-19; see Appendix A). For YT24-4.9 dissolved Al mean concentrations ranged from 79 to 422 µg/L with values generally exceeding the BC ENV WQG of 100 µg/L in early Spring and Summer periods.

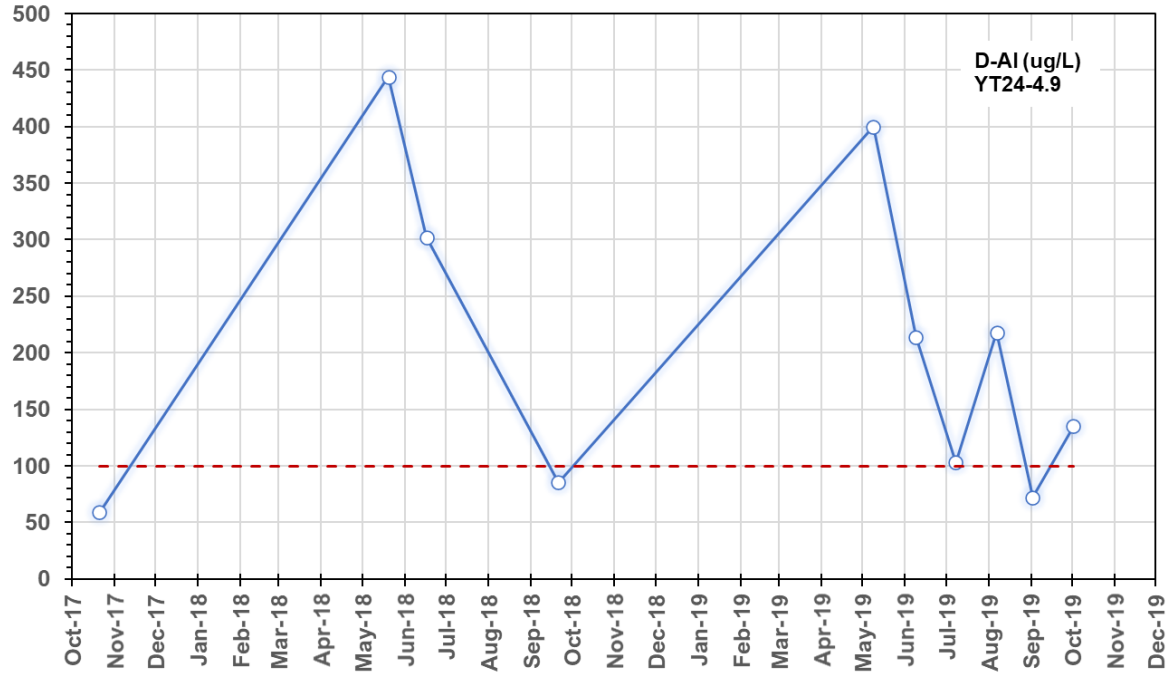

Figure 3.3-19: Dissolved aluminum (D-Al) concentrations at YT24-4.9 for the period October 2017 to October 2019 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

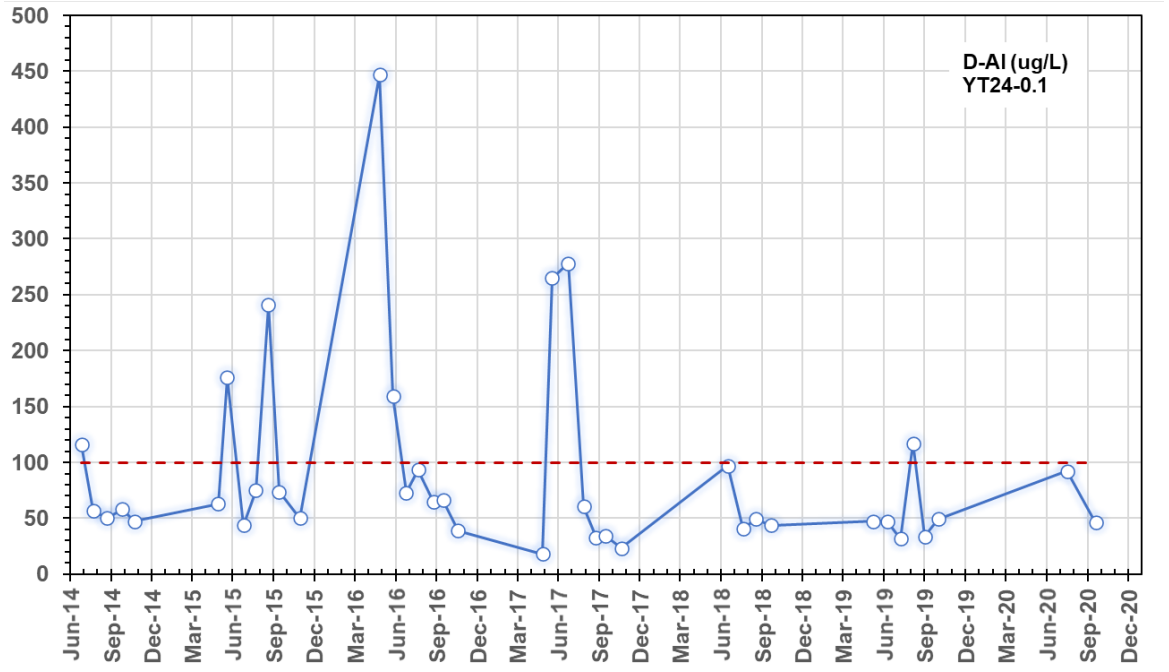

Figure 3.3-20: Dissolved aluminum (D-Al) concentrations at YT24-0.1 for the period June 2014 to December 2020 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

Concentrations of total Cu in YT24-4.9 consistently exceeded applicable CCME WQG, specifically prior to 2019 (Figure 3.3-21). For YT24-0.1 concentrations of total Cu exceed the CCME hardness-dependent guideline for the protection of aquatic life, particularly in 2016. However, these exceedances are not evident in more recent years (2017, 2018, 2019), as shown in Figure 3.3-22. Low magnitude exceedances to the CCME WQG are once again noted in 2020.

Total Cd concentrations do not exceed either of the CCME hardness-dependent chronic or acute WQG for protection of aquatic life for any of these two YT-24 stations (Figure 3.3-23 and Figure 3.3-24).

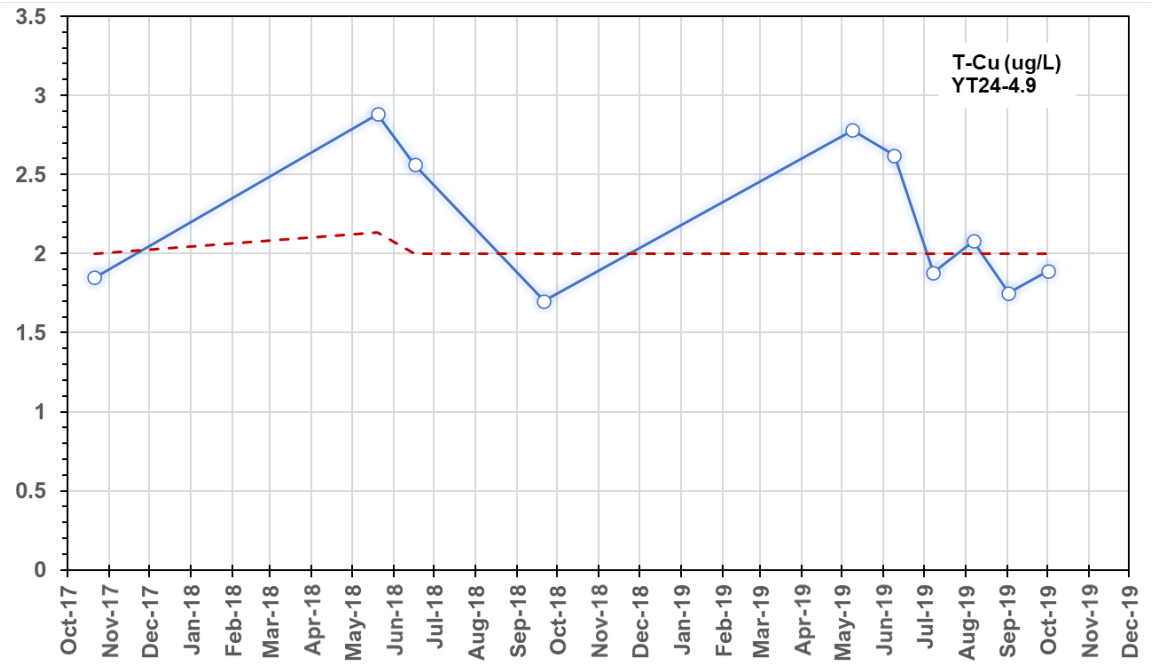

Figure 3.3-21: Total copper (T-Cu) concentrations at YT24-4.9 for the period October 2017 to October 2019 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent water quality guidelines (red dashed line) for the protection of aquatic life

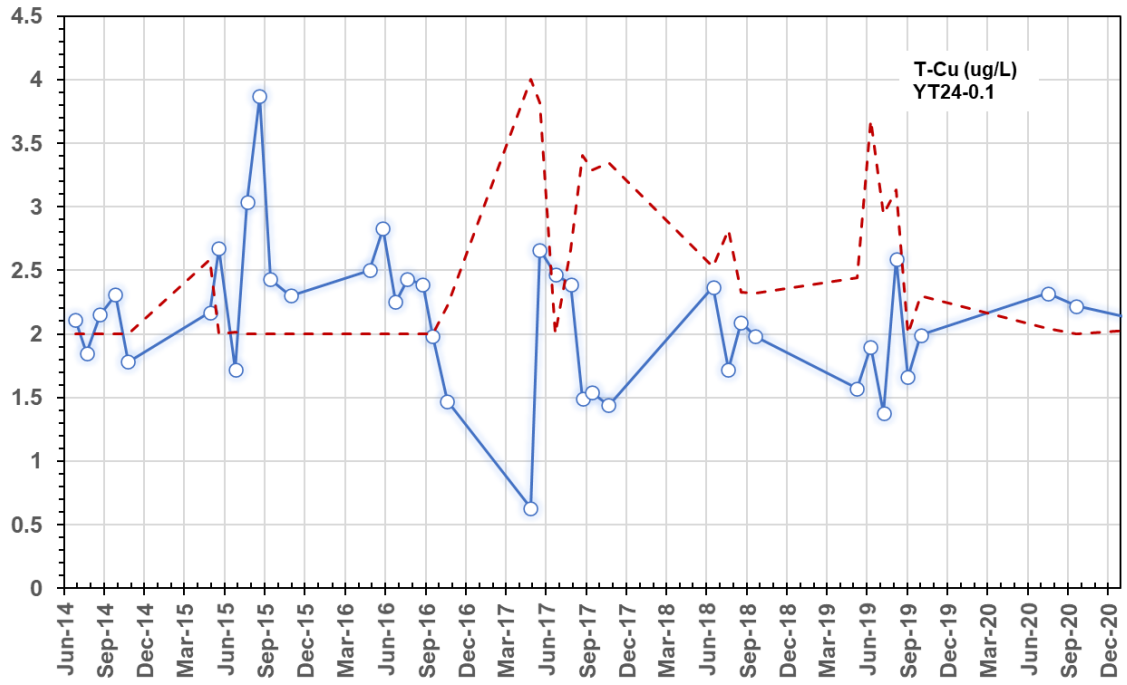

Figure 3.3-22: Total copper (T-Cu) concentrations at YT24-0.1 for the period June 2014 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent water quality guidelines (red dashed line) for the protection of aquatic life

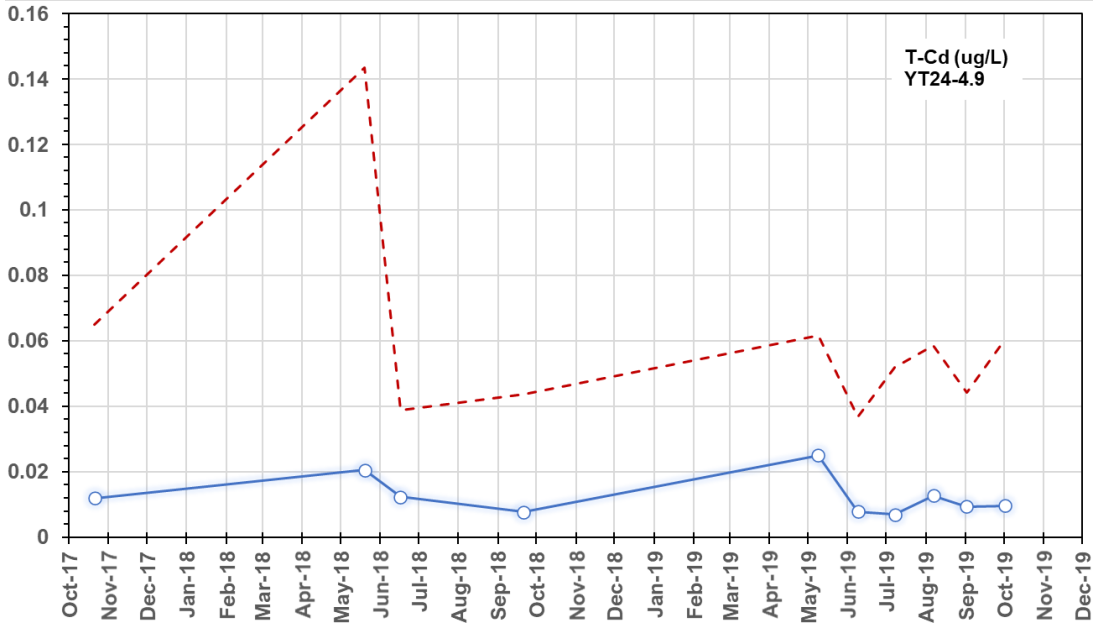

Figure 3.3-23: Total cadmium concentrations at YT24-4.9 for the period October 2017 to October 2019 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent water quality guidelines for the protection of aquatic life.

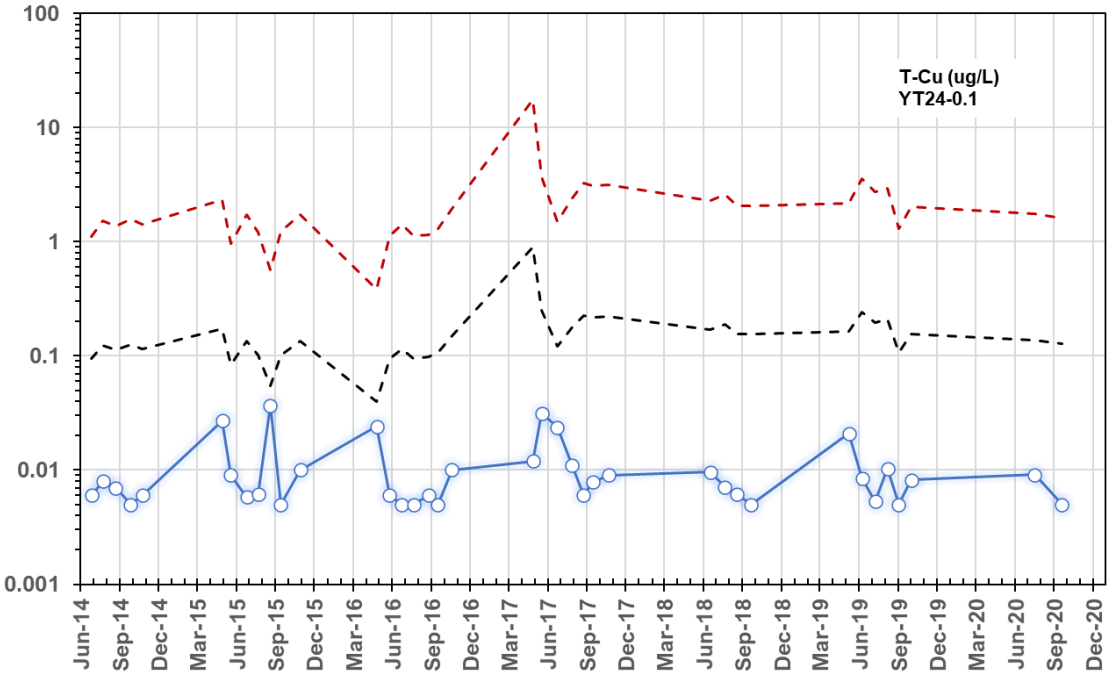

Figure 3.3-24: Total cadmium concentrations at YT24-0.1 for the period June 2014 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent water quality guidelines for the protection of aquatic life.

3.4 Yukon River Stations

3.4.1 YUK-51.3 and YUK-26.1

The following section describes baseline water quality results for the Yukon River in the immediate vicinity of the proposed project. Specifically, data are summarized for stations YUK-51.3 and YUK-26.1 (see Figure 2.1-2) that are located immediately upstream of Coffee Creek and downstream of Independence Creek, respectively.

3.4.1.1 Summary Statistics

Table 3.4-1 and Table 3.4-2 summarize the mean monthly values for a suite of the key parameters for station YUK-51.3 and YUK-26.1, respectively.

3.4.1.2 Major Ions

Yukon River major ion chemistry at stations YUK-51.3 and YUK-26.1 is assessed with respect to hardness, sulphate and pH. The Yukon River is characterized as dominantly hard waters with mean monthly hardness values for both stations ranging primarily

between approximately 83 mg/L and 120 mg/L (as $CaCO_3$) (Table 3.4-1 and Table 3.4-2; Figure 3.4-1)

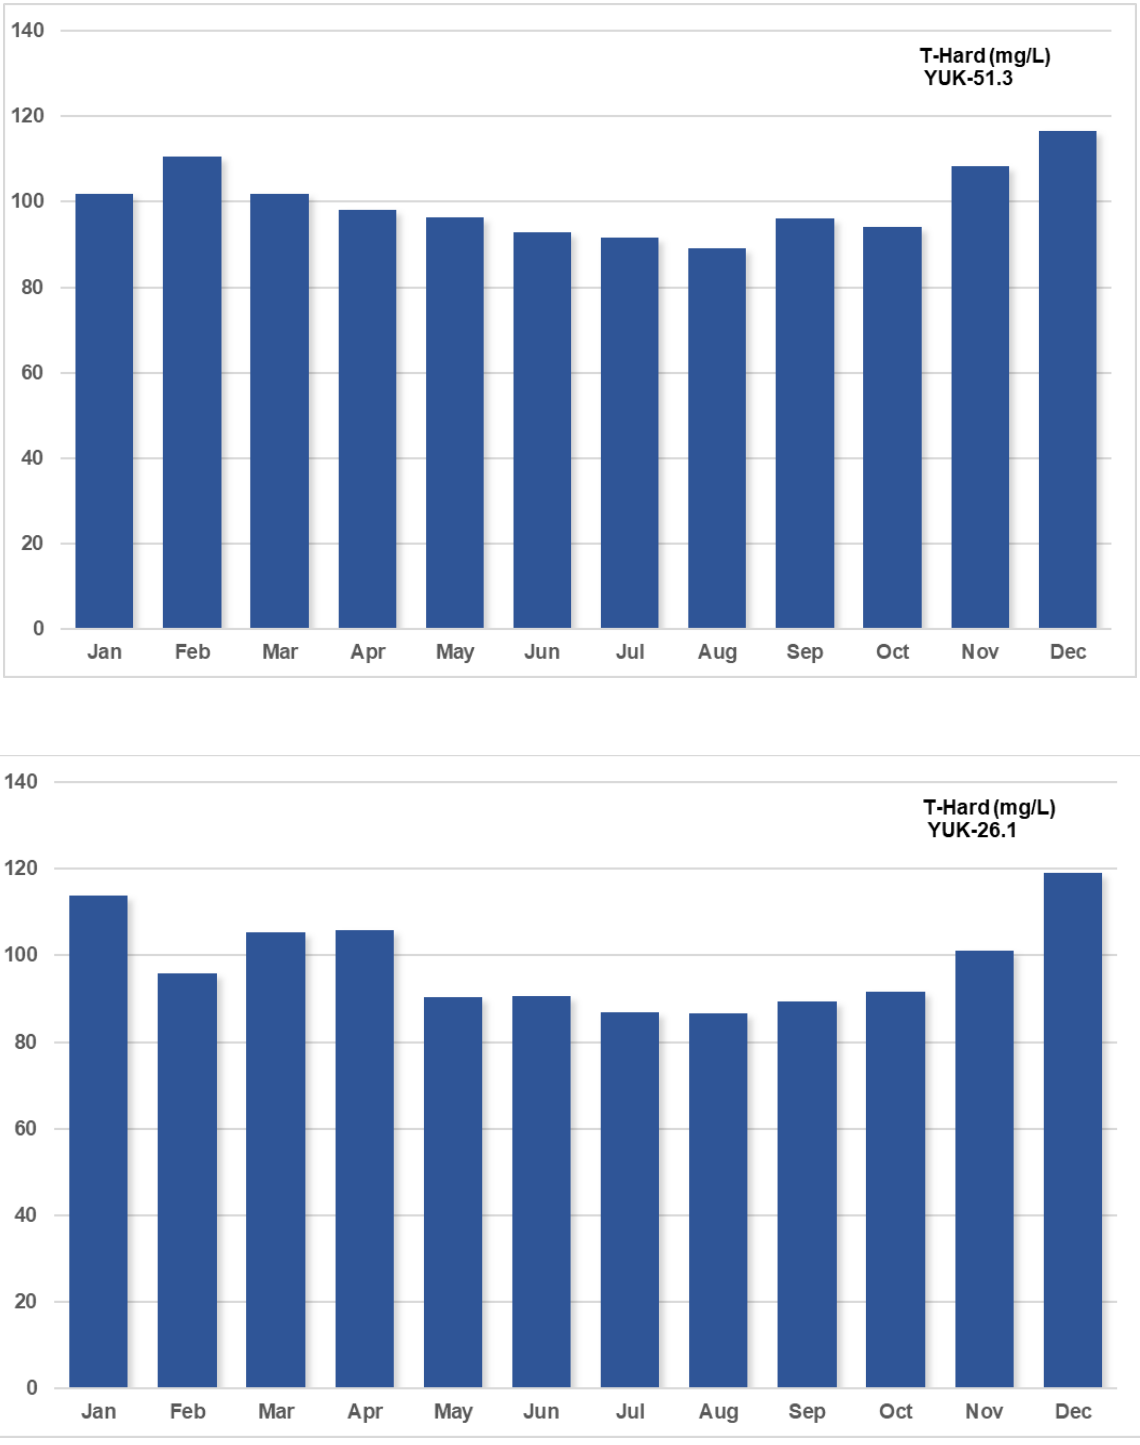

Figure 3.4-1: Mean monthly total hardness (T-Hard., as mg/L $CaCO_3$) in the Yukon River at YUK-51.3 and YUK-26.1 for the period October 2010 to December 2020.

Baseline concentrations of sulphate in the Yukon River are consistent throughout the year and don't exhibit a pronounced seasonal signature. Mean monthly sulphate values for both stations narrowly range between 21 and 28 mg/L (Table 3.4-1 and Table 3.4-2).

The pH remains roughly at 8.0 and is relatively uniform throughout the year at both stations. The neutral to slightly basic pH conditions can be linked to bicarbonate alkalinity. All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

TSS concentrations in the Yukon River show maxima coinciding with the peak snowmelt months (*e.g.*, May and June). Elevated TSS also occurs during summer flow periods and generally decrease to values less than 10 mg/L during the late fall and winter low flow conditions (Table 3.4-1 and Table 3.4-2).

3.4.1.3 Nutrients

Nutrient parameters are found in low concentrations in the Yukon River at stations YUK-51.3 and YUK-26.1. Ammonia-N concentrations are low with mean monthly values roughly between 0.01 to 0.03 mg/L. Mean monthly nitrate-N concentrations at both Yukon River stations were low and ranged between 0.03 mg/L and 0.11 mg/L. Dissolved phosphorus concentrations at both stations were low with mean monthly values narrowly ranging between 0.002 mg/L and 0.01 mg/L and indicative of oligotrophic to ultra-oligotrophic conditions (Appendix B).

Unlike the other project streams, TOC and DOC are present in lower concentrations in the Yukon River. Mean monthly DOC concentrations ranged from less than 3.0 mg/L during baseflow periods, to roughly 9.0 mg/L (Table 3.4-1 and Table 3.4-2).

3.4.1.4 Trace Elements

Baseline trace element concentrations in the Yukon River were derived from data collected from October 2010 to December 2020 at YUK-51.3 and YUK-26.1. In general, mean monthly concentrations of total and dissolved trace elements are low (*e.g.*, Al, As, Sb, Co, Cr, Pb, Hg, Ni, Se, U and Zn). Mean monthly total As concentrations in the Yukon River are typically well below 1.0 µg/L for most flow periods of the year with maximum values coincident with elevated TSS (Table 3.4-1 and Table 3.4-2). Similarly, total U concentrations in the Yukon River are also low with mean monthly values roughly around 1.0 µg/L.

In contrast to all the other monitoring locations in the vicinity of the project site, dissolved Al in the Yukon River never exceed the BC ENV guideline for the protection of aquatic life of 100 µg/L.

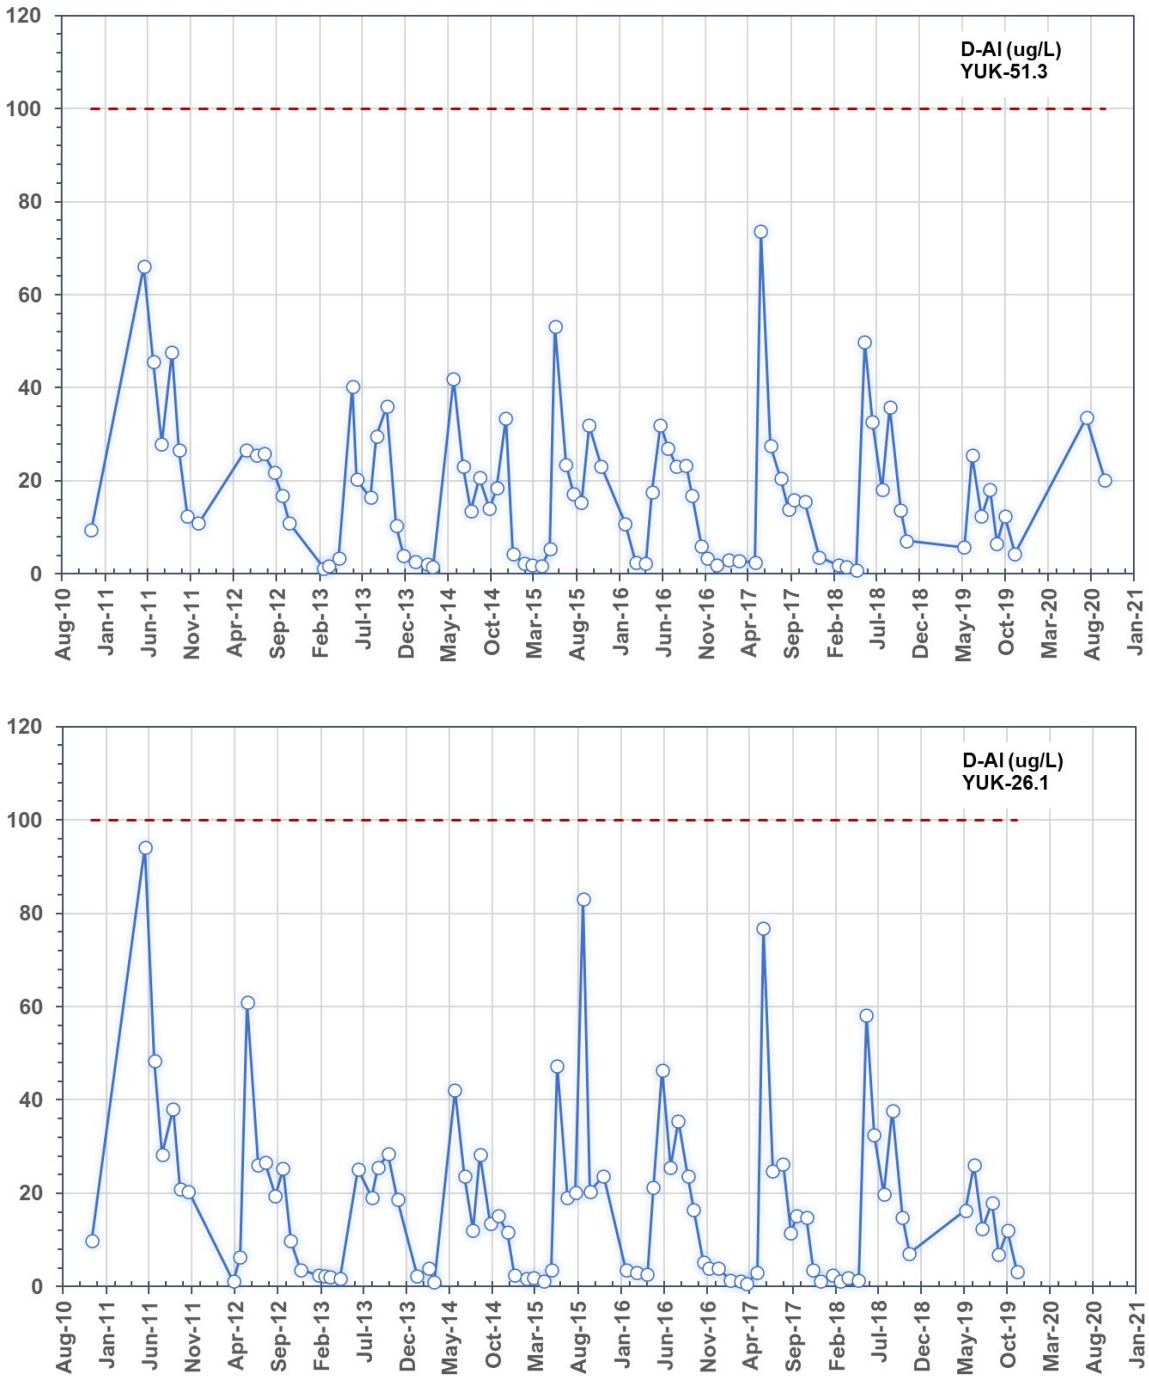

Figure 3.4-2: Dissolved aluminum (D-Al) concentrations at YUK-51.3 and YUK-26.1 in the Yukon River for the period October 2010 to December 2020 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

Interestingly, concentrations of total Cu in the Yukon River at station YUK-51.3 and YUK-26.1 routinely exceeded the CCME hardness-dependent Cu guideline for the protection of aquatic life even in these moderately hard to hard waters Figure 3.4-3). Mean monthly total Cu concentrations at both Yukon River stations indicate that elevated total Cu concentrations are associated with the peak flow months of May and June (Figure 3.4-4).

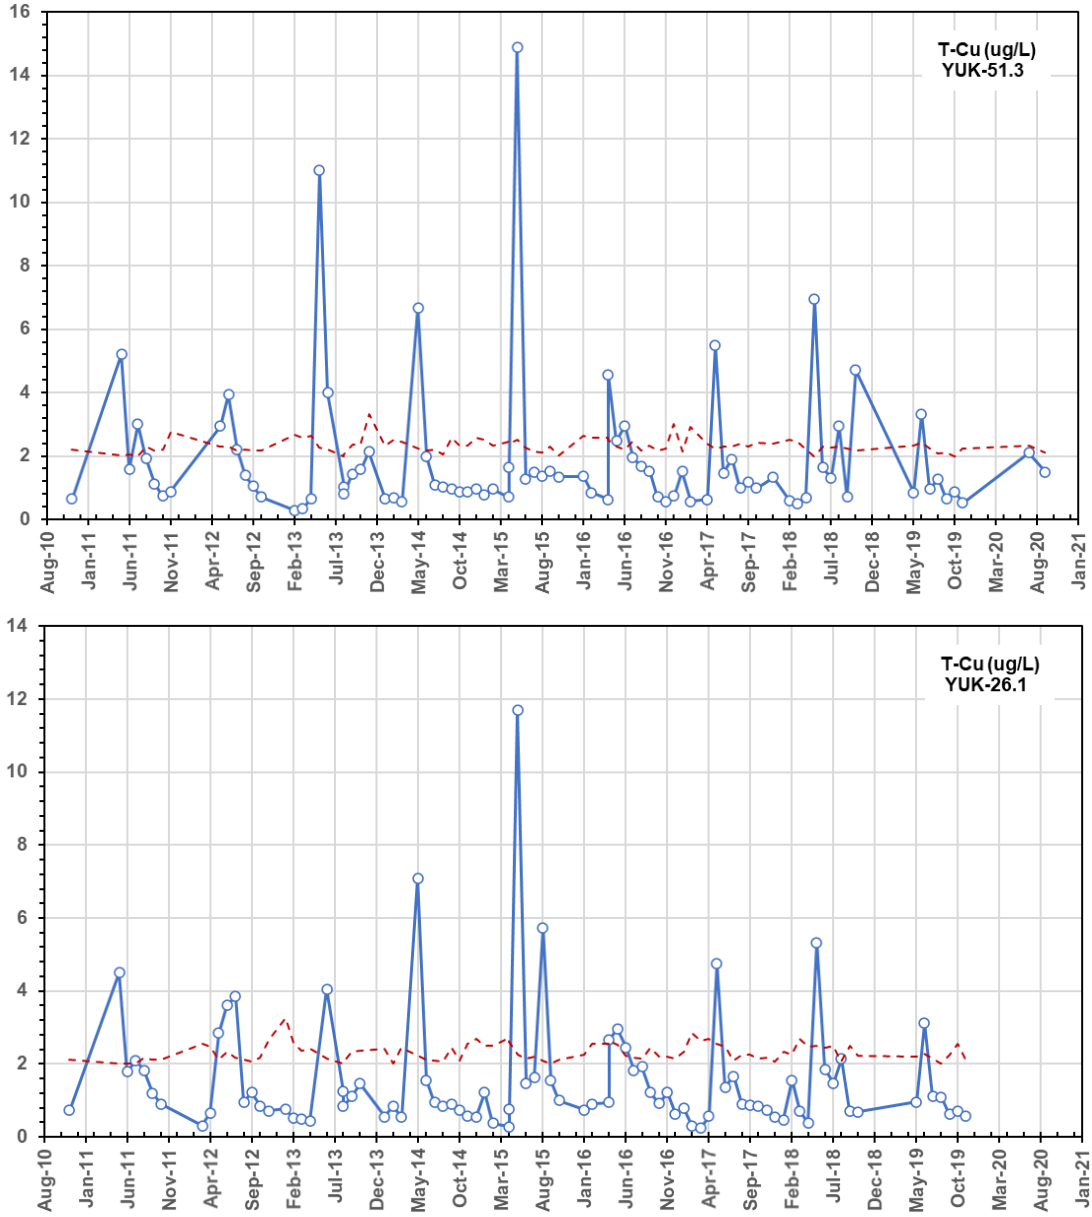

Figure 3.4-3: Total copper (T-Cu) concentrations at YUK-51.3 and YUK-26.1 in the Yukon River for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent guidelines (red dashed line) for the protection of aquatic life.

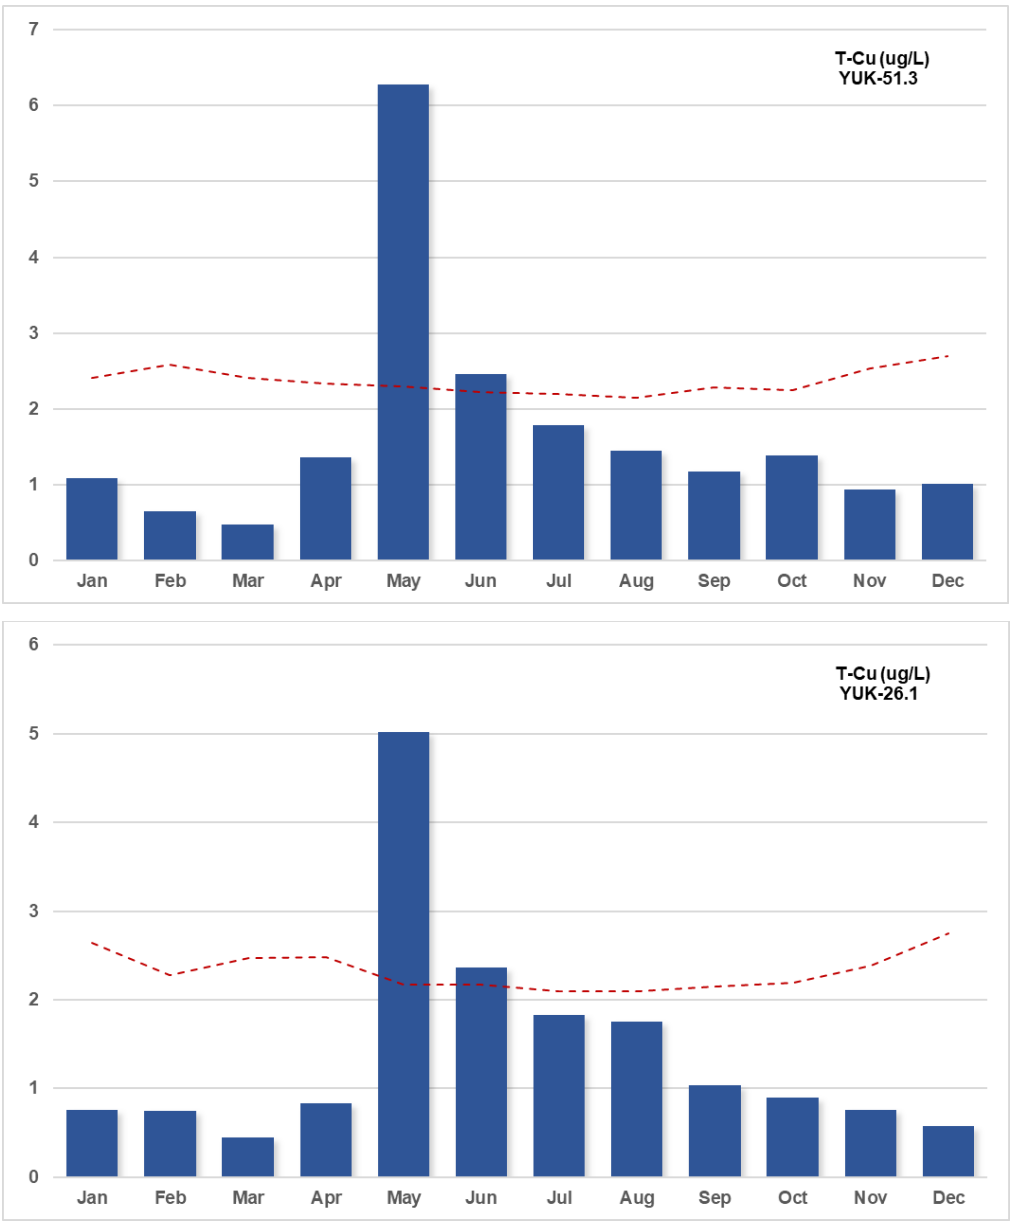

Figure 3.4-4: Monthly mean total copper (T-Cu) in the Yukon River at station YUK-51.3 and YUK-26.1 for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent water quality guidelines (red dashed line) for the protection of aquatic life.

Similar to Cu, total Cd concentrations slightly exceeded the CCME hardness-based chronic guideline for protection of aquatic life for Cd during peak flow periods (Figure 3.4-5). However, observed Cd concentrations do not exceed the CCME acute exposure guidelines for the protection of aquatic life for Cd at stations YUK-51.3 and YUK-26.1.

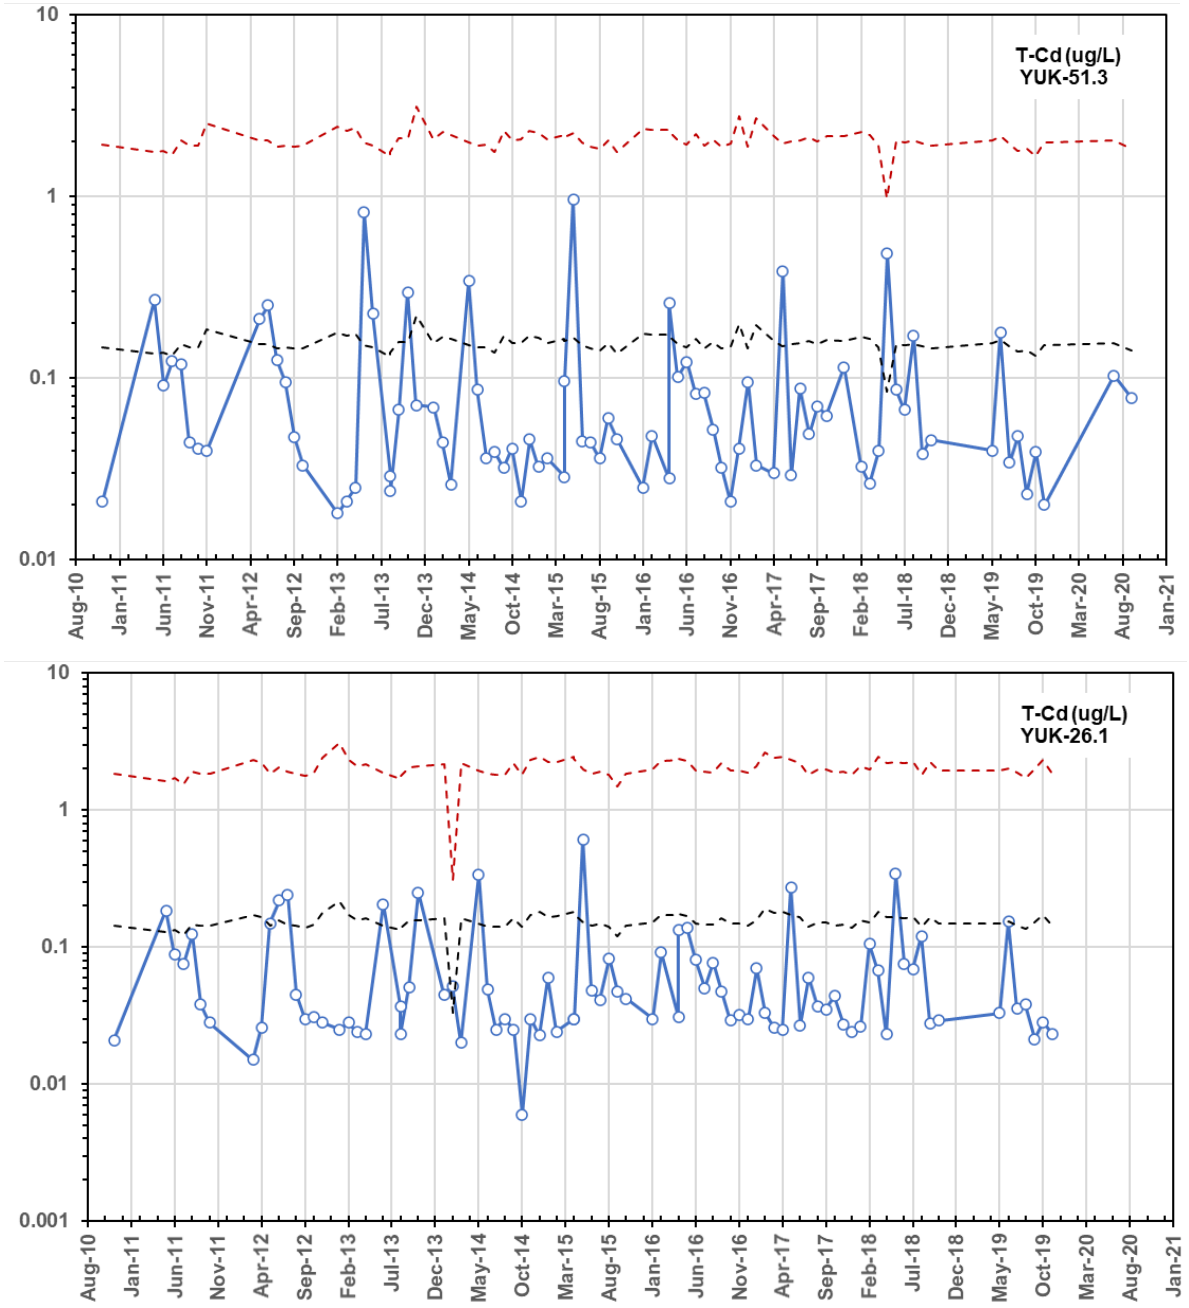

Figure 3.4-5 Total cadmium (T-Cd) concentrations at YUK-51.3 and YUK-26.1 in the Yukon River for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent guidelines for the protection of aquatic life.

3.4.2 YUK -49.3 and YUK-37.6

The following section describes baseline water quality results for the Yukon River in the immediate vicinity of the proposed project. Specifically, data are summarized for stations YUK-49.3 and YUK-37.6 (see Figure 2.1-2) specifically located in the confluence of Coffee Creek and Halfway Creek, respectively. Collection from these stations occurred only during the open water period (July to October) owing to safety issues around ice in the Yukon River.

3.4.2.1 Summary Statistics

Table 3.4-3 and Table 3.4-4 summarize the mean monthly values for a suite of the key parameters for station YUK-49.3 and YUK37.6, respectively.

3.4.2.2 Major Ions

Yukon River major ion chemistry at stations YUK-49.3 and YUK-37.6 is assessed with respect to hardness, sulphate and pH. The Yukon River at these stations is characterized by moderately hard waters with mean monthly hardness values for both stations remaining below 100 mg/L (as $CaCO_3$) (Figure 3.4-6; Table 3.4-3 and Table 3.4-4)

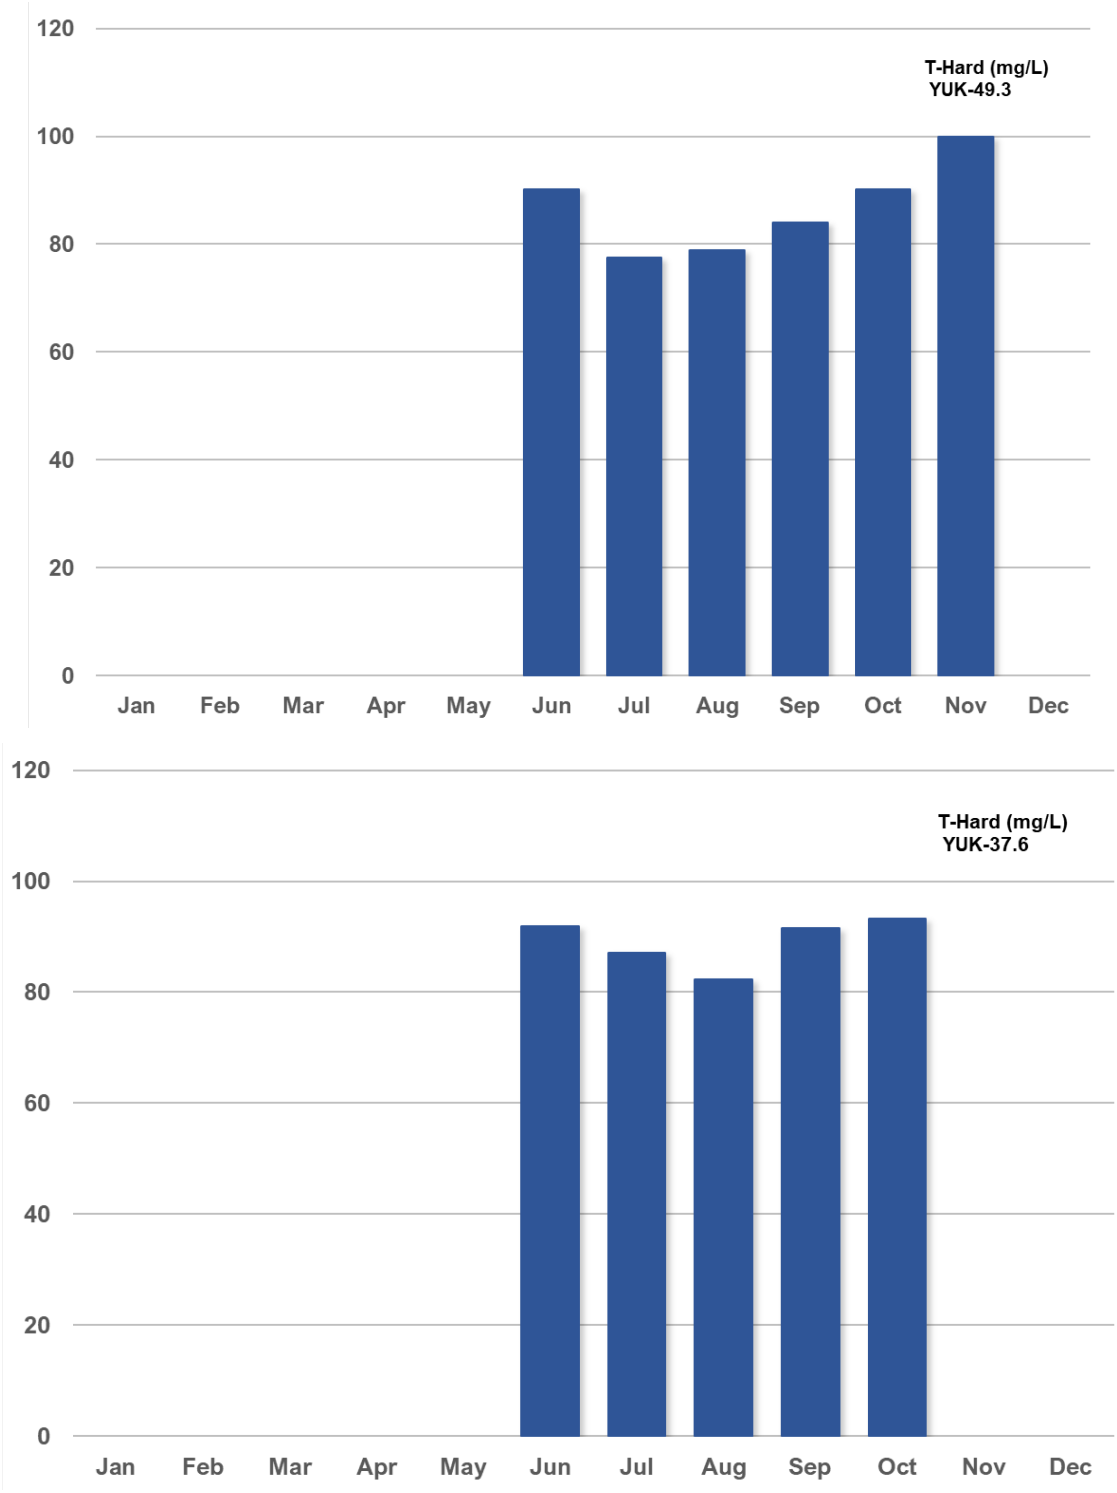

Figure 3.4-6: Mean monthly total hardness (T-Hard., as mg/L $CaCO_3$) in the Yukon River at YUK-49.3 and YUK-37.6 for the period July 2017 to September 2020.

Baseline concentrations of sulphate in the Yukon River are consistent throughout the year and don't exhibit a pronounced seasonal signature with values remaining < 40 mg/L. (Table 3.4-3 and Table 3.4-4). The pH is relatively uniform throughout the year at both stations remains with values roughly between 7 and 8.0. All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Concentrations of TSS in the Yukon River show maxima coinciding with the peak snowmelt months (*e.g.,* June). Elevated TSS also occurs during summer flow periods (*e.g.*, July, August) and generally decrease to values less than 5 mg/L during late fall (Table 3.4-3 and Table 3.4-4).

3.4.2.3 Nutrients

Nutrient parameters are found in low concentrations in the Yukon River at stations YUK-49.3 and YUK-37.6. Ammonia-N concentrations are low with mean monthly values roughly between 0.005 to 0.2 mg/L. Mean monthly nitrate-N concentrations at both Yukon River stations were low and ranged between 0.04 mg/L and 0.2 mg/L. Dissolved phosphorus concentrations at both stations were low with mean monthly values roughly between 0.003 mg/L and 0.01 mg/L and indicative of ultra-eutrophic to oligotrophic conditions (Appendix B). Concentration of TOC and DOC in both Yukon River stations ranged from 3.3 to 8.3 mg/L and from 4.7 to 8.6 mg/L, respectively (Table 3.4-3 and Table 3.4-4).

3.4.2.4 Trace Elements

Baseline trace element concentrations in this section of the Yukon River were derived from data collected from July 2017 to December 2020 at YUK-49.3 and YUK-37.6. In general, mean monthly concentrations of total and dissolved trace elements are low (*e.g.*, Al, As, Sb, Co, Cr, Pb, Hg, Ni, Se, U and Zn). Mean monthly total As concentrations in the Yukon River ranged from 66 to 356 mg/L, with noticeable lower values in late fall (Table 3.4-3 and Table 3.4 -4). In contrast to all the other monitoring locations in the vicinity of the project site, dissolved Al concentrations in the Yukon River exceeded the BC ENV guideline of 100 µg/L only in a few instances during the summer flow period (Figure 3.4-7). U concentrations in the Yukon River are also low with mean monthly values roughly below 5 µg/L (Table 3.4-3 and Table 3.4-4).

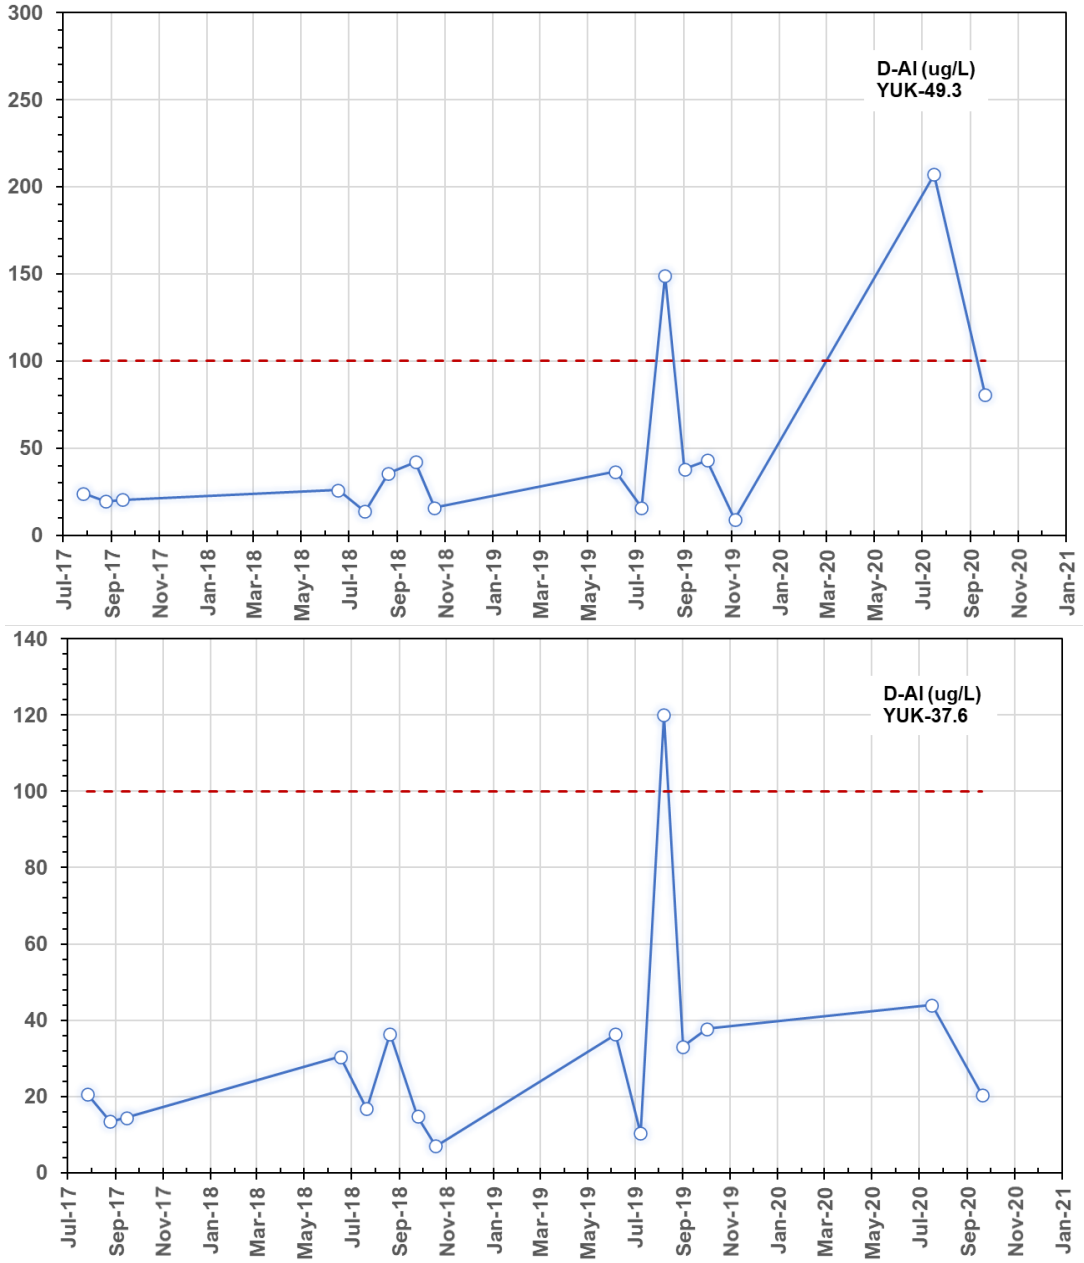

Figure 3.4-7: Dissolved aluminum (D-Al) concentrations at YUK-49.3 and YUK-37.6 in the Yukon River for the period July 2017 to September 2020 compared to British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dashed line) for protection of aquatic life.

Concentrations of total Cu in the Yukon River at station YUK-49.3 and YUK-37.6 rarely exceeded the CCME hardness-dependent Cu guideline for the protection of aquatic life most likely due to the moderately hardness in water (Figure 3.4-8). Mean monthly total Cu concentrations at both Yukon River stations indicate that elevated total Cu

concentrations are associated with the peak TSS events (*e.g.,* May-July). Cadmium concentrations remained below hardness dependent WQGs, with only one exceedance slightly above WQGs during summer flows (Figure 3.4-9).

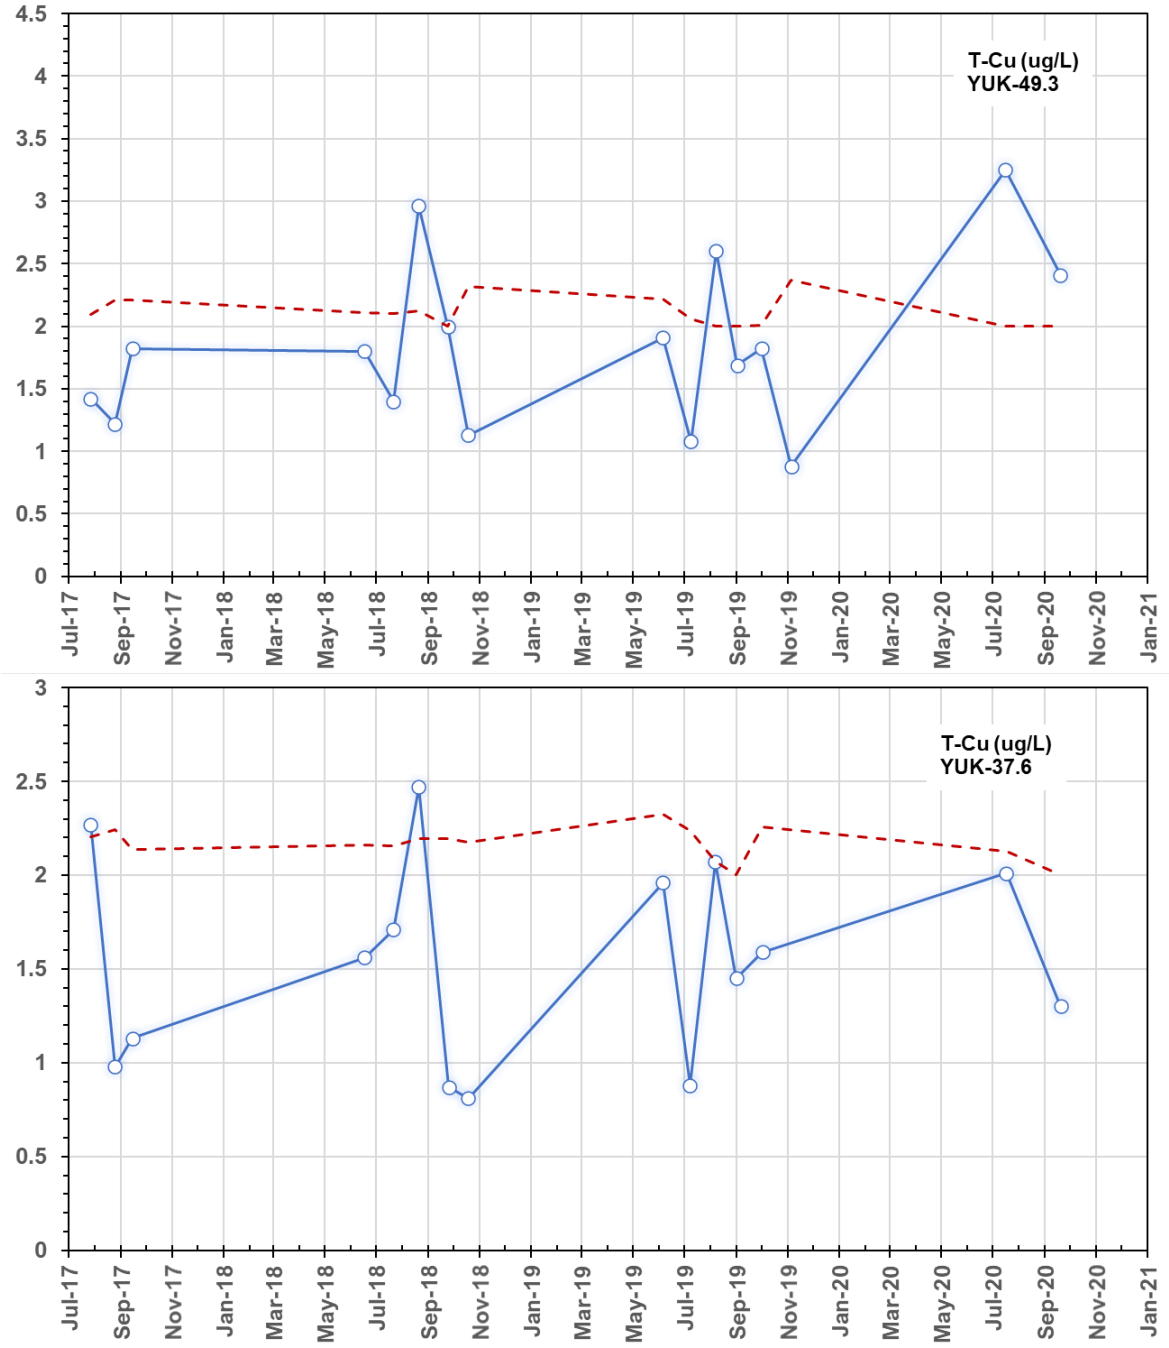

Figure 3.4-8: Total copper (T-Cu) concentrations at YUK49.3 and YUK-37.6 in the Yukon River for the period July 2017 to September 2020 compared to the Canadian Council of Ministers of the Environment (CCME) hardness-dependent guidelines (red dashed line) for the protection of aquatic life.

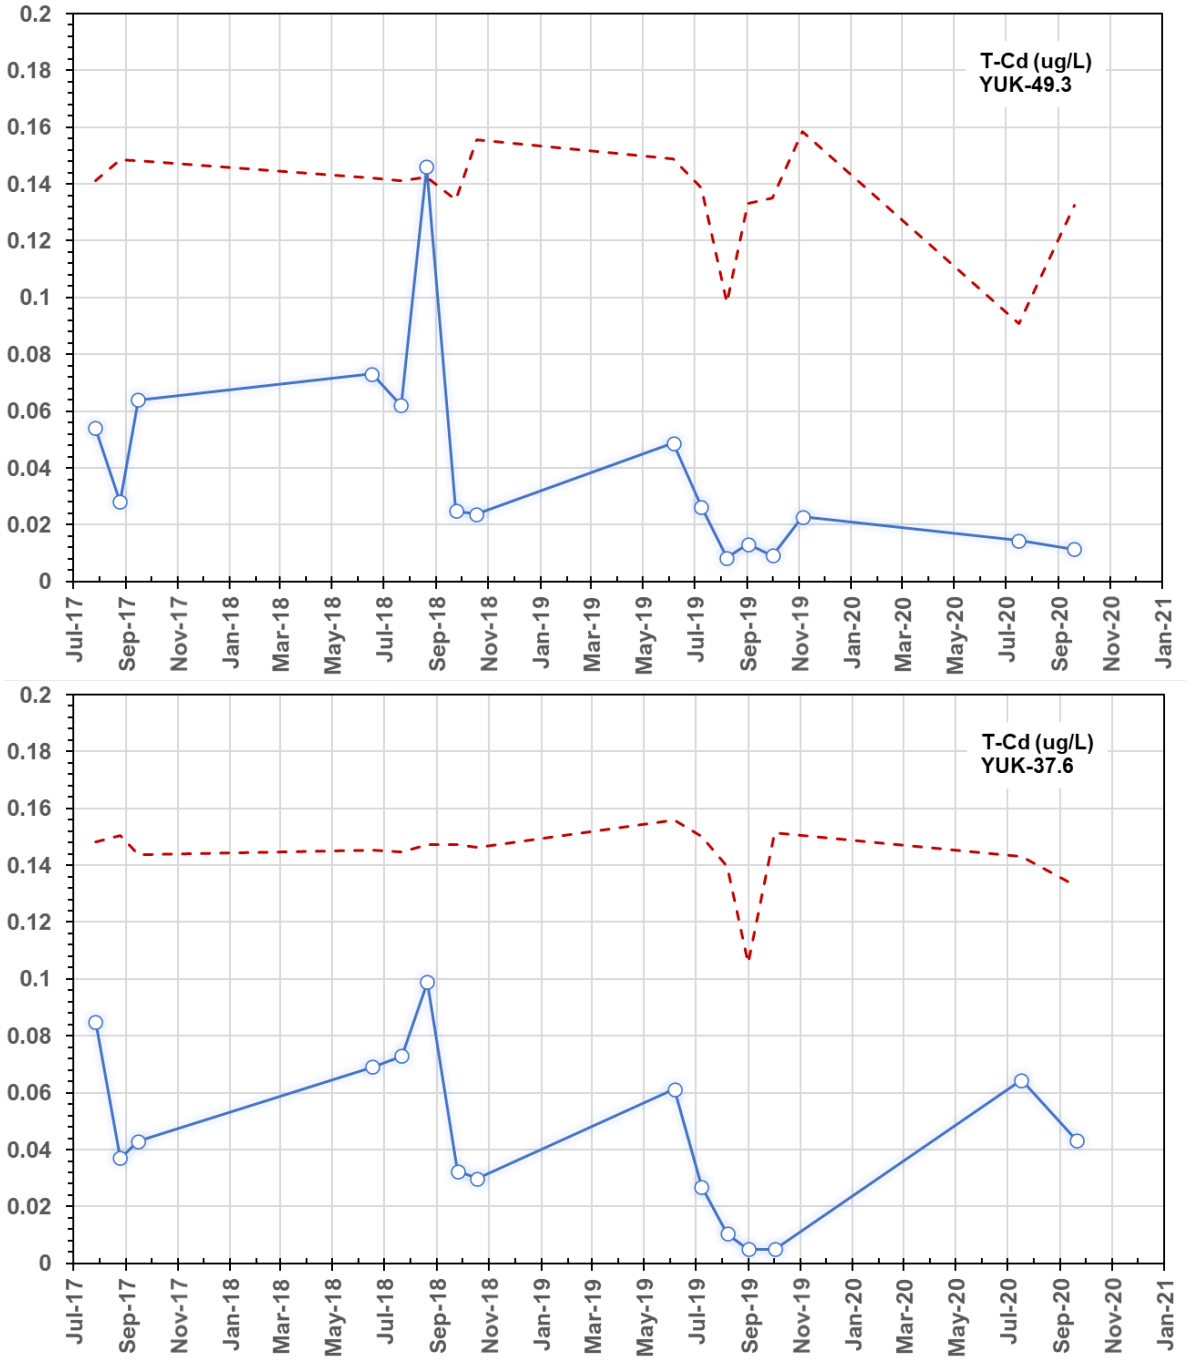

Figure 3.4-9: Total cadmium (T-Cd) concentrations at YUK-49.3 and YUK-37.6 in the Yukon River for the period July 2017 to September 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed line) hardness-dependent guidelines for the protection of aquatic life.

3.5 Independence Creek

This section describes baseline water quality results for Independence Creek. Independence Creek is not affected by proposed mining operations and therefore serves as a reference monitoring watershed.

Independence Creek is characterized by water quality measured at Station IC-2.7 (Figure 3.5-1) which reflects water quality conditions in lower Independence Creek and downstream of contributions from three small catchments that drain the east slope of the drainage divide between upper Latte Creek and Independence Creek (IC-16.1 and IC-14.6) and the eastern slope of the drainage divide of Halfway Creek and Independence Creek (KT-0.4) in Kona Creek (see Figure 2.1-2 and Figure 3.5-1).

Results are presented for station IC4.5 (mainstem of Independence Creek) and KT-0.4 in Kona Creek, a tributary to Independence Creek (Figure 3.5-1); complete results for all other stations are presented in Appendix A along with summary statistics for all stations in Appendix C.

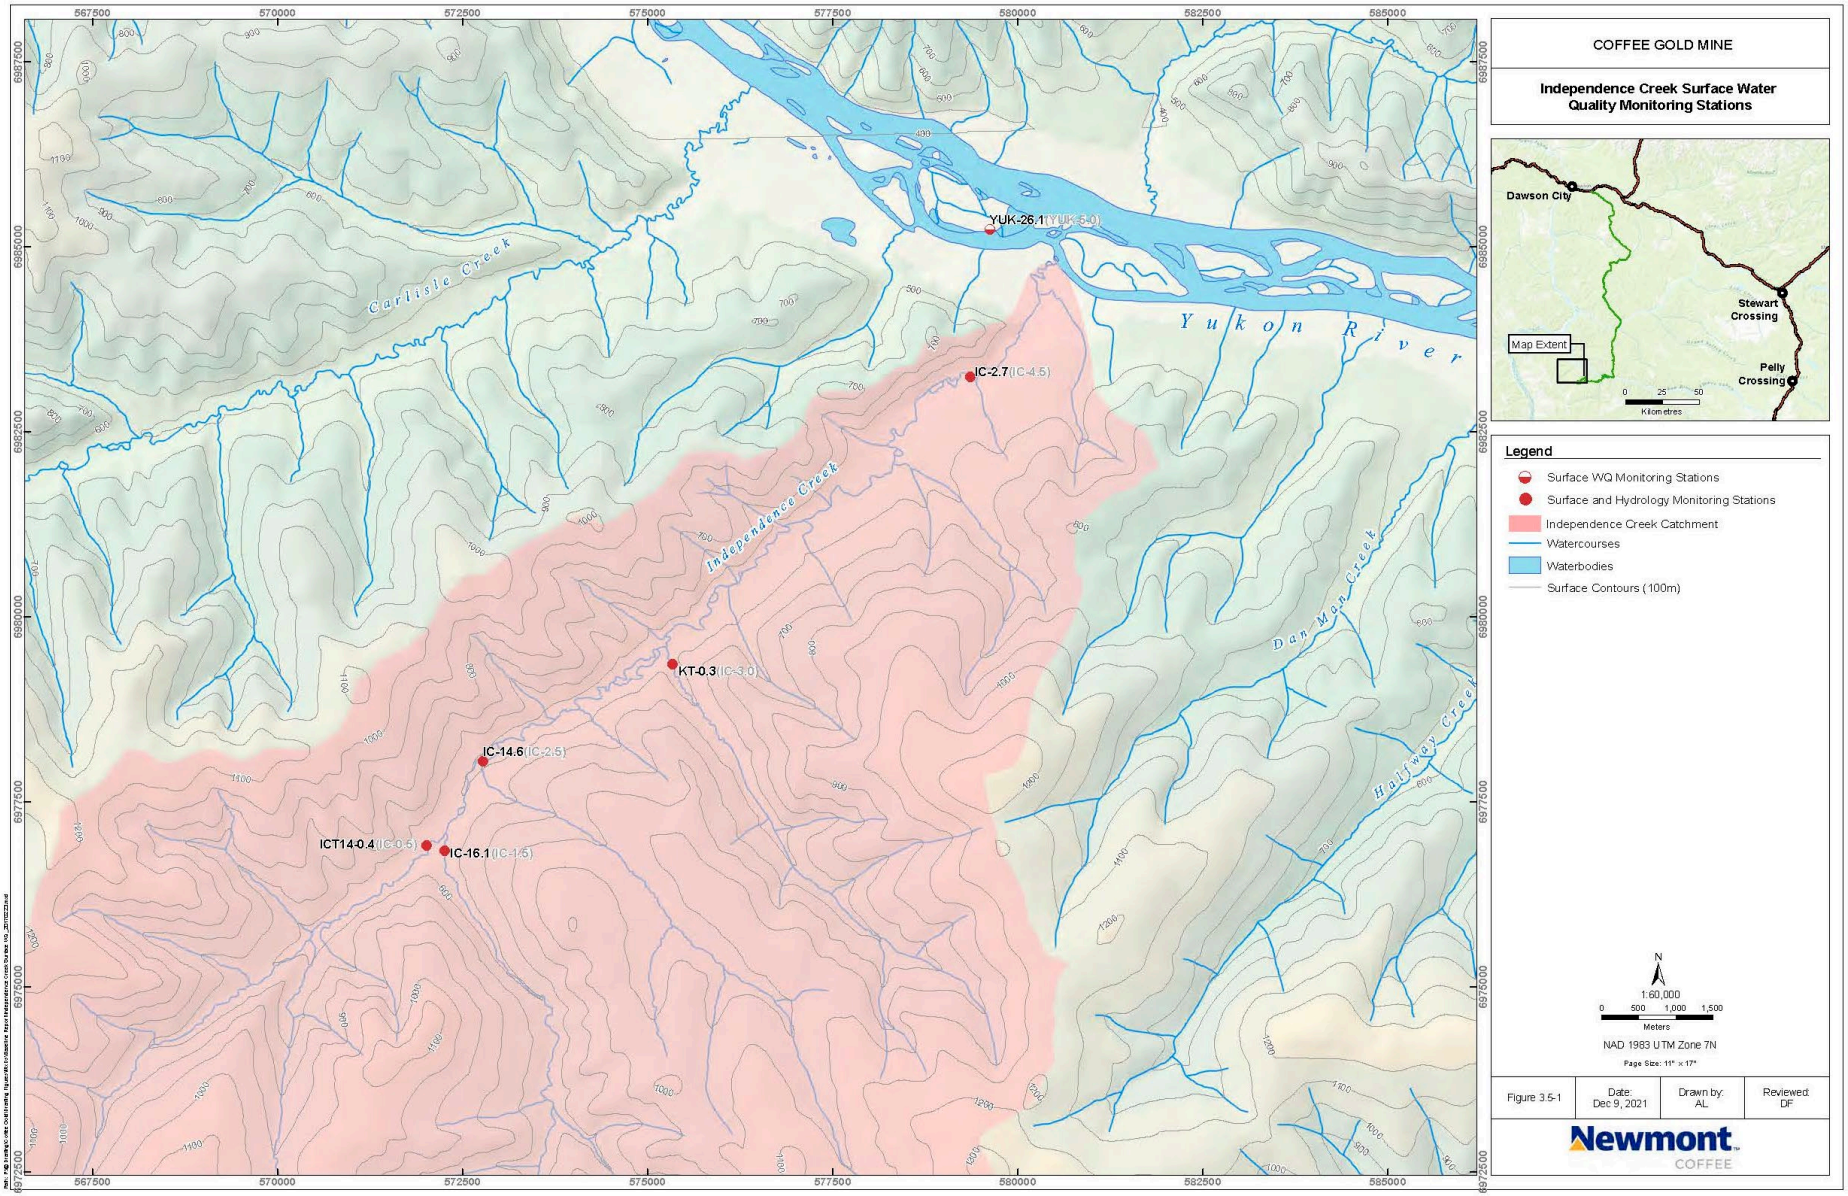

Figure 3.5-1: Detail of Independence Creek drainage illustrating key monitoring station locations

3.5.1 Station IC-2.7

3.5.1.1 Summary Statistics

Table 3.5-1 summarizes the mean monthly values for a suite of the key parameters for station IC-2.7 in Independence Creek.

3.5.1.2 Major Ions

The major ion chemistry of Independence Creek is assessed with respect to hardness, sulphate and pH. Station IC-2.7 is characterized by seasonally moderately soft waters (roughly 50 to 60 mg/L as $CaCO_3$) during open water periods of May to September) and moderately hard to hard waters (ranging from approximately 80 mg/L to 120 mg/L [as $CaCO_3$]) during lower flow periods and winter low flows (Table 3.5-1; Figure 3.5-2).

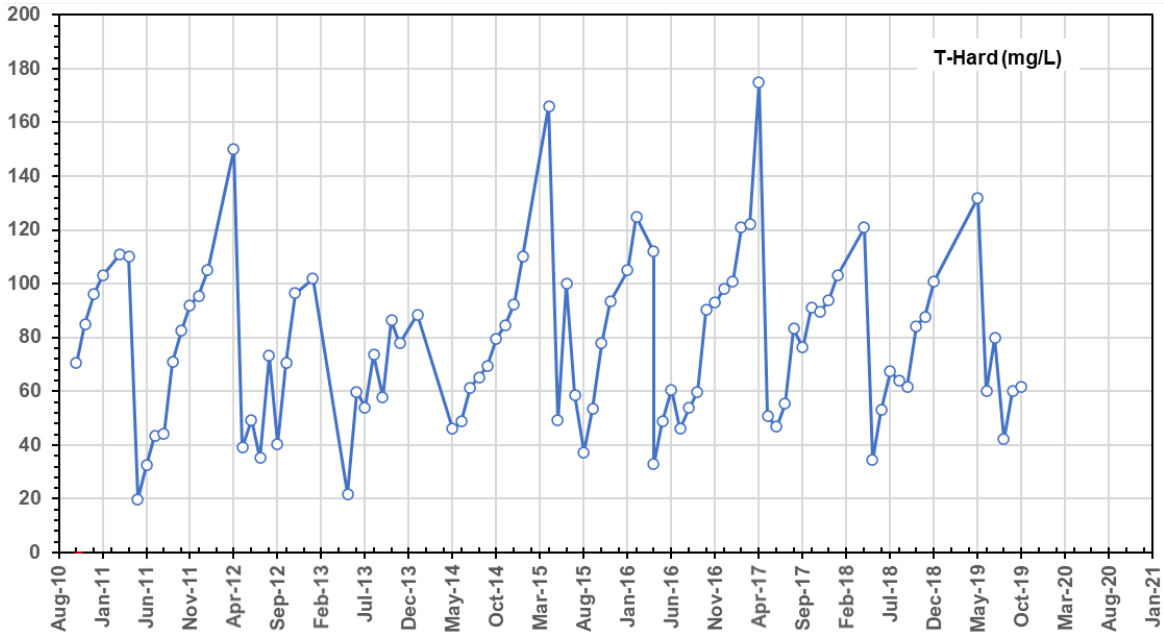

Figure 3.5-2: Total Hardness (T-Hard., as mg/L $CaCO_3$) in Independence Creek (IC-2.7) for the period October 2010 to December 2020.

The pH in Independence Creek remains relatively uniform throughout the year with values generally ranging between 7.3 and 7.7 (Table 3.5-1). All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in Independence Creek also exhibit a strong seasonal signature with lowest concentrations occurring during peak runoff conditions. During peak flow periods, mean sulphate concentrations at IC-2.7 is approximately 20 mg/L (Table 3.5-1). Mean monthly sulphate concentrations during late fall and winter low flows range from roughly 35 mg/L to 68 mg/L.

As with the other stations monitored, TSS concentrations in Independence Creek exhibit maxima coincident with the peak snowmelt months (Table 3.5-1). At most other flow periods of the year, TSS values in Independence Creek at IC-2.7 are generally below 2.0 mg/L.

3.5.1.3 Nutrients

As with all other stations monitored, nutrient parameters are found in low concentrations in Independence Creek at station IC-2.7. Ammonia-N concentrations are low with mean monthly values typically less than 0.04 mg/L (Table 3.5-1). Mean monthly nitrate-N concentrations in Independence Creek are ranged almost an order of magnitude, with peak flow minima of 0.06 mg/L and winter low flow maxima of 0.60 mg/L. Independence Creek waters are oligotrophic to ultra-oligotrophic with monthly mean dissolved phosphorus concentrations at IC-2.7 ranging between 0.002 mg/L to 0.01 mg/L (Table 3.5-1).

Total organic carbon and DOC exhibit a similar marked seasonal signature as observed in other catchments within the project area. The highest DOC values are observed during peak runoff periods at station IC-2.7. DOC accounts for virtually all of the TOC. DOC concentrations range from approximately 7.0 mg/L during baseflow periods to concentrations in excess of 15 mg/L during higher flow periods (Figure 3.5-3).

3.5.1.4 Trace Elements

Baseline trace element concentrations in Independence Creek were derived from data collected from October 2010 to December 2020 at IC-2.7 (Figure 3.5-1). For most parameters monitored, mean monthly concentrations of total and dissolved trace elements are low; the sole exceptions to this observation are for dissolved Al and total Cu. Of note is the absence of elevated total U in Independence Creek (Table 3.5-1; Figure 3.5-4).

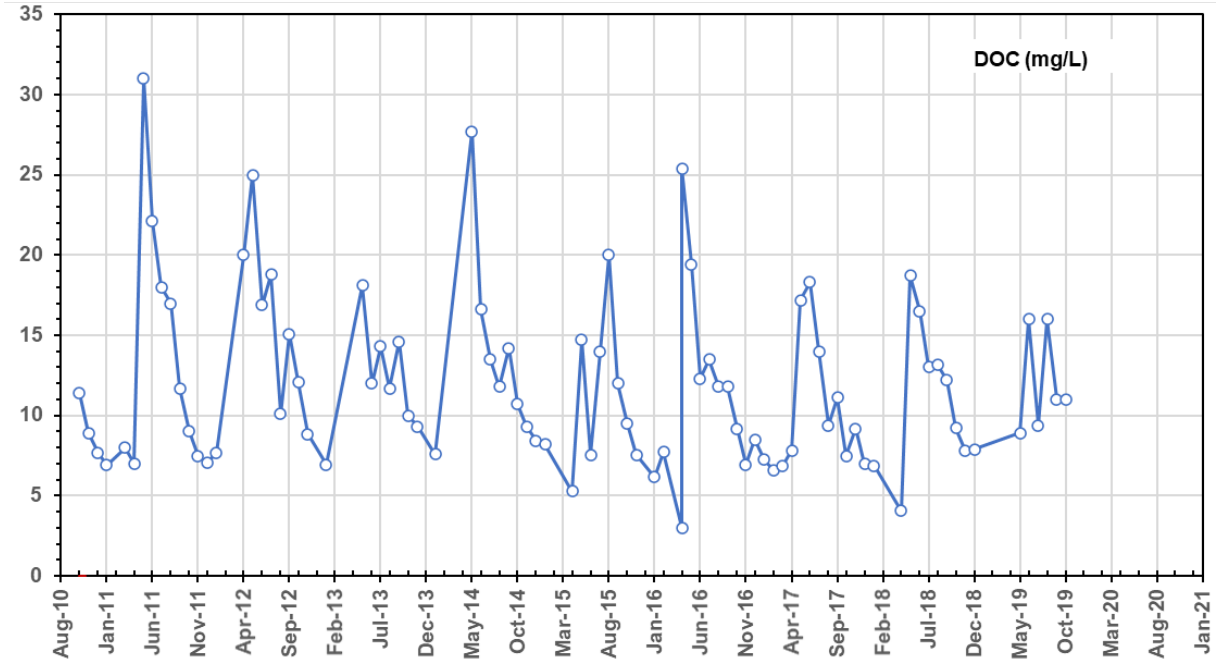

Figure 3.5-3: Dissolved organic carbon (DOC) in Independence Creek (IC-2.7) for the period October 2010 to December 2020.

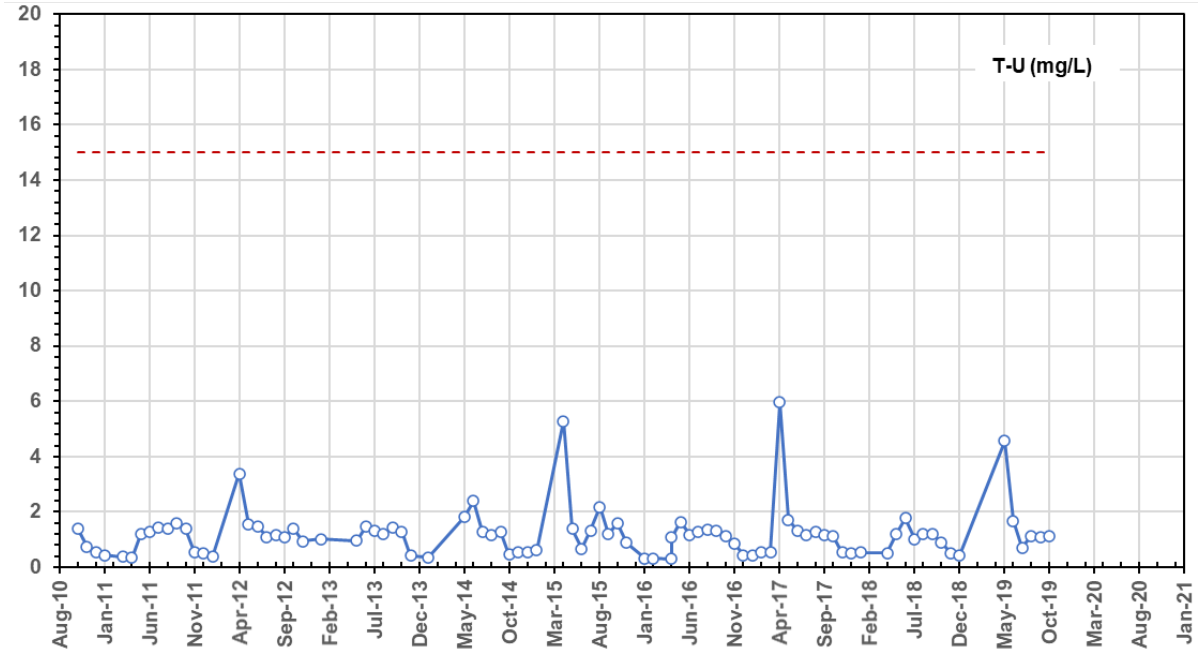

Figure 3.5-4: Total uranium (T-U) in Independence Creek (IC-2.7) for the period October 2010 to December 2020.

Dissolved Al at IC-2.7 is seasonally elevated in Independence Creek and consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L during peak runoff periods (Figure 3.5-5).

During baseflow periods, dissolved Al concentrations in Independence Creek are roughly between 40 and 70 µg/L (Table 3.5-1 and Figure 3.5-5).

Concentrations of total Cu in Independence Creek exhibit a strong seasonal signature with maxima associated with peak runoff periods that exceed the CCME hardness-dependent Cu guideline for the protection of aquatic life (Figure 3.5-6). During most months of the open water period including May to September, mean monthly total Cu concentrations are naturally above CCME guidelines (Figure 3.5-7).

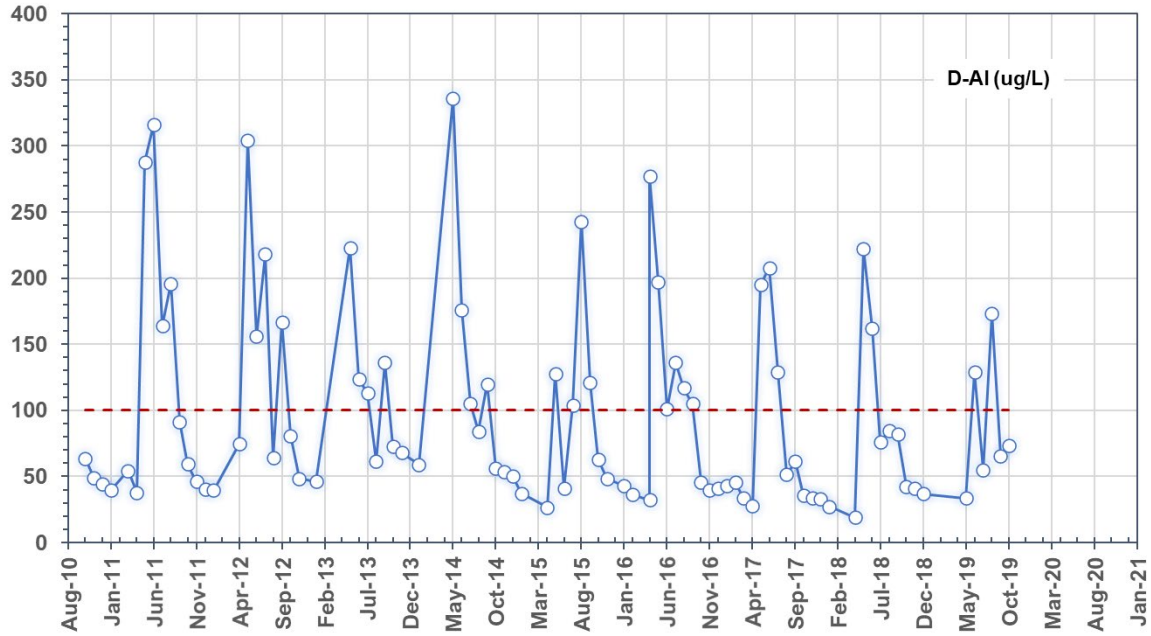

Figure 3.5-5: Dissolved aluminum (D-Al) in Independence Creek (IC-2.7) for the period October 2010 to December 2020 compared to the British Columbia Ministry of Environment and Climate Change Strategy (BC ENV) water quality guidelines (red dahsed lines) for the protection of aquatic life.

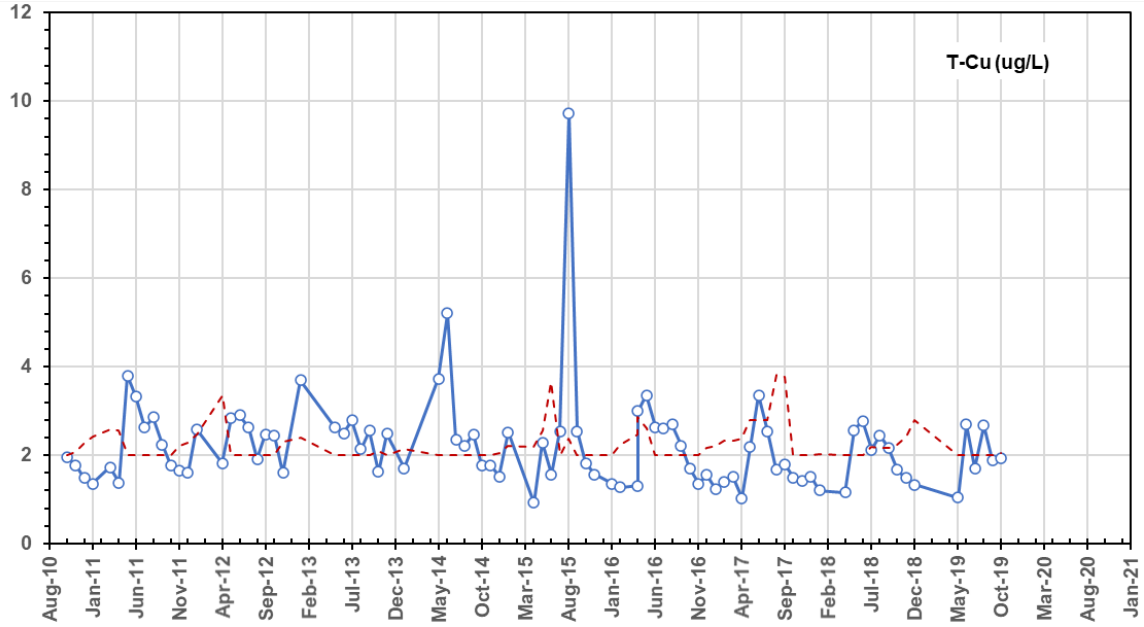

Figure 3.5-6: Total copper (T-Cu) in Independence Creek (IC-2.7) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (red dashed line) hardness-dependent guidelines for the protection of aquatic life.

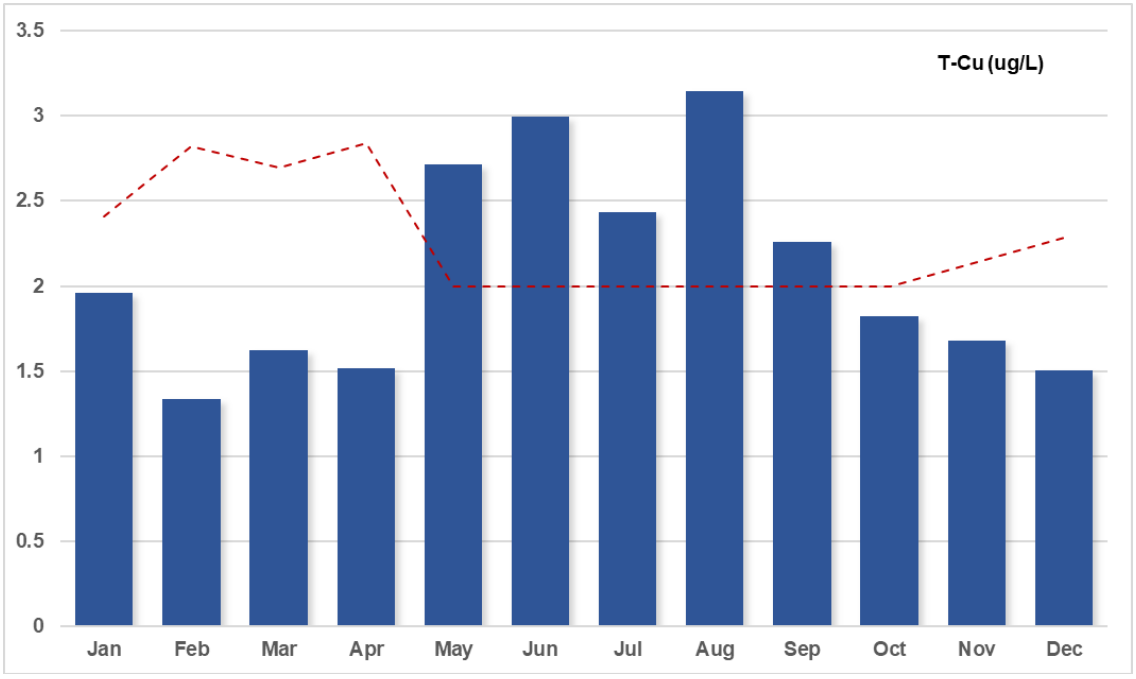

Figure 3.5-7: Mean monthly total copper (T-Cu) in Independence Creek (IC-2.7) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (red dashed line) hardness-dependent guidelines for the protection of aquatic life.

Total Cd concentrations in Independence Creek at IC-2.7 generally do not exceed the chronic or short-term CCME hardness-dependent guidelines for protection of aquatic life (Figure 3.5-8).

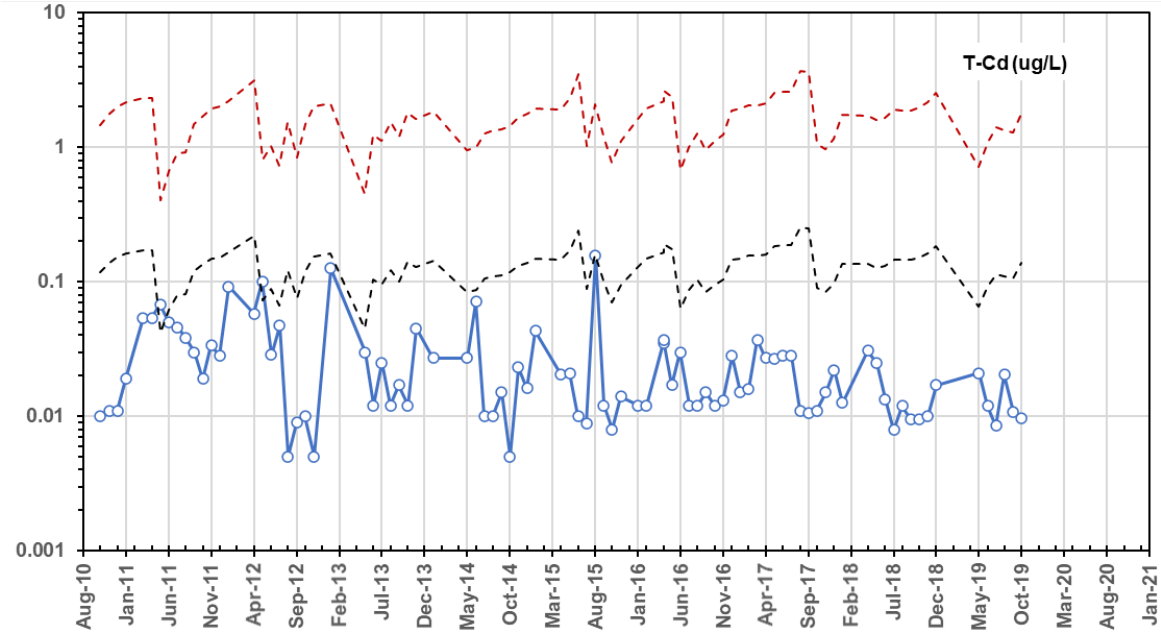

Figure 3.5-8: Total cadmium (T-Cd) in Independence Creek (IC-2.7) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed line) and acute (red dashed lines) hardness-dependent guidelines for the protection of aquatic life.

3.5.2 Station KT-0.4

3.5.2.1 Summary Statistics

Table 3.5-2 summarizes the mean monthly values for a suite of the key parameters for station KT-0.3 in Kona Creek.

Table 3.5-2:

3.5.2.2 Major Ions

The major ion chemistry of Kona Creek is assessed with respect to hardness, sulphate and pH. Station KT-0.3 is characterized by seasonally moderately soft waters (between 65 mg/L and 100 mg/L [as $CaCO_3$]) during open water periods of May to September) and moderately hard to hard waters (ranging from approximately 110 mg/L to 190 mg/L [as $CaCO_3$]) during lower flow periods and winter low flows (Table 3.5-2; Figure 3.5-11).

The pH in Kona Creek remains relatively circumneutral throughout the year with values generally ranging between 7.2 and 7.9 (Table 3.5-2). All pH values reported to date have remained within the CCME freshwater guideline range for pH of 6.5 to 9.0.

Baseline concentrations for sulphate in Kona Creek also exhibit a strong seasonal signature with lowest concentrations occurring during peak runoff conditions. During peak flow periods, mean sulphate concentrations at KT-0.3 range from less than 28 mg/L to approximately 47 mg/L (Table 3.5-2). Mean monthly sulphate concentrations during late fall and winter low flows range from 42 mg/L to 120 mg/L.

As with the other stations monitored, TSS concentrations in Kona Creek exhibit maxima coincident with the peak snowmelt months and high summer rainfall events (Table 3.5-2; Figure 3.5-10). At most other flow periods of the year, TSS values in Kona Creek at KT-0.3 are generally below 2.0 mg/L.

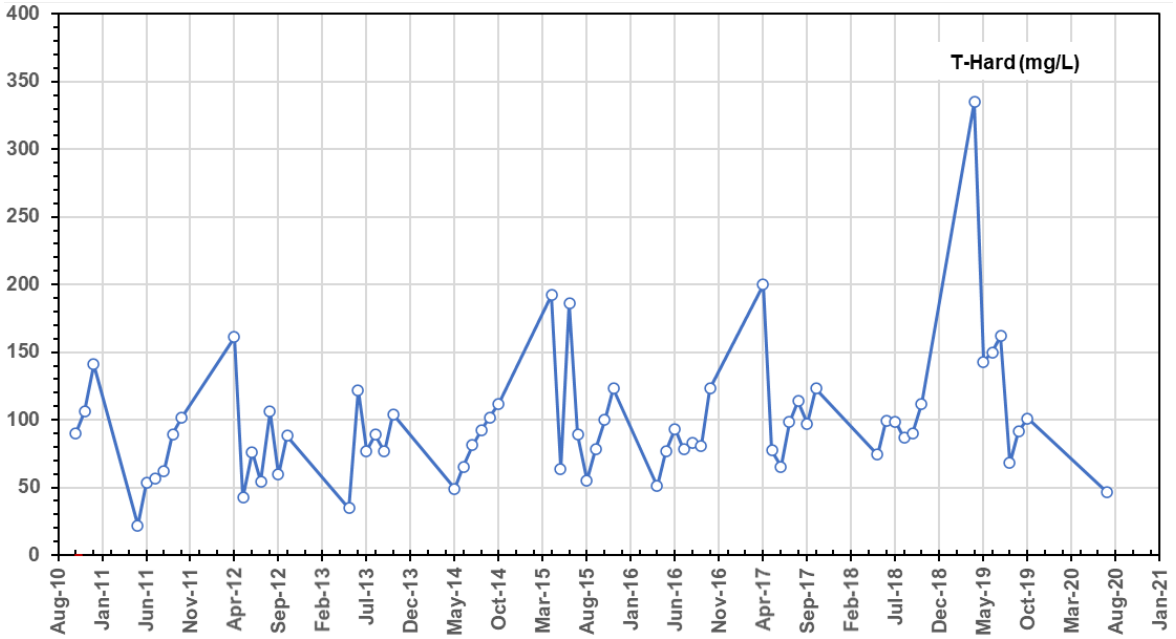

Figure 3.5-9: Total Hardness (T-Hard., as mg/L of $CaCO_3$) in Kona Creek (KT-0.3) for the period October 2010 to December 2020.

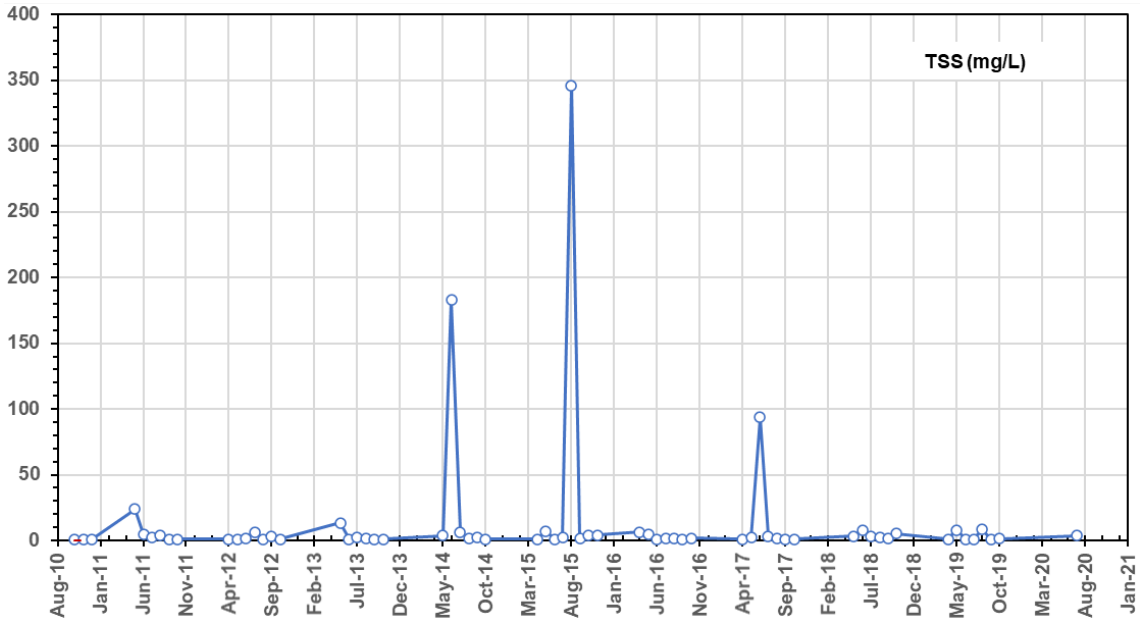

Figure 3.5-10: Total Suspended Solids (TSS) in Kona Creek (KT-0.4) for the period October 2010 to December 2020.

3.5.2.3 Nutrients

As with all other stations monitored, nutrient parameters are found in low concentrations in Kona Creek at station KT-0.3. Ammonia-N concentrations are low with mean monthly values typically less than 0.03 mg/L (Table 3.5-2). Mean monthly nitrate-N concentrations in Kona Creek ranged from a minima of 0.02 mg/L and winter low flow maxima of roughly 0.7 mg/L. Kona Creek waters are oligotrophic to ultra-oligotrophic with monthly mean dissolved phosphorus concentrations at KT-0.3 ranging between 0.003 mg/L to 0.009 mg/L (Table 3.5-2).

Total organic carbon and DOC exhibit a similar marked seasonal signature as observed in other catchments within the project area. The highest DOC values are observed during peak runoff periods at station KT-0.3. DOC accounts for virtually all of the TOC. DOC concentrations range from approximately 11 mg/L to 20 mg/L (Figure 3.5-11).

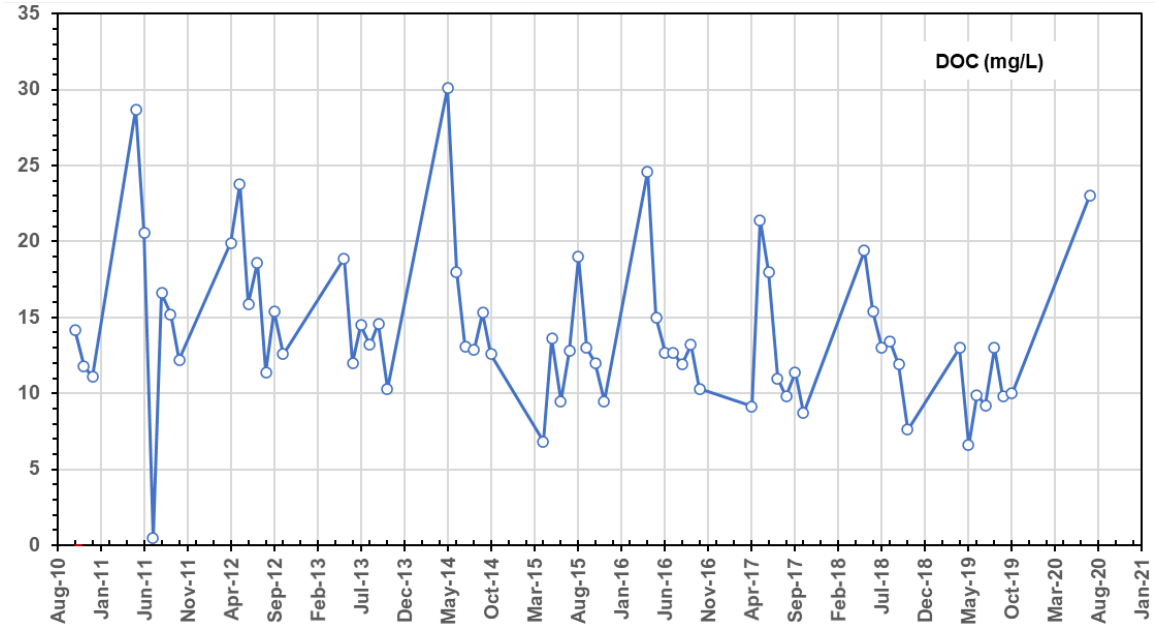

Figure 3.5-11: Dissolved organic carbon (DOC) in Kona Creek (KT-0.4) for the period October 2010 to December 2020.

3.5.2.4 Trace Elements

Baseline trace element concentrations in Kona Creek were derived from data collected from October 2010 to December 2020 at KT-0.3 (Figure 3.5-1). For most parameters monitored, mean monthly concentrations of total and dissolved trace elements are low; the sole exceptions to this observation are for dissolved Al and total Cu (Figure 3.5-12 and Figure 3.5-13, respectively).

Dissolved Al at KT-0.3 is seasonally elevated in Kona Creek and consistently observed to be elevated well above BC ENV guideline for the protection of aquatic life of 100 µg/L during peak runoff periods with concentrations up to 220 mg/L during freshet (Figure 3.5-12). During baseflow periods, dissolved Al concentrations in Kona Creek are roughly 45 µg/L (Table 3.5-2 and Figure 3.5-12).

Concentrations of total Cu in Kona Creek exhibit a seasonal and flow signature with maxima associated with peak runoff periods that exceed the CCME hardness-dependent Cu guideline for the protection of aquatic life (Figure 3.5-6). During most months of the open water period including May to September, mean monthly total Cu concentrations are naturally above CCME guidelines (Table 3.5-2).

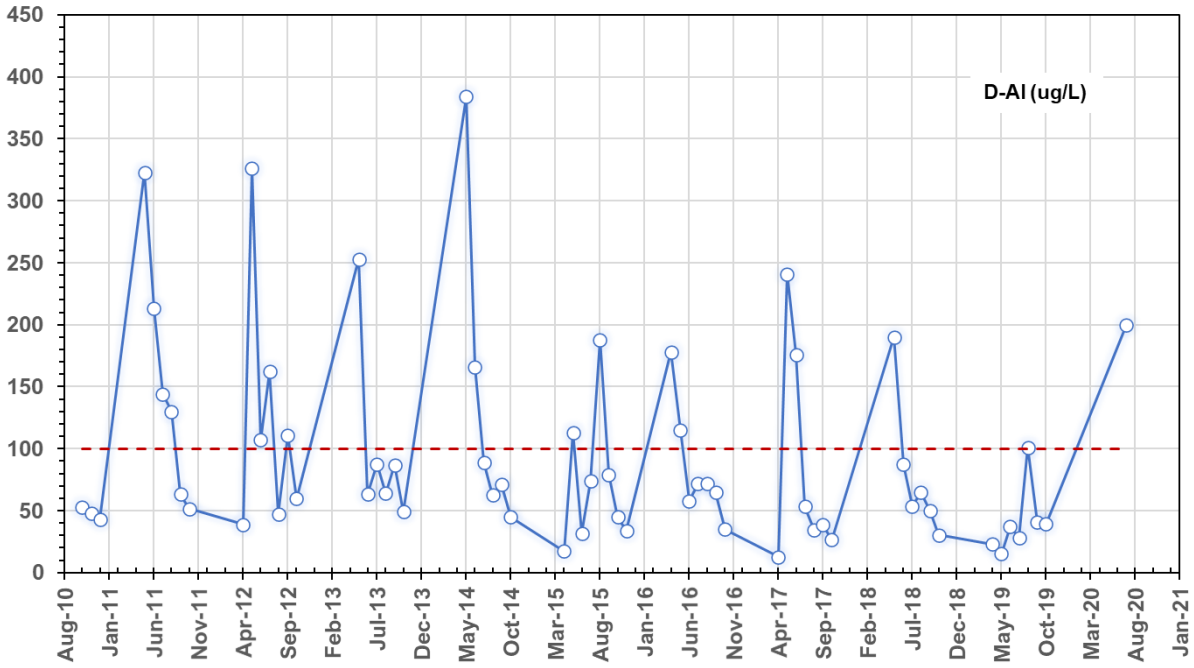

Figure 3.5-12: Dissolved aluminum (D-Al) in Kona Creek (KT-0.3) for the period October 2010 to December 2020.

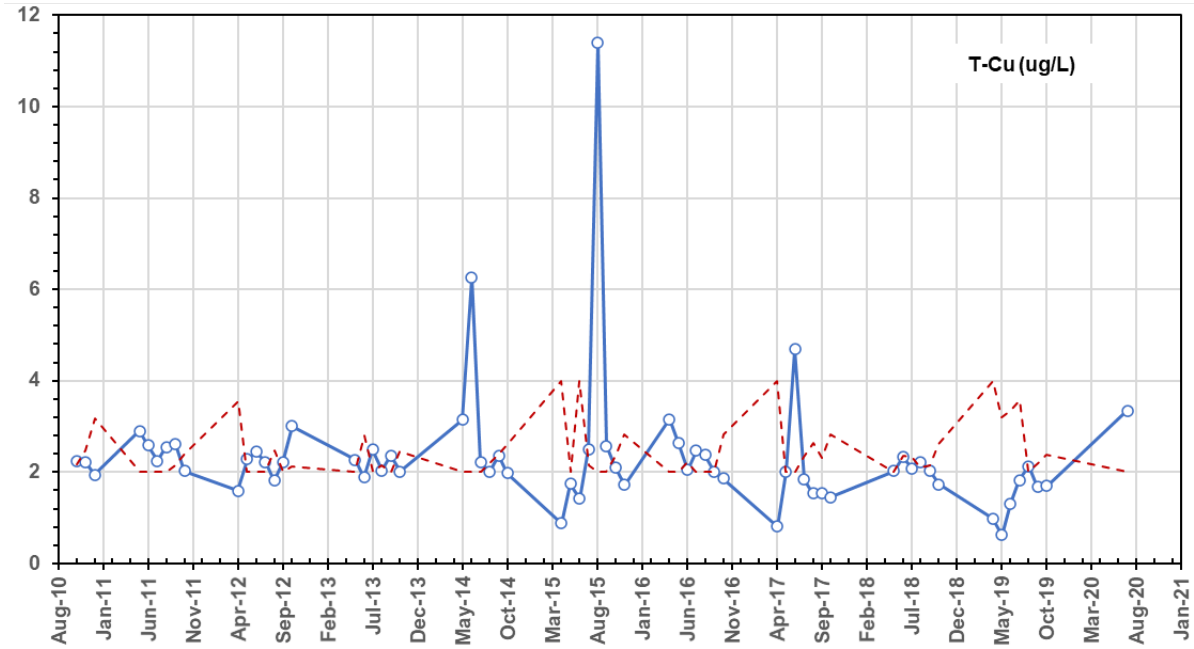

Figure 3.5-13: Total copper (T-Cu) in Kona Creek (KT-0.3) for the period October 2010 to December 2020.

Despite being downgradient of elevated As in groundwater in the vicinity of the Kona deposit, concentrations of total and dissolved As are low in Kona Creek. The posit for this absence of As in surface waters receiving groundwater elevated in As is due to changing

redox conditions. As, is a redox sensitive species. For As under circumneutral pH conditions, this metalloid is more soluble under suboxic or reducing conditions. Conversely, under more oxic conditions, As is less soluble and strongly sorbs onto Fe/Mn oxyhydroxide surfaces. Dissolved As in groundwater near the ridgetop at Kona is on the order of 2,000 µg/L, whereas the maximum dissolved As measured to date in Kona Creek at KT-0.3 is 1.2 µg/L (Figure 3.5-14; Appendix C).

Total As concentrations in Kona Creek are influenced by elevated TSS and peak As concentrations above the CCME guideline of 5.0 µg/L are coincident with high flow and elevated TSS (see Figure 3.5-10).

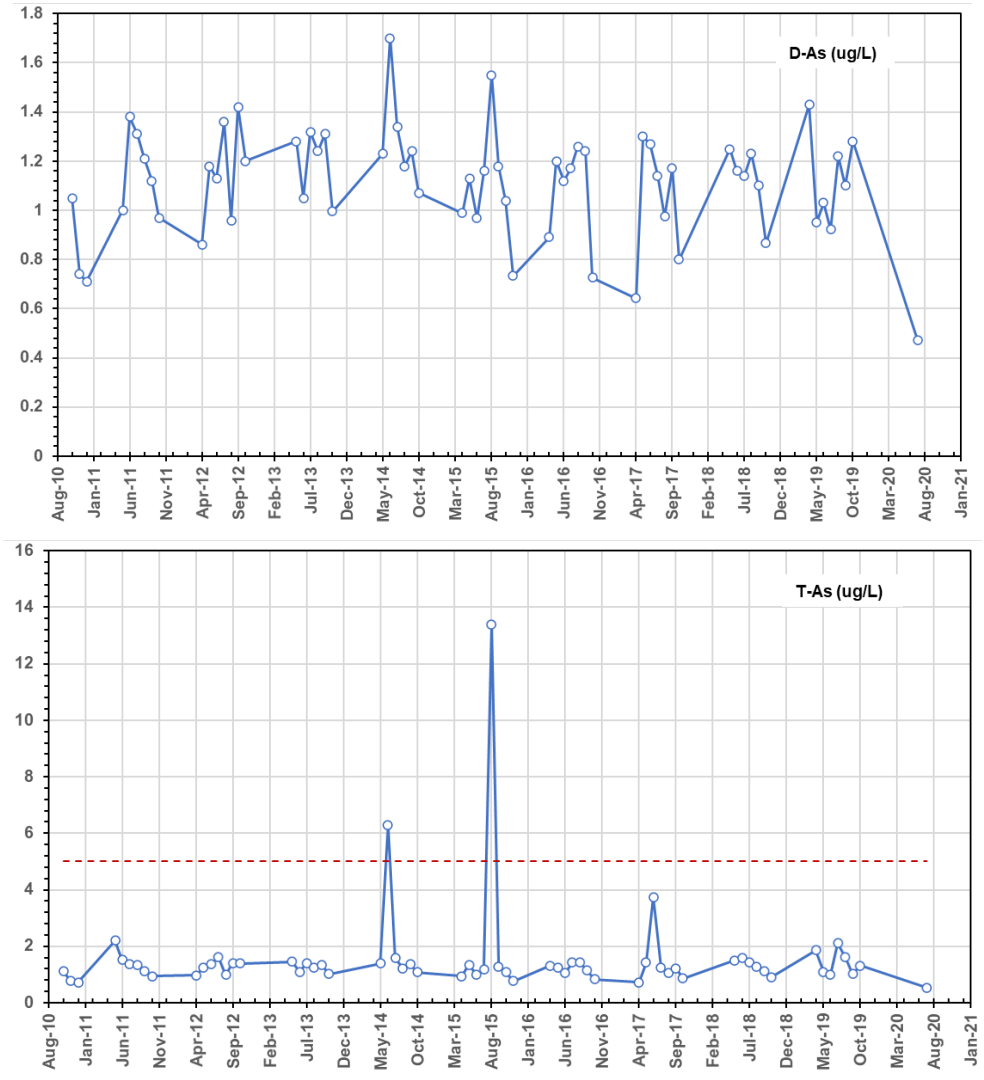

Figure 3.5-14: Comparison of Dissolved arsenic (D-As) and Total arsenic (T-As) in Kona Creek (KT-0.3) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) water quality guidelines (red dashed lines) for the protection of aquatic life.

Total Cd concentrations in Independence Creek at KT-0.3 generally do not exceed the chronic or short-term CCME hardness-dependent guidelines for protection of aquatic life (Figure 3.5-15).

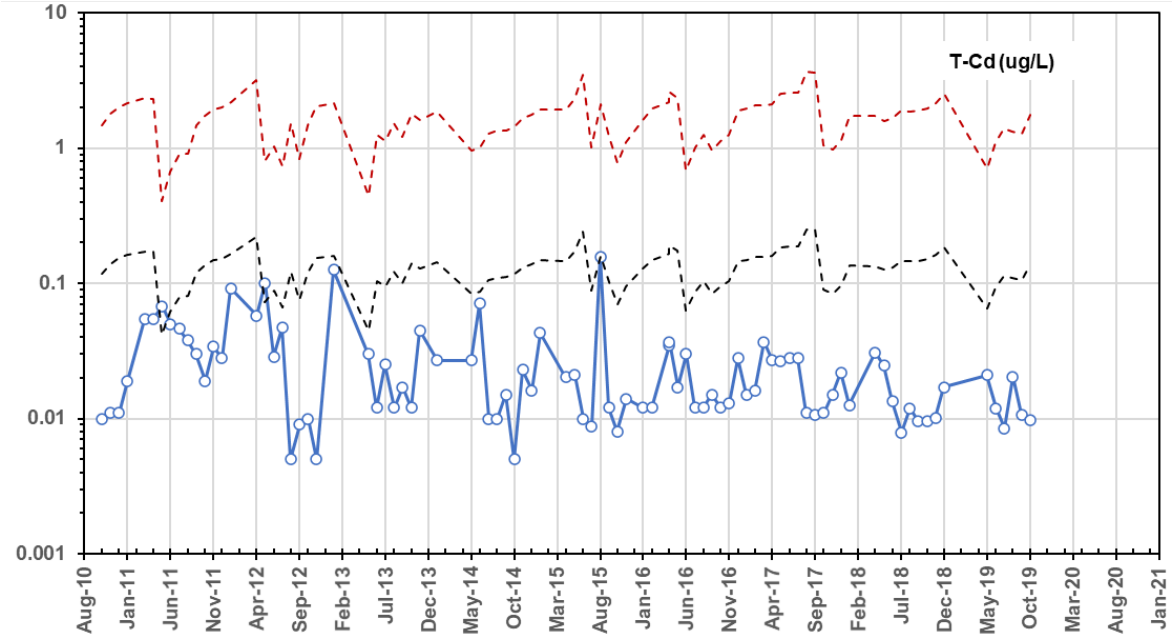

Figure 3.5-15: Total cadmium (T-Cd) in Independence Creek (KT-0.3) for the period October 2010 to December 2020 compared to the Canadian Council of Ministers of the Environment (CCME) chronic (black dashed lines) and acute (red dashed lines) water quality guidelines for the protection of aquatic life.

Coffee Gold Baseline Hydrogeological Assessment 2019 Update

Project No. A362-4
14 December 2021

LORAX ENVIRONMENTAL

Executive Summary

Newmont™
COFFEE

Executive Summary

The Coffee Gold Project (the Project) is a proposed open-pit heap leach mine development located in west-central Yukon, 130 kilometers (km) south of Dawson City. The Project is subject to an assessment under the *Yukon Environmental and Socio-economic Assessment Act*. A Project Proposal and other related documents have been submitted to the Government of Yukon. This report constitutes an update to the baseline hydrogeological assessment of the Project that was submitted in support of the Project Proposal. Physical and chemical hydrogeological data collected up to August 2019 are summarized.

A combination of hydrogeological, geotechnical and geocryological field programs have established a robust network of hydrogeological monitoring installations in, around and downgradient of major mine facilities. The instrumentation includes eleven conventional monitoring wells, seven Westbay multilevel groundwater monitoring systems, nine combination vibrating wire piezometer (VWP)/thermistor strings, plus twelve stand-alone thermistor strings, twenty-five stand-alone shallow thermistor beads, and four stand-alone VWP strings. Groundwater level information is available from selected sites from as early as 2013, with all installations recording high frequency (sub-daily) water level and ground temperature information from mid-2015 onward.

Ground temperature data obtained from thermistors, as well as observations from drilling and monitoring well sampling indicate that permafrost is discontinuous but extensive across the project area. The thickest permafrost at site is measured on the north-facing slopes, a thermistor string at the north end of the proposed Supremo pit reports ~168 metres of permafrost. Permafrost appears to decrease in thickness with declining ground surface elevation. Permafrost in the project area is relatively warm (between 0 and -2ºC) and is coolest (-1.4ºC to -1.9ºC) on north-facing slopes.

Sixty successful measurements of bedrock hydraulic conductivity (K) have been obtained through a combination of different hydraulic testing methods. Bedrock hydraulic conductivity ranges over several orders of magnitude, from below test resolution (<1E-10 m/s) to over 1E-06 m/s, consistent with expectations for a fractured bedrock system. Hydraulic conductivity broadly decreases with depth and does not appear correlated to lithology. The median hydraulic conductivity of mineralized structures and faulted rock is 2E-07m/s with tests ranging up to 275 m depth.

At several higher elevation installations, the water table resides below the base of permafrost. The deepest water level at site, more than 220 meters below ground surface is found along the northwest extent of the proposed Supremo pit. At high elevation

installations near the proposed Kona and Latte pits, water levels are on the order of 110 to 150 m deep. A high elevation installation on the margins of the proposed heap leach facility, however, registers artesian pressures in a faulted area confined by permafrost.

Artesian groundwater pressures are reported at many lower elevation installations in both permafrost and permafrost-free areas. While groundwater pressures may be artesian adjacent to creek traces, often vertical gradients are downwards, suggesting groundwater is under-drained by the intercepted faults. This is particularly true at installations along Latte Creek. Upward hydraulic gradients are measured in the lower reaches of Halfway Creek near the intersection of a crosscutting fault.

Most groundwater hydrographs are smooth and broadly sinusoidal with one annual maximum that occurs weeks to months after freshet. A few recorded hydrographs from low elevation installations adjacent to creeks show flashier records that respond to rainfall events. Groundwater hydrographs fluctuate from less than 2 meters per year to over 30 metres at one location. Drier-than-average conditions in 2017 manifest as a smaller annual fluctuation compared to other years.

Groundwater sampling was conducted on nineteen occasions between 2014 and 2019. Sampling was conducted at monitoring wells installed by Lorax between 2014 and 2016 and covers the period from September 2014 to August 2019. Data from these sampling events are included in the evaluation of groundwater quality, although several results were discounted due to potential influences from drilling and well installation artifacts.

Groundwater in the Project area is predominantly circum-neutral (pH 6 to 8), with most groundwater samples between pH 6.5 and 8. Groundwater quality shows variable influence from weathering of sulphide minerals and/or dissolution of sulphate minerals, either from the deposits or other disseminated mineralization across the Project area. Sulphate concentrations range from low to substantial (7 to 1120 mg/L) and salinity is variable (field specific conductance readings between 28 and 2390 µS/cm). Major ion chemistry in overburden wells is calcium-bicarbonate-type. The bedrock groundwater in gneiss has a major ion chemical signature which ranges widely from calcium-bicarbonate to mixed magnesium-calcium-sodium-sulphate-type water, reflecting variable influence of sulphide weathering. Groundwater in the granite is calcium-bicarbonate-type but is generally more sodic than other groundwater on site. The groundwater sampled from the hydrothermal breccia and schist tends to be calcium-bicarbonate to magnesium-sulphate-type.

Baseline groundwater quality in the Project area is characterized by the presence of elevated dissolved arsenic and uranium. Dissolved arsenic and uranium concentrations were generally highest in the bedrock groundwater, ranging from 0.12 to 2650 µg/L and 1.2 to 589 µg/L, respectively.

Glossary and Abbreviations

Terminology used in this document is defined where it is first used. The following list will assist readers who may choose to review only portions of the document.

DO	dissolved oxygen
EBA TT	EBA Tetra Tech
F_{paleo}	fraction of young groundwater (that recharged since 1953)
F_{young}	fraction of paleo groundwater (that recharged prior to ~11,700 years ago)
HCO_3	bicarbonate
HLF	heap leach facility
K	hydraulic conductivity
km	kilometre
KP	Knight Piésold
LMWL	local meteoric water line
$L/s/km^2$	litres per second per square kilometre
m	metre
m asl	metres above sea level
m bgs	metres below ground surface
m/s	metres per second, unit of hydraulic conductivity
mg/L	milligram per litre, unit of concentration
mm	millimetre
mm/yr	millimetres per year
Mt	megatonne
mV	millivolt
NH_3	ammonia
NO_3	nitrate
NTU	Nephelometric Turbidity Unit, unit of turbidity
O_2	oxygen
^oC	degrees Celsius
ORP	oxidation-reduction potential
the Project	the Coffee Gold Project
RC	reverse circulation

RDL	reportable detection limit
S^{2-}	sulphide
SC	specific conductance
SO_4	sulphate
TDS	total dissolved solids
TSS	total suspended solids
TU	tritium units
U/S	upstream
µg/L	micrograms per litre, unit of concentration
µS/cm	microsiemens/centimetre, unit of specific conductance
v m bgs	vertical metres below ground surface
VWP	vibrating wire piezometer
^{2}H	hydrogen-2, a stable isotope of hydrogen
^{3}H	tritium (or hydrogen-3), a radioactive isotope of hydrogen
^{13}C	carbon-13, a stable isotope of carbon
^{14}C	carbon-14 (or radiocarbon), a radioactive isotope of carbon
^{18}O	oxygen-18, a stable isotope of oxygen
δ	delta notation used to describe the stable isotope composition of a sample by normalizing the ratio of heavy to light isotopes (*eg.*, $^{2}H/^{1}H$, $^{13}C/^{12}C$, $^{18}O/^{16}O$) in a sample relative to that of a standard
‰	per-mil units, used to express the normalized difference between an isotope sample and its standard

1. Introduction

Newmont™
COFFEE

1. Introduction

1.1 Project overview

The Coffee Gold Project (Project) is a proposed open-pit heap leach mine development located in west-central Yukon, approximately 130 km south of Dawson City (Figure 1-1). The Project is located in the Yukon-Tanana Terrane, an accreted pericratonic rock sequence that covers a large portion of the Omineca Belt in the Yukon and extends into Alaska and British Columbia. The Project has undergone a detailed Feasibility Study (Coffee Gold 43-101 FS) with project engineering and mine design progressing forward with full consideration of the environmental conditions at the property.

The Coffee Gold Project is amenable to development as an open pit mine with gold recovery recommended by heap leach mining methods. The general arrangement for the Project includes the following major infrastructure: primary and secondary crushing facilities; a carbon adsorption plant; a gold refinery; the heap leach facilities; waste rock storage facilities (WRSF); open and backfilled pits; water drainage structures and storage ponds; haul roads; an accommodations complex; and an all-weather airstrip.

The open pits associated with the Project are the Latte, Double Double, Supremo and Kona pits (Figure 1-2). Waste rock associated with the undertaking is proposed to be placed in one main facility (the Alpha WRSF), with additional backfill of waste in Latte, Double Double, Kona, and Supremo (SU1) pits. Proposed pits and WRSFs are all situated at high elevation (*i.e.*, median drainage basin elevations range from 945 to 1,220 m above sea level (m asl), and are proposed to be situated either on, or adjacent to, headwater tributaries of the Halfway Creek, Latte Creek, YT-24 (an unnamed tributary of the Yukon River) and Kona Creek (a tributary of Independence Creek) watersheds.

In parallel to exploration activities and feasibility studies, Newmont has resourced a full suite of baseline programs (*e.g.*, meteorology, hydrology, surface water quality, groundwater, soils, air, fish and fish habitat, wildlife) to support the preparation of an already submitted Project Proposal and related regulatory submissions to the Government of Yukon, as required by the *Yukon Environmental and Socio-economic Assessment Act*.

1.2 Scope of this document

This report constitutes the assessment of baseline groundwater conditions at the Project. This report updates the 2017 Coffee Gold Baseline Hydrogeological Assessment (Lorax, 2017c) submitted as part of the Yukon Environmental and Socio-economic Assessment Board assessment. It presents data collected in multiple hydrogeological field investigations completed between 2013 and 2019. This report presents data collected

through August 2019, which corresponds to the last monitoring round conducted by Lorax personnel. Collection of baseline groundwater quality and water levels is ongoing and will be continued through the licensing process.

Section 2 of this report provides background information from other disciplines which inform interpretation of the groundwater system. Section 3 describes hydrogeological and geotechnical studies undertaken at the site that have contributed to the baseline hydrogeological characterization. Section 4 presents the results of physical groundwater data collection including permafrost occurrence, hydraulic testing and water levels. Section 5 presents groundwater quality results and an interpretation of isotope samples collected from groundwater. Section 6 presents main findings and a summary of the baseline groundwater monitoring program.

2. Background

Newmont™
COFFEE

2. Background

The following section provides a high-level summary of climatic, hydrologic and geological information relevant to the groundwater system at the Coffee Gold Project. Detailed baseline reports for each discipline below are presented under separate cover.

2.1 Climate

A baseline meteorological program was initiated at the Project in July 2012. Baseline hydrometeorological data have most recently been summarized in Lorax (2019). The prevailing climate conditions at the Project site are typical for central Yukon. The average annual temperature is -2.0°C, with average monthly air temperatures that range from -17°C (December) to +14°C (July). Locally, the Project site experiences notable temperature inversions in the winter months, with observed ridgetop temperatures up to 10°C higher than measurements recorded at valley bottom locations.

Mean annual precipitation at the proposed undertaking (~1,300 m asl) is estimated to be 499 mm, with rainfall comprising 65% of this total precipitation during the months of May through September, and the remaining 35% occurring as snow from October through April. Precipitation gradients were ascertained by inspecting site and regional precipitation data and were established as follows: 4%/100 m elevation gain for rainfall; and 7.5%/100 m elevation gain for snowfall. Annual site evapotranspiration is estimated to be 190 mm/yr, roughly 40% of the estimated potential evaporation which is consistent with other studies of the Yukon.

Precipitation data measured at the lower elevation site weather station (at kilometer 11) during the 2013 to 2018 water years is presented as a percent anomaly from the six-year trend in Figure 2-1. For this interpretation, the water year extends from October of the previous year to the end of September of the current year. Data for 2019 are not included as the most recent interpretation (Lorax, 2019) predates collection of the full water year data. Average runoff anomalies computed for site hydrometric stations are also included in Figure 2-1. At a cursory level, the runoff data indicate that 2014 and 2017 were drier years while 2013, 2015 and 2018 were wetter years and 2016 was an average year. The implication is that less water may have been available to recharge groundwater in 2014 and 2017, while the opposite would be true for 2013, 2015, and 2018.

Figure 2-1: Snow, rain and total precipitation anomaly for 2013-2018 water years (October-September)

2.2 Hydrology

A baseline surface water hydrology monitoring program was initiated in the autumn of 2010 and augmented with enhanced instrumentation and additional stations in the spring of 2014. The result is an extensive hydrometric network with a high quality and high-resolution streamflow data set. The most recent hydrometric data have been summarized in Lorax (2019).

Local patterns of streamflow are dominated by a snowmelt freshet that typically occurs between late April and early June. Following freshet, patterns of streamflow are punctuated by several rainfall-induced runoff events which occur throughout the summer and autumn. In general, these high flow events are short duration, persisting usually for a 1 or 2-day period. Flows in local creeks and streams abate in October in response to freezing temperatures and it is notable that local watersheds typically experience zero flow conditions throughout the winter (*i.e.,* November through end March). Aufeis (*i.e.,* frozen

groundwater seepage that accumulates within, and adjacent to, local watercourses) is pervasive in creeks and streams at the Project site and melts during the freshet but can persist into the early summer.

Based on measurements at Coffee Creek hydrometric stations, average unit yields across the Project site are 8 L/s/km^2 for the open water season (May to October), and range from 3 to 13 L/s/km^2, with specifics of the runoff regime for each monitoring station being dependent on drainage characteristics (*i.e.,* basin area, shape, mean elevation, extent of permafrost, *etc.*). Unit yields range from 0.6 –3.4 L/s/km^2 in October and decrease steadily to annual minima in March (*i.e.,* 0 – 0.7 L/s/km^2), before increasing again in April in response to low-elevation snow melt and spring rains. At Coffee Creek, instantaneous peak flows, expressed as unit yields, are typically between 120 and 200 L/s/km^2, but measurements vary widely across the site (from 60 to >300 L/s/km^2).

2.3 Physiography

The Project is located in the northern Dawson Range of the Yukon-Tanana terrane, forming a moderate plateau that escaped Pleistocene glaciation. The landscape evolved through erosional and periglacial processes. The dominant periglacial processes at the Coffee Gold site are cryoturbation, solifluction, slope wash and thermal erosion. The topography generally consists of rounded ridges with incised v-shaped valleys (AECOM, 2012). Elevations across the property range from 400 to 1,500 m asl with the majority of the property above the tree line and supporting short shrubby vegetation (JDS, 2016). The property has local mature pine forests with thick moss cover on the ground. Bedrock exposures on the property are rare (<5%).

A surficial geology map of the Coffee Creek area has been compiled by the Geological Survey of Canada (Huscroft, 2002). AECOM (2012) was retained by Kaminak Gold Corporation (Kaminak), a previous owner of the Project, to compile a detailed geomorphological map to aid in the selection of appropriate sampling sites for soil geochemical characterization. Both maps identify colluvium as the most widespread surficial material within the project area. The ridgetops and upper slopes are generally dominated by in-situ residual soils and colluvium derived from weathering of bedrock. The colluvial material is variable and typically contains mixtures of gravels, sands and silts with organic materials in the upper 0.1 to 0.2 m layer. The ridgetop soils are up to approximately 1.8 m deep and generally ice-poor. The thickness of the strongly-weathered bedrock is variable but is generally less than a metre. The build up of colluvium is greatest on lower slopes, which tend to be steeper than upper slopes. Dominant colluvial processes include slope creep, debris slides and minor rock fall.

2.4 Permafrost

The Project is located in an area classified by Natural Resources Canada (1995) as extensive discontinuous permafrost (*i.e.,* 50% to 90% of the land underlain by permafrost). The most recent estimates of permafrost distribution at the site indicate that approximately 66% of the mine area is underlain by permafrost with 34% of the area estimated to be permafrost free (Tetra Tech, 2017). Of the 66% underlain by permafrost, 35% is underlain by predominantly ice-poor permafrost, 30% by predominantly ice-rich permafrost; and approximately 1% by very ice-rich permafrost.

Permafrost is an important consideration in the conceptualization of groundwater systems as it imparts controls on groundwater movement. Active groundwater circulation can occur above, within and beneath permafrost (supra, intra and sub-permafrost groundwater). When ground temperatures fall below the freezing point, the hydraulic conductivity sharply decreases as unfrozen water content drops and pores and cracks are increasingly filled with ice (Woo, 2012). Permafrost is considered to behave like an aquiclude or an aquitard and can confine sub-permafrost groundwater such that it exhibits artesian conditions (Woo, 2012). Recharge of sub-permafrost groundwater in discontinuous regions can be directly from adjacent non-permafrost uplands or through supra and intra-permafrost connections (Woo, 2012). Multiple studies have indicated that some recharge can occur through frozen ground (Kane *et al.,* 2013; Niu and Yang, 2006; Bosson *et al*., 2013; Gruber and Haeberliem, 2007; Scheidegger, 2013).

Frozen ground has been mapped at the Project using a variety of methods. AECOM (2012) first mapped frozen ground on the property for a geomorphological mapping study supporting strategic soil sampling for exploration purposes. EBA Tetra Tech (EBA TT) further investigated permafrost occurrence through field mapping and air photo interpretation (2016). A terrain stability/geohazard map was produced by Palmer (2016). As described in Section 3, various investigations to characterize permafrost occurrence and extent have been completed for the Project which have resulted in the establishment of numerous thermistor installations (*e.g.,* EBA TT in 2013, Knight Piésold in 2014, SRK in 2015, Lorax in 2014, 2015, 2016, 2017, Tetra Tech and SRK in 2016 and Tetra Tech in 2017).

2.5 Geology

A detailed account of the geologic setting and mineralization of the Coffee Gold Project is provided in the 2016 Feasibility Study (JDS, 2016). The Project is underlain by a package of metamorphosed Paleozoic rocks of the Yukon-Tanana terrane that was intruded by a large granitic body in the Late Cretaceous. The Paleozoic rock package is predominantly a biotite (+ feldspar + quartz + muscovite ± carbonate) schist that overlies an augen

orthogneiss. Both the Paleozoic metamorphic rocks and Cretaceous granite are cut by intermediate to felsic dykes of andesitic to dacitic composition. Grodziki *et. al.* (2015) have compiled the most recent geological map of the Coffee Gold deposit area, informed by a combination of geological traverses, bedrock mapping, borehole data, soil geochemistry, and geophysics. This map has been used as the base map for Figure 2-2, which also shows mine facilities and instrument locations for reference.

The main Coffee Gold mineralization is associated with an extensional deformation event that occurred during the Cretaceous. This event resulted in formation of steep-to-vertical brittle fractures and normal faults crosscutting all lithologies at the Project area (Berman et al*.,* 2007). A CO_2-rich fluid flowed through the region and travelled upwards in the system into the epizonal domain of the Coffee Gold Project, where it was controlled by the structural framework of the Coffee fault system and reacted with favorable host rocks (Buitenhuis *et. al.*, 2015; Buitenhuis, 2014). The fluid travelled along brittle structures and deposited gold-rich arsenian pyrite through sulphidation, and in high-energy pulses, formed gold-rich hydrothermal breccias (Buitenhuis, 2014). The planar gold mineralized zones at the Project exhibit a number of strike orientations, dominated by east-west, north-south, and east-northeast–west-southwest strike directions.

The Supremo zone is housed in several drill-tested T-structure gold corridors which are 5 to 30 m wide. The Latte zone consists of a stacked set of moderately-to-steeply south-southwest dipping, east-southeast striking brittle-ductile structures. The Double Double zone consists of a number of discrete, high-grade strands of mineralization up to several metres wide, trends east-northeast steeply dipping to the north and consists of a number of discrete, high-grade strands of mineralization up to several metres wide. The Kona zone is hosted in equigranular granite and consists of east-northeast trending, steeply south-dipping stacked structures. The gold structures are associated with narrow, less than 5 m wide, sparsely feldspar phenocrystic to aphanitic andesite to dacite dykes.

Kaminak (2015) prepared a map of all confirmed mineralized structures identified on the property. The map identifies structures confirmed by drilling, trenching, or soil sampling and does not include regional-scale inferred faults. Structures identified in this map have been included in hydrogeologic maps provided in subsequent sections of this report due to their relevance as potential groundwater conveyance pathways.

3. Hydrogeological Field Investigations

Multiple hydrogeological field programs have been undertaken at the Project between 2013 and 2019 (Table 3-1). The field programs have established a robust network of hydrogeological installations in, adjacent to and downstream of proposed major mine facilities (Figure 1-2). The location and configuration of some mine facilities (*e.g.* Heap Leach Facility (HLF), WRSF) has evolved since hydrogeological field investigations were initiated, with the mine plan layout shown in Figure 1-2 current to date. The groundwater field installations are as summarized as follows:

- Eleven conventional monitoring wells (five wells less than 10 meters deep; six wells between 150 and 220 metres deep);
- Seven individual multi-port Westbay installations monitoring groundwater 10 to 286 metres deep;
- Twenty-six stand-alone thermistor strings, 14 multi-bead thermistors strings ranging from 20 to 300 metres deep and 26 single bead shallow thermistor strings installed between 4 and 10 metres deep;
- Four stand-alone vibrating wire piezometer (VWP) installations ranging from 120 to 185 metres deep; and,
- Twelve combination VWP/thermistor installations ranging from 52 to 268 metres deep.

Completion details of the conventional monitoring wells, Westbay systems, VWP and thermistor are provided in Table 3-2 through Table 3-6. Borehole logs and instrumentation documentation are provided in Appendices 3-A through 3-C.

Many of the drilling programs have incorporated hydraulic testing of bedrock, predominantly through a combination of packer testing and airlift testing. Limited slug testing has also been conducted. In conjunction with monitoring well installations, multiple groundwater sampling events have been undertaken to characterize baseline groundwater quality and its range of variability. The discussion below provides a high-level overview of the field programs with emphasis on those conducted by Lorax.

3.1 EBA Tetra Tech 2013 Program

The first hydrogeological field program, supervised by EBA TT in the fall of 2013, collected hydraulic testing data from, and installed, four single-point VWPs in NQ2-sized (75.7 mm diameter) boreholes advanced as a part of the exploration program. The program utilized a diamond drill rig owned and operated by Cyr Drilling International Ltd. of Manitoba. The majority of the field work was conducted by Kaminak staff, with training

from EBA TT. A total of four VWPs (Table 3-4, Figure 1-2) manufactured by RST Instruments, were installed with readings taken on a monthly basis with a manual readout unit (as these installations were not equipped with dataloggers).

3.2 Lorax 2014 Drilling Program

The data from the EBA TT 2013 program were used to inform the design of detailed hydrogeological baseline program conducted by Lorax between August 10th and September 25th, 2014. The primary goals of the 2014 program were to collect additional hydraulic testing data downgradient of mine facilities and to establish long-term groundwater monitoring and sampling locations. The program was undertaken using both skid-mounted and heli-portable diamond drill rigs (Boyles 37, Duralite D-10 and Silver Bear A5) owned and operated by Cyr Drilling. Two drill rigs were run concurrently for the majority of the program. Most drillholes were HQ-sized (96 mm) with the exception of two PQ-sized (122.6 mm) holes (MW14-06A and MW14-06B). The use of drilling additives was initially avoided to minimize potential impacts to groundwater quality following well installation, but drilling conditions necessitated their use in holes numbered MW14-03A/B and higher. Drilling additives used included AMC Pure-Vis, AMC Corewell, MATEX Ultra-Vis and Di-Corp G-Stop. All drilling and installations were supervised by Lorax personnel.

The 2014 program was limited to upland areas in and around planned pits and the formerly proposed valley-fill HLF footprint on account of challenging ground conditions including permafrost. Three deep (>150 m) 2-inch conventional well pairs were established at Kona (MW14-05A/B), Latte (MW14-03A/B) and southern Supremo (MW14-02A/B) pit areas. Two additional monitoring well pairs were established north of the Supremo pit complex (MW14-01A/B and MW14-06A/B locations, Figure 1-2); however, both wells in both pairs later became blocked, presumably due to ice-jacking. Logs for the 2014 monitoring wells are provided in Appendix 3-A with construction details summarized in Table 3-2. Note that construction details for MW14-01A/B and MW14-06A/B are not included in Table 3-2 since these became blocked and are not part of the baseline monitoring dataset.

A 300-metre, grouted-in thermistor string was established in the northern portion of Supremo Pit (MW14-04T) and a combination thermistor/VWP string was established in the valley-fill HLF footprint (MW14-07T) (Appendix 3-A). A variation on the Mikkelson mix (Mikkelson, 2002) was used for the grouting the combination thermistor/VWP string. Both locations were equipped with a dedicated datalogger housed inside a steel enclosure at surface for acquisition of high resolution (hourly) data (Figure 3-1). Similar dataloggers were also installed at the four VWPs installed by EBA TT in 2013. All instrumentation was manufactured by RST Instruments with documentation provided in Appendix 3-C. VWP and thermistor construction details are summarized in Table 3-4.

Table 3-1:
Summary of hydrogeological drilling programs undertaken at the Coffee Gold Project

Date	Consultant	Study Objective	Installations	Hydraulic Testing	Reference
Fall 2013	EBA Tetra Tech	Preliminary hydrogeological data collection to support a detailed work plan for the hydrogeological baseline assessment.	Vibrating wire piezometer (VWP) installations (4) in the Supremo and Latte pit footprints	✓	2013 Hydrogeological Data Collection, Coffee Gold Project, Yukon (EBA, 2013).
Summer 2014	Knight Piésold	Geotechnical site investigations and laboratory testing to assess: (1) subsurface conditions within the footprint of the Heap Leach Facility (HLF) (former valley fill location) and stockpile and (2) the geotechnical engineering material properties of the materials encountered.	Thermistor string installation (2) in formerly proposed valley-fill HLF footprint area in Latte Creek headwaters.		Kaminak Gold Corporation Coffee Gold Project: Report on Feasibility Study Level Geotechnical Investigations, March 12, 2015 (Knight Piésold, 2015)
Summer/Fall 2014	Lorax	First phase of a detailed hydrogeological baseline program establishing groundwater sampling locations in and around proposed pits.	Conventional monitoring well (10) and thermistor (1) installations in pit areas and thermistor/VWP installation (1) in the formerly proposed valley-fill HLF area	✓	Coffee Creek Hydrogeological Drilling Program – Program Summary, Memorandum to Kaminak Gold. October 17, 2014 (Lorax, 2014).
March 2015	Lorax	Second phase of a detailed hydrogeological baseline program establishing ground conditions, permafrost conditions and groundwater pressures downgradient of waste facilities ahead of a larger, subsequent field program.	Thermistor/VWP installations (2) in YT-24 and Latte Tributary drainages		2015 Phase l Baseline Hydrogeology Field Program – Program Summary, Memorandum to Kaminak Gold. April 7, 2015 (Lorax, 2015).
April - June 2015	Lorax	Third phase of a detailed hydrogeological field program establishing supplemental groundwater quality, groundwater pressure and ground temperature stations downgradient of mine facilities.	Thermistor/VWP (6), Westbay groundwater monitoring systems (sub-permafrost groundwater) (6); shallow monitoring wells (overburden) (5) installations.	✓	2016 Coffee Gold Mine Hydrogeology Drilling Program Summary, Memorandum to Goldcorp. March 13, 2017 (Lorax, 2017b)
					This report.
June/July 2015	SRK	Hydrogeological investigation targeting principal geologic structures that will be mined in the open pits, combined with a geotechnical program characterizing permafrost in proposed facility footprint areas.	Thermistor/VWP (4) and thermistor (2) installations in proposed waste rock storage facility (WRSFs) and stockpile locations.	✓	Hydrogeologic Investigations Report Coffee Project, Yukon, December 18, 2015 (SRK, 2015)
					2015 Geotechnical Field Investigation Report Coffee Gold Project, Yukon, Canada, January 4, 2016.
August/September 2016	Lorax	Hydrogeological field program aimed at establishing groundwater quality, groundwater pressure and ground temperature downgradient of the hilltop HLF.	Thermistor/VWP installation (1) along NW margin of hilltop HLF.	✓	2016 Coffee Gold Mine Hydrogeology Drilling Program Summary. Memorandum to Goldcorp. March 13, 2017. (Lorax, 2017b).
					This report.
Fall 2016	Tetra Tech/ SRK	Geotechnical site investigation to acquire geotechnical and permafrost data, to inform the design of the WRSF and sedimentation pond dams.	Thermistor installation (2 multi-bead thermistor strings and 1 single thermistor bead) in proposed WRSFs and sedimentation pond footprints.		Fall 2016 Geotechnical Investigation Data Report, Coffee Mine Site, Coffee Gold Project. March 20, 2017 (Tetra Tech and SRK, 2017)
Summer 2017	Tetra Tech	Geotechnical site investigation to acquire geotechnical and permafrost data, including frozen and unfrozen overburden and bedrock conditions, to inform design of the mine infrastructure, in particular to support the modified design of the Alpha WRSF and its respective components.	Thermistor installation (8 multi-bead thermistor strings and 25 single thermistor beads) in proximity to the Alpha WRSF and other mine infrastructure.	✓	Summer 2017 Geotechnical Investigation Data Report, Coffee Mine Site, Coffee Gold Project. November 30, 2017 (Tetra Tech, 2017).
August 2017	Lorax	Hydrogeological field program aimed at establishing depth of permafrost, depth of overburden, groundwater pressures, and groundwater occurrence NW of the proposed Kona Pit, as part of the larger Tetra Tech geotechnical investigation.	Thermistor/VWP installation (1) downgradient of the proposed Kona Pit.	✓	2017 Coffee Gold Mine Hydrogeology - Drilling Program Summary. Memorandum to JDS Energy and Mining. October 20, 2017. (Lorax, 2017a).
					This report.

Notes:
VWP – vibrating wire piezometer, HLF – heap leach facility, WRSF – waste rock storage facility.

1. Measured by RTK (real time kinematic) (UTM NAD83 Zone 7). All drillholes vertical.
2. All diamond drillholes advanced using NQ3 tools except GT17-21 (HQ3).

Figure 3-1: Thermistor installation at MW14-04T (left) and VWP installation at CFD-0318 (right).

One borehole at each drilling location was packer tested using a single packer setup. Both a hydraulic packer (Inflatable Packers International) and pneumatic packer (RST Instruments) were utilized during the 2014 drilling program. The 2014 packer testing comprised constant head or step tests.

3.3 Knight Piésold 2014 Program

Between August 28th and September 21st, 2014, Knight Piésold (KP) conducted a geotechnical field program comprised of test pits and boreholes in the formerly proposed valley-fill HLF footprint area. KP established two 50-metre thermistor strings (manufactured by RST Instruments) in the valley-fill HLF footprint area. The thermistors strings are inserted into sealed 1" PVC standpipes that have been cemented in place and are connected to dedicated loggers at surface. Details of the KP thermistor installations are provided in Table 3-5.

3.4 Lorax 2015 Drilling Programs

The widespread occurrence of permafrost encountered during the 2014 field programs prompted a refinement of the instrumentation required to collect water quality samples

from sub-permafrost groundwater. This led to the selection of Westbay technology for this purpose. Illustrated in Figure 3-2, the Westbay system is comprised of a versatile, modular, sealed custom-manufactured PVC pipe with sampling zones located at the discretion of the hydrogeologist in the field. The pipe is lowered down the hole and packer elements bracketing each zone of interest are inflated with a specialized tool. Figure 3-3 shows a photograph of the Westbay pipe and a packer element as it is being lowered into a borehole during installation. Groundwater is monitored/sampled using a specialized tool deployed from surface which docks into valved monitoring ports located within the sampling zone. In permafrost environments, a steel guide tube (typically HQ rods) is left in place which blinds off the frozen ground. A packer element resides inside the HQ rods, near the base, to prevent water ingress (and thus ice formation) in the annular space between the steel casing and Westbay system. The inside of the Westbay pipe and the annulus between the Westbay and steel protective casing is filled with a 3:1 mixture of water to propylene glycol to prevent ice formation inside and outside of the Westbay pipe. Westbay's custom-built sampling tool docks with the sampling ports in the assembly, opening the ports only after a seal has been established to prevent any exchange between the glycol inside the assembly and the groundwater outside.

Given the complexity and costs associated with Westbay system installations, the approach for installations in low-lying valleys was to first establish a thermistor/VWP installation at each drilling location and use the drilling and thermistor data to inform the Westbay installation at a second hole located off the same drill pad. A third, shallow (5 to 10 metres deep) conventional monitoring well was installed from an adjacent, smaller drill pad to screen shallow groundwater in overburden/weathered bedrock.

The 2015 baseline hydrogeological program was implemented by Lorax in two phases. The first program was undertaken between March 18th and March 26th, 2015 and utilized a heli-portable Hornet reverse circulation (RC) rig owned and operated by Northspan Explorations Ltd. (Northspan). Two combination thermistor/VWP strings were installed in the YT-24 and Latte tributary drainages, at locations MW15-01T and MW15-02T, respectively (Figure 1-2). The boreholes were drilled vertically; 5-inch casing was keyed into competent bedrock followed by direct circulation open hole drilling using a 4.5-inch bit. Borehole logs are found in Appendix 3-A. The VWP calibration sheets and thermistor wire diagrams provided by the manufacturer, RST Instruments, are found in Appendix 3-C with installation details summarized in Table 3-4.

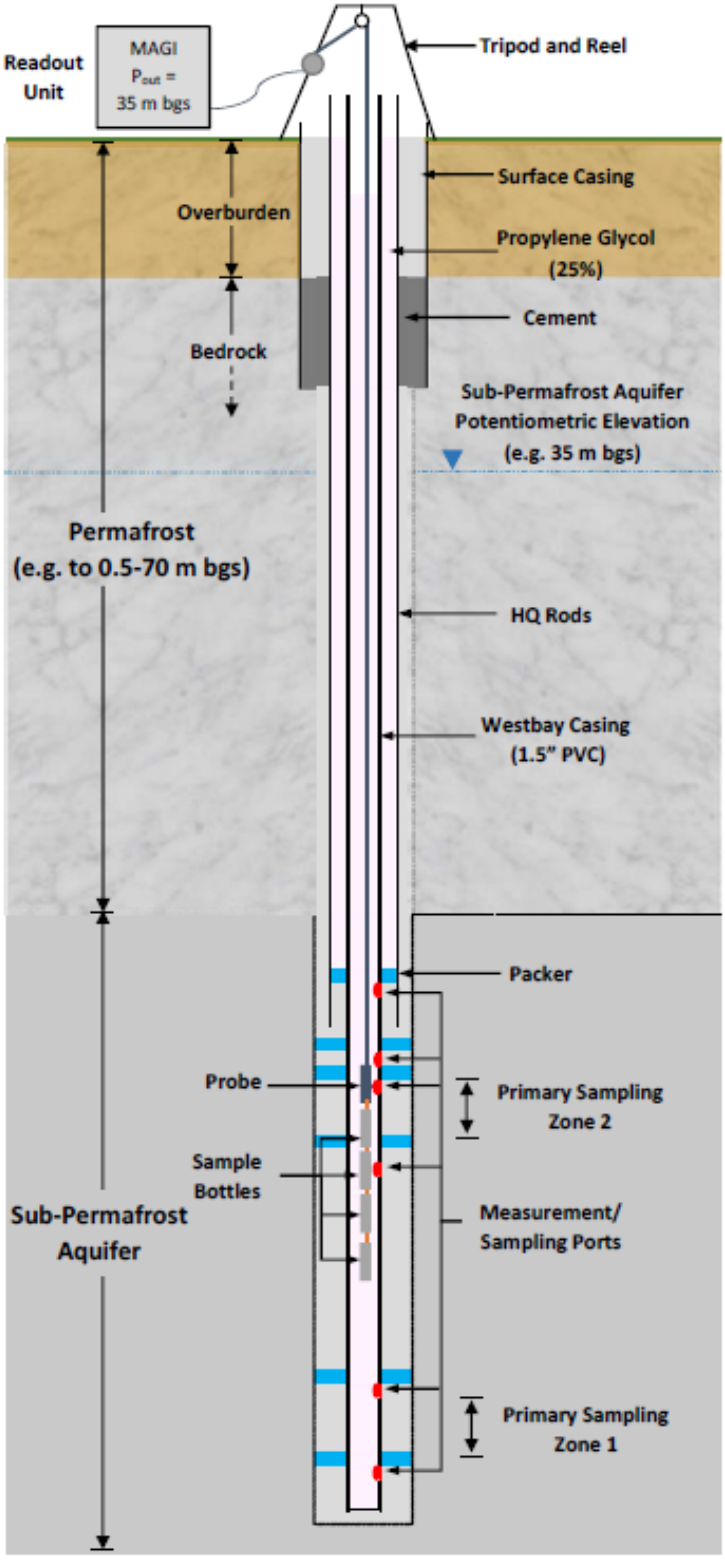

Figure 3-2: Schematic of an example Westbay system installed in permafrost (drawing not to scale).

Figure 3-3: Westbay installation at MW15-06T (BH5) using the Boyles 37 diamond drill rig. Blue gland is packer element which is inflated downhole with diluted propylene glycol. PVC is 1.5" Sched 80 with ends machined to mate with Westbay System couplings incorporating a shear-rod connection and an o-ring seal (no glue).

The initial drilling campaign in March provided critical information on permafrost depth for the planning of a subsequent, larger field program undertaken by Lorax between April 30th and June 9th, 2015. All drillholes were advanced using the Hornet RC rig operated by Northspan, with exception to MW15-06WB, which is discussed separately below. No drilling additives were used on the RC holes. Westbay systems were installed in vertical holes at all valley drilling locations. Each Westbay installation was preceded by thermistor/VWP installations in sub-vertical angled holes (80° dip) advanced from the

same pad. The thermistor holes were located on the downgradient edge of the pad and pointed in the downgradient direction to maximize the separation between the grouted VWP/thermistor hole and the Westbay completion. The grout backfill securing each thermistor/VWP installation was allowed to cure for 24 hours before drilling of the adjacent Westbay hole was initiated.

During advancement of each Westbay hole, formation water reporting to the cyclone was regularly field-tested for pH and electrical conductivity (EC) to assess whether grout from the adjacent hole had influenced water quality. Where there was suspicion of grout influence (*e.g.,* high pH), the Westbay zones were configured to avoid each potentially impacted area. Generally, two primary Westbay sampling zones were implemented at each installation. The zones were situated to intercept the first occurrence of substantial water and a second productive zone at depth (Table 3-3). The intention was to have a back-up zone should one zone become compromised or inaccessible. Westbay field technicians installed the Westbay instrumentation with assistance from Lorax and Northspan personnel. The Westbay completion report is provided in Appendix 3-B. Westbay installation details are summarized in Table 3-3.

Shallow conventional wells (>4.5 m to 10 m deep) were initiated at valley drilling locations to characterize potential groundwater flow in the active zone in areas of permafrost, or groundwater flow in the overburden where permafrost is absent. Most of the 'active zone' wells were advanced from a separate pad ~25 metres away from the thermistor/VWP and Westbay pad. These holes were advanced using 4.5" ODEX casing which was withdrawn as the installation was completed.

A combination of drilling methods was used to establish MW15-06WB, a Westbay system north of Supremo pit implemented to replace the 2014 conventional well pair (MW14-01A/B) that ice-jacked at the previous BH5 location. A 4.5" ODEX drillhole was first advanced using the Hornet RC rig to 200 metres, the depth limit of the rig, and found to be dry. A Boyles 37 diamond rig operated by Cyr was then mobilized onto the hole and HWT casing (4.5" OD) was reamed down to 162 m bgs. The hole was then deepened to 293 m bgs using HQ coring methods. A heavy mud (using AMC drilling additives Pure-Vis, Corewell and CR-650) was used during reaming and drilling. The hole was flushed for three hours prior to the commencement of the Westbay installation. HQ rods were left in the hole to a depth of ~ 204 m to act as a protective guard against permafrost.

Hydraulic testing during the Lorax 2015 field program consisted of airlift yield measurements at regular intervals during drilling plus an extended airlift yield test with monitored water level recovery on selected boreholes. A shut-in, constant head test was also conducted on MW15-04T, an artesian hole in Halfway Creek (Figure 1-2).

3.5 SRK 2015 Program

In the summer of 2015, SRK conducted a hydrogeological program targeting geologic structures intersecting the pits and led a site-wide geotechnical program characterizing ground conditions in mine facility footprint areas (SRK, 2015). Airlift tests and/or packer tests were performed on the structures and thermistor/VWP strings were installed directly beneath or near proposed waste rock and ore stockpile footprint areas. VWP/thermistor construction details are summarized in Table 3-4.

3.6 Lorax 2016 Drilling Program

In the summer/fall of 2016, Lorax conducted a hydrogeological program providing information on groundwater characteristics below the base of permafrost downgradient of the proposed HLF, which had been relocated to its currently proposed hilltop location (Figure 1-2). Two boreholes and accompanying instrumentation were installed. Details of the 2016 field program are outlined in Lorax (2017b) and summarized here.

Both vertical boreholes were advanced using a Hornet RC drill operated by Northspan. Five-inch ID casing was advanced into competent bedrock using a double-sided casing advancer system. Once the casing was keyed into bedrock, the casing advance system was exchanged for a COP44 hammer with 4.5-inch bit and open hole drilling ensued using reverse circulation. Significant formation water was encountered at each hole which impeded bit advancement. The drill bit was switched out for a 3.5-inch hammer and MW16-01T was advanced several meters further to a total depth of 189. 3 m, while MW16-01WB was terminated at 120 m.

The first borehole, MW16-01T, was advanced and completed in mid-August to gain insight on depth of permafrost, depth of overburden, ground conditions and groundwater pressures ahead of the drilling and installation of a Westbay system. Two thermistor strings and two VWPs were installed in MW16-01T. One thermistor string, 185 meters long and consisting of 13 individual sensors, was grouted in while a second individual thermistor was deployed above ground and above the grout level in the surface casing to measure ambient air temperature.

The Westbay well, MW16-01WB, was drilled and installed over a month later. HQ rods were permanently deployed from the surface casing to a depth of 68.4 m to protect the Westbay from permafrost. Westbay personnel supervised the installation which followed procedures outlined in Section 3.4. Borehole logs are available for both MW16-01T and MW16-01WB in Appendix 3-A, with installation details summarized in Table 3-4 and Table 3-3, respectively. The Westbay installation report is included in Appendix 3-B while VWP calibration sheets and thermistor configuration diagrams are found in Appendix 3-C.

Spot airlift yields were measured at regular intervals during drilling on both MW16-01T and MW16-01WB. Two constant rate injection packer tests and a pumping and recovery test were conducted on MW16-01T.

3.7 Tetra Tech 2016 Geotechnical Program

Between August 24 and October 5, 2016, Tetra Tech Canada Inc. (Tetra Tech) and SRK Consulting Inc. (SRK) conducted a geotechnical field program to acquire data on frozen and unfrozen overburden and bedrock conditions to inform design of proposed waste rock storage areas and respective sedimentation dams (Tetra Tech and SRK, 2017). The program consisted of advancing 35 vertical boreholes using a diamond-drill rig to depths ranging from 4.0 m to 21.2 m. Boreholes were advanced using chilled drilling fluid comprised of Perma-Drill ES or propylene glycol to preserve frozen conditions in the core.

Of significance to hydrogeological assessment of the Project, Tetra Tech established two multi-bead thermistor strings; GT-14 in the footprint of the formerly contemplated North WRSF area and GT-63, located north of the HLF in the upper portion of the Halfway Creek drainage within the footprint of the formerly contemplated Halfway Pond. A single bead thermistor was installed at GT-66, located near GT-63.

3.8 Lorax 2017 Program

In August 2017, Lorax conducted a hydrogeological investigation to gain insight on the extent of permafrost along the northwest margin of the proposed Kona Pit. One borehole, MW17-01T, also referenced as GT17-01 in Tetra Tech (2017), was advanced and completed with a multi-bead thermistor string and VWP sensors (Table 3-4). The field investigation was described in Lorax (2017a), appended to Tetra Tech (2017), and is summarized here.

MW17-01T was advanced as a vertical hole using a Hornet RC drill operated by Northspan. Drilling methods followed those described in Section 3.6, with the exception that minimal formation water was returned, allowing the borehole to be advanced to total depth (201.5 m) using the 4.5” bit. Hydraulic testing consisted of two constant head packer tests followed by recovery tests after the borehole had reached target depth. The borehole was completed with a 13-bead thermistor string installed to a depth of 181 meters and two VWP sensors targeting fracture zones (Appendix 3-A, 3-C).

3.9 Tetra Tech 2017 Geotechnical Program

Between June 28 and August 21, 2017, Tetra Tech conducted a second phase of the geotechnical field investigation initiated in 2016. The purpose of the program was to acquire geotechnical and permafrost data, including frozen and unfrozen overburden and

bedrock conditions to inform design of the Alpha WRSF and other mine facilities (*e.g.,* HLF, event ponds, stockpiles, plant site and infrastructure) (Tetra Tech, 2017).

The program consisted of advancing 43 vertical boreholes using a diamond-drill rig to depths ranging from 4.5 m to 201.5 m. These holes were advanced using chilled propylene glycol to produce undisturbed frozen core samples. Five shallow testpits were also hand dug to further characterize shallow subsurface conditions. Tetra Tech established seven multi-bead thermistor strings as well as twenty-five single bead thermistor strings. The multi-bead thermistors are summarized in Table 3-5 while the single bead thermistors are summarized in Table 3-6. In addition, hydraulic tests (packer tests) were conducted in six boreholes within the proposed footprint of the Alpha Pond.

3.10 Groundwater Sampling

All monitoring wells were developed after installation and prior to groundwater sampling. Well development was conducted using several methods, including purging with a bailer-winch system, inertial pump actuated with a Hydrolift-II, Westbay sampler, and air-lift pumping. The available well development method(s) depended on the type of well installation and depth to groundwater. Details regarding the development of MW14-series (completed in 2014), MW15-series wells (completed in 2015), and MW16-01WB (completed in 2016) are described in Lorax (2017c).

Groundwater monitoring events were conducted in September/October 2014, and four times annually since 2015, except in 2016 and 2019 when three monitoring events were completed (Table 3-7). The groundwater monitoring events have been conducted between April and October annually; this modified quarterly sampling frequency is often employed in the Yukon to capture the range of seasonal variability accounting for extended winters and compressed spring/summer/fall seasons.

All new monitoring wells installed between 2014 and 2016 have been sampled for groundwater quality with the exception of MW14-06A, MW14-06B, MW15-01AZ, and MW15-04 AZ which could not be sampled due to damage or water limitations (*e.g.,* frozen or dry) (Table 3-7). Table 3-7 presents a summary of the groundwater sampling programs between 2014 and 2019, including sampling methods used at each monitoring well.

Groundwater sampling was conducted in accordance with methods outlined in the BC Field Sampling Manual (BC MOE, 2013). Sampling was conducted using several different types of pumps. The pump employed at each well depended on the type of well installation, permeability of the geological unit being sampled, and depth to groundwater. Inertial pumps actuated with a Hydrolift-II mechanical actuator and peristaltic pumps were used to sample monitoring wells screened in permeable formations. Bladder pumps were used to

collect groundwater samples from deep wells screened in low permeability bedrock which would not permit sampling with conventional methods (*e.g.,* inertial pump), while the Westbay sampler was necessarily used to collect groundwater samples from the Westbay installations. In general, low-flow sampling methods were employed, and groundwater samples were collected after water levels in monitoring wells and purge water field parameters had stabilized. Field parameters were continuously monitored with a multi-parameter probe (YSI 556 MPS or YSI Professional Plus) coupled to an in-line flow-through cell during groundwater purging. Field parameters were monitored to ensure collection of representative samples and to provide reliable field-based estimates of temperature, pH, specific conductance (SC), dissolved oxygen (DO), and oxidation-reduction potential (ORP).

De-icing was required at monitoring wells MW14-02A and MW14-02B prior to groundwater sampling. Artesian conditions at both wells resulted in the top of the water column freezing inside the well casing installed through permafrost. De-icing was conducted with a hot water pressure washer equipped with high-pressure hoses and a drain jetting nozzle. Groundwater sampling was conducted after the volume of injected de-icing water plus a minimum of one well volume had been purged and purge water field parameters had stabilized.

Low water levels and low yields at monitoring well MW14-05B challenged the equipment capabilities and sampling procedures. Consequently, a modified purging/sampling procedure was employed to obtain the most representative formation groundwater at MW14-05B. The water level was drawn down to the lowest possible level (pump elevation) to maximize the amount of purged groundwater. The well was then allowed to recover overnight prior to sampling the next day, to ensure the greatest displacement and the largest buffer between ‘new’ formation water and ‘old’ residual standing water.

Table 3-7:
Summary of Groundwater Sampling Programs (2014 to 2019)

Station	2014	2015				2016			2017				2018				2019			Count	True Count [5]

Notes:
BP = bladder pump, IP = inertial pump actuated with a Hydrolift-II, PP = peristaltic pump, WB = Westbay sampler; D/S = downstream
1. Water inside monitoring well had started freezing at time of well development.
2. Monitoring well riser pipe collapsed near surface, likley due to freeze/thaw action in the active layer. Consequently, well screen could not be accessed.
3. Monitoring well decommissioned by Kaminak.
4. Monitoring wells MW15-01AZ and MW15-05AZ were damaged in July 2019 due to channel and stream bank erosion caused by a summer precipitation event in the Project area.
5. True Count - reflects the number of samples believed to be representative, collected at each station (samples screened-out due to drilling and well installation artifacts discussed in Lorax (2017c) and in Appendix 5-D of this report are not included in this count, and are highlighted in yellow).
6. At MW15-03WB, Port 6 (~47 m) was sampled between June 2015 and May 2016, and Port 4 (~82 m) was sampled thereafter between July 2016 and August 2019. Groundwater quality results corresponding to the two sample depths indicate that there is no apparent difference in the major ion compositions, and concentrations of field parameters, redox parameters, trace element parameters, and stable isotopes.

Since Westbay sample zones are isolated (*i.e.* not in direct contact) from atmospheric conditions, collecting representative groundwater samples does not require the use of typical sampling methods whereby large volumes of water are purged. Westbay installations MW15-01WB to MW15-06WB were sampled after completion of well development and purging in June 2015, while MW16-01WB was sampled after completion of development in October 2016. Additional well development was conducted at MW15-06WB in July and August 2015 due to the suspected presence of drilling additives observed during sampling in June 2015. Subsequent groundwater sampling of all Westbay installations was conducted after purging a minimum of 4 L. Additional detail regarding groundwater sampling methods is included in Lorax (2017c).

The data record at MW15-03WB consists of samples collected from Port 6 (~47 m bgs) between June 2015 and May 2016, while subsequent sampling was completed at Port 4 (~82 m) between July 2016 and August 2019 due to a transcription error. However, both sampling depths intersect similar geology (*i.e.*, mixed mafic gneiss and mixed felsic gneiss) and a strong upward hydraulic gradient was measured by MW15-03T between VWP sensors at 95 and 49 m bgs. The groundwater quality results corresponding to the two sampling depths indicate that there is no apparent difference in major ion compositions, and concentrations of field parameters, redox parameters, trace element parameters, and stable isotopes.

Groundwater samples were collected and preserved in the field with the appropriate laboratory supplied bottles and preservatives, with the exception of select dissolved samples collected in 2015 which were not preserved in the field when filtered at the lab. Samples analyzed for dissolved parameters were filtered in the field with disposable in-line 0.45-micron filters, except for groundwater samples collected from Westbay installations in 2015 which were filtered in the lab. Quality control sampling was conducted in the field and included the collection of field blank, trip blank, and field replicate samples. After collection, samples were kept cool in the field and during shipping until delivery to the laboratory. Groundwater samples were submitted for chemical analysis to the ALS Environmental (ALS) laboratory in Burnaby, BC in 2014, and to the Maxxam Analytics (Maxxam) laboratory in Burnaby, BC in 2015. In 2016, groundwater samples were submitted to Maxxam for all analyses, except cyanide species analyses which were completed by ALS. Since 2017, samples have been submitted to Maxxam (later becoming Bureau Veritas) for all analyses. Groundwater samples were analyzed for physical parameters, anions, nutrients, organic and inorganic carbon, total and dissolved metals, and cyanide species. Groundwater quality parameters and the corresponding detection limits are presented in Table 3-8.

Notes:
1. Detection Limit for Total Metal
2. Detection Limit for Dissolved Metal

Groundwater samples were collected for the analysis of stable isotopes of hydrogen (^{2}H) and oxygen (^{18}O), and the radioisotopes tritium (^{3}H) and carbon-14 (^{14}C). The stable isotope of carbon (^{13}C) in dissolved bicarbonate was also analyzed as part of the ^{14}C analyses to facilitate the calculation of groundwater radiocarbon ages. In addition, aufeis and surface water samples were collected to support the interpretation of groundwater stable isotope results. Groundwater stable isotope samples were typically collected from all monitoring wells, with radioisotope samples collected at select wells. Aufeis and surface water samples were collected from select locations in Latte, Halfway and YT-24 Creeks. Table 3-9 presents a summary of the groundwater stable isotope and radioisotope samples collected from each monitoring well between 2014 and 2019, as well as aufeis and surface water isotope samples collected between 2014 and 2017.

Table 3-9:
Summary of Isotope Sampling Programs (2014-2019)

Station	Sample Matrix	2014			2015			2016	2017		2019

Notes:
A = aufeis, SW = surface water, GW = groundwater
1. Sample counts shown in the table include duplicate samples.
2. Isotope samples were not collected in 2018.

Stable isotope and tritium samples were typically collected in 1 L high-density polyethylene (HDPE) bottles between 2014 and 2019. Radiocarbon samples were collected in 1 L HDPE bottles in 2014 and 2015, and subsequently in 0.25 L amber glass bottles with a septum in August 2019. Radiocarbon samples collected in August 2019 were field filtered (0.45-micron), preserved with $ZnCl_2$ (1.25 grams per 250 mL sample), and kept cool until delivery to the laboratory.

Groundwater, surface water and aufeis samples were submitted to the Brigham Young University Laboratory of Isotope Geochemistry (BYU-LIG) in Provo, Utah for isotope analyses (δ^2H, $\delta^{18}O$, ^3H, $\delta^{13}C$, ^{14}C) in 2014 and 2105. Groundwater and surface water samples collected between 2016 and 2019 were submitted to the University of Waterloo - Environmental Isotope Laboratory (UW-EIL) in Waterloo, Ontario for isotope analyses. Stable isotope and radioisotope analyses and the corresponding precisions are presented in Table 3-10.

Table 3-10:
Stable isotope and radioisotope parameters and precisions (2014-2019)

Parameter	Units	BYU-LIG	UW-EIL
		2014-2015	2016-2019
δ^2H	‰ VSMOW	1.0	0.8
$\delta^{13}C$	‰ VPDB	0.04 or 0.1 [1]	0.2
$\delta^{18}O$	‰ VSMOW	0.20 or 0.40 [2]	0.2
^3H	TU	0.3	0.8
^{14}C	pMC	0.07 - 0.20 [3]	0.040 - 0.26 [3]

Notes:
BYU-LIG = Brigham Young University Laboratory of Isotope Geochemistry, pMC = percent modern carbon, TU = tritium units, UW-EIL = University of Waterloo-Environmental Isotope Laboratory, VPDB = Vienna Pee Dee Belemnite, VSMOW = Vienna Standard Mean Ocean Water
1. Precision of $\delta^{13}C$ analyzed at BYU-LIG was 0.04 ‰ for samples collected between June and September 2015 and 0.1 ‰ for samples collected between September 2014 and April 2015.
2. Precision of $\delta^{18}O$ analyzed at BYU-LIG was 0.2 ‰ for samples collected between May and October 2015 and 0.4 ‰ for samples collected between September 2014 and April 2015.
3. Precision of radiocarbon counts vary by sample; consequently, a range is presented.

4. Physical Hydrogeology Results

Newmont™
COFFEE

4. Physical Hydrogeology Results

This section discusses physical groundwater data collected during the field programs outlined in Section 3. The discussion covers permafrost characterization, hydraulic testing results, water level time series and hydraulic gradients. Overall, the physical hydrogeological data reveal a complex groundwater system influenced by both discontinuous permafrost and a well-developed fracture system.

4.1 Permafrost

The permafrost data presented in this section is based on ground temperatures measured by thermistors installed by Lorax, SRK, Tetra Tech (or EBA TT), and KP, and other anecdotal observations of bedrock ice occurrence from the Lorax field programs. Key findings are summarized Table 4-1.

4.1.1 Observations of Visible Ice

Observations of ice in bedrock include visible ice shards in RC chips from shallow, fractured bedrock in Halfway Creek (MW15-03) and small lenses of ice at depth in core holes in Latte (MW14-03B) and Kona North (exploration hole CFD0376) (Figure 4-1). Not included in Table 4-1 are observations of ice in bedrock from drill holes advanced in the 2016 and 2017 geotechnical programs (Tetra Tech and SRK, 2016; Tetra Tech, 2017). These programs used chilled drilling fluids to preserve ice in core. Ice infilling of fractures and joints in bedrock was observed in some boreholes, typically within several metres of ground surface.

Detailed observations of ice in overburden are described in Tetra Tech and SRK (2016) and Tetra Tech (2018). Occasionally, ice was returned in RC cuttings in drillholes advanced by Lorax. Most notably, three large lobes of ice were intercepted between 8 and 13 metres below ground surface at MW15-01T (Figure 4-2). This drill pad is located on a slope classified as poorly drained colluvial veneer modified by solifluction (xszCv-S:p-i) (AECOM, 2012).

4.1.2 Permafrost Occurrence and Thickness

Ground temperature profiles for select multibead thermistor locations are provided in Appendix 4-A. Readings from VWP temperature sensors are included in the plots noting that the thermistors contained within VWPs are less accurate than those used in thermistor strings. A typical ground thermal profile, as measured at thermistor MW14-07T, is shown in Figure 4-3.

Table 4-1:
Observations of permafrost depth from thermistor installations, exploration drilling and monitoring well sampling.

Hole ID	Ground Surface (m asl)	Inferred Base of Permafrost (m bgs)	Temperature at 20 m bgs (°C)	Comments
Halfway Creek				
MW14-05B	1270.3	<134	NR	Water level in well remains unfrozen to 134 m.

MW14-02B	1030.9	>34	NR	Inferred base of permafrost estimated from ice surface in conventional MW after several months of inactivity.
CFD0324	992.9	na	NR	Single point VWP at 178 m, unfrozen (EBA 2013)
MW15-02T	737.1	na	0.5 to 0.6	Permafrost absent.
SRK-15D-09T	784.3	na	0.8	Permafrost absent.

Notes:
m asl = metres above sea level; m bgs = metres below ground surface; °C = degrees Celsius.
NR = no reading; na = not applicable

Figure 4-1: Ice lens observed in exploration hole CFD0376 (Kona North). Depth is ~85 m vertical.

Figure 4-2: Ice "cuttings" intercepted at MW15-01T while advancing casing through colluvium.

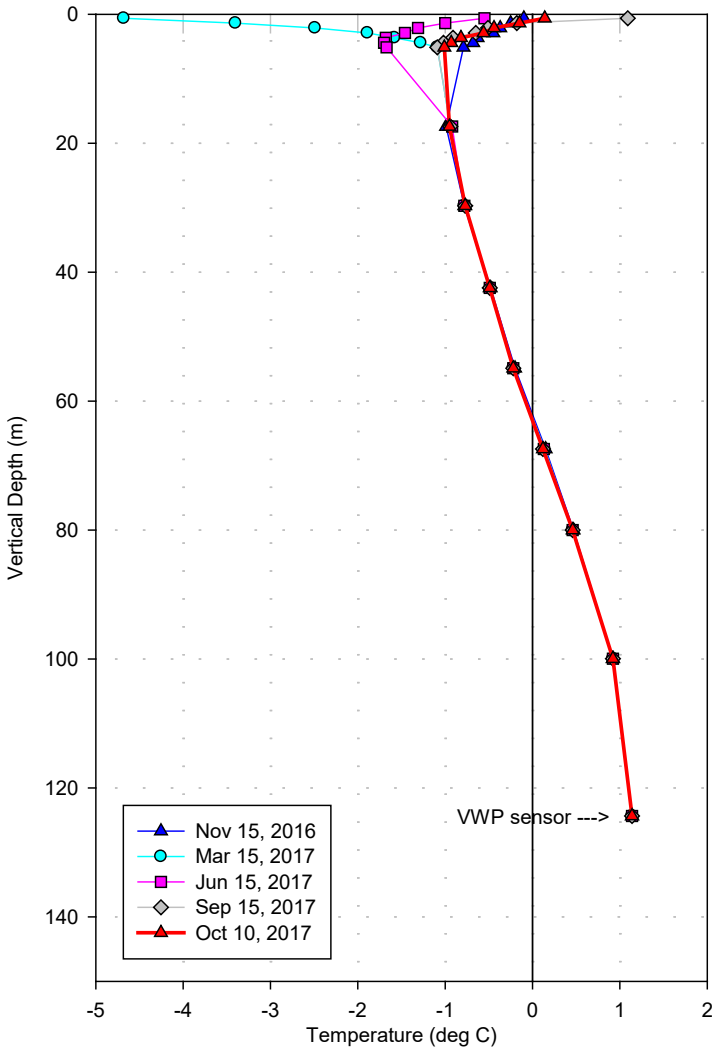

Figure 4-3: Thermal profile at MW14-07T, downgradient of the proposed heap leach facility.

Table 4-1 summarizes the thickness of permafrost measured or inferred from site thermistors. This depth is based on where the thermal profile crosses the 0°C line, or where it is extrapolated to cross the 0ºC line as illustrated in Figure 4-3. The generally low levels of total dissolved solids (TDS) in the sub-permafrost groundwater (<1000 mg/L) suggest that freezing point is not depressed below 0ºC. Permafrost in the project area is relatively warm (between 0 and -2°C) and at 20 metres depth (*i.e.* beyond the depth of zero annual fluctuation), is coolest (-1.4°C to -1.9°C) on north facing slopes.

Figure 4-4 plots permafrost thickness versus instrument elevation at locations where permafrost thickness could be constrained. The data reveal a general trend of permafrost thickness decreasing towards areas of lower elevation. North-facing slopes tend to have thicker permafrost than south-facing slopes. The thickest permafrost (~168 metres) encountered is near the north end of the proposed Supremo pit at MW14-04T.

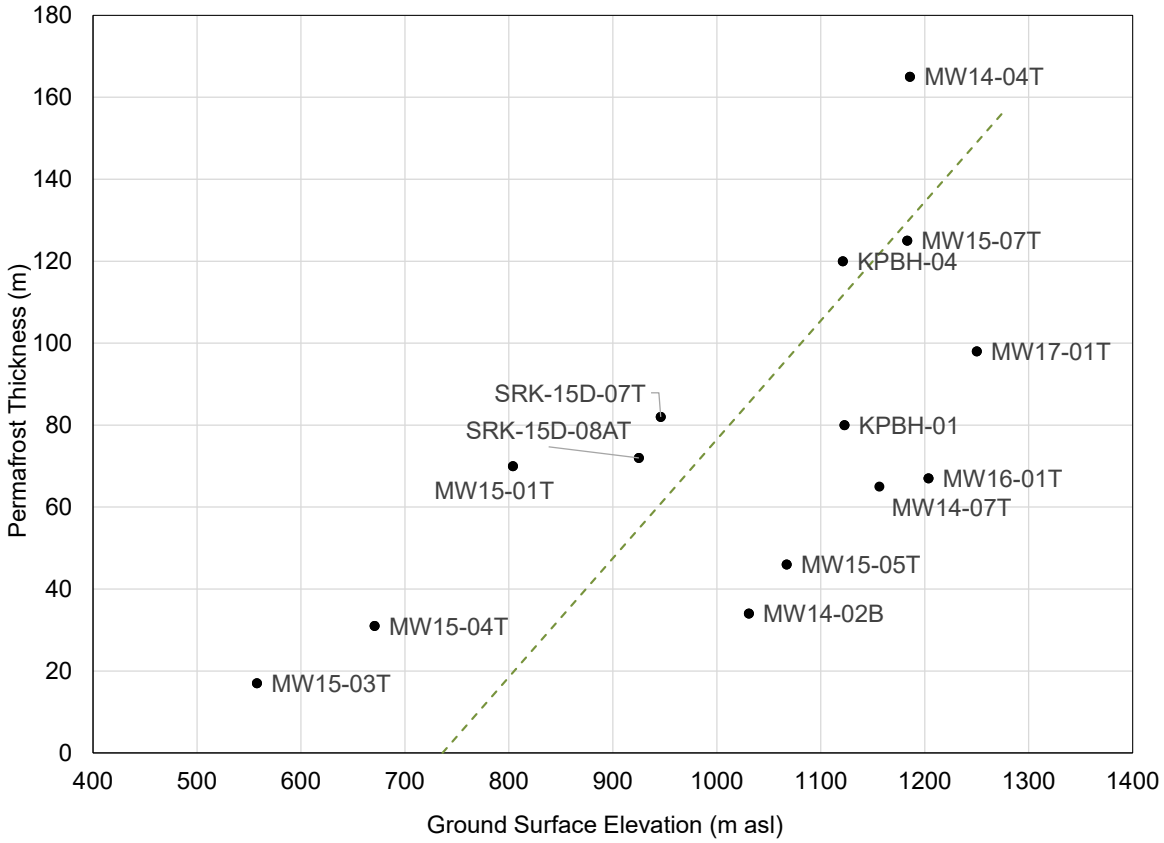

Figure 4-4: Depth of permafrost versus ground surface elevation at the Coffee Gold Project.

The point measurements provided in Table 4-1 are plotted on the permafrost distribution map in Figure 4-5. The map is based on the 2017 permafrost distribution map compiled by Tetra Tech (2017). Versions of this map and the permafrost thickness versus elevation trend (Figure 4-4) have been used to inform the groundwater model constructed for the Project (Lorax, 2016).

4.1.3 Active Zone

The active zone is defined as the top layer of ground that overlies permafrost and seasonally freezes and thaws. Table 4-2 summarizes time periods for which shallow temperature sensors record above zero readings in 2016, 2017 and 2018 and hence provides insight as to when the active zone is "active". Time series plots of the shallow temperature data are found in Appendix 4-B. Only thermistors where continuous data loggers are deployed are considered in Table 4-2 and Appendix 4-B.

The active zone is conceptualized as a highly heterogeneous zone that is variable in timing and duration between location and between years at the same location. In the Halfway Creek catchment, the thickest active zone (3.1 m) is measured at the highest elevation thermistor, MW14-04T, within the footprint of the Supremo pit (Figure 1-2) and along a road cut. MW15-03T, the lowest elevation thermistor in Halfway Creek, appears to be on the fringe of permafrost coverage. The upper 1.2 m appears seasonally active, but the thermistors between 1.9 m and 4.9 m register above zero temperatures essentially all year. While the presence of permafrost at this station is not identified in the temperature record, drilling observations of ice in the rock cuttings suggest that it does intercept permafrost. In this drainage, the active layer becomes active any time between March and August and stays unfrozen between September and December. The timing and duration of the active zone is highly variable between 2016 and 2018.

In YT-24, both the highest elevation (MW15-07T) and lowest elevation (MW15-01T) instruments intercept the active zone which becomes active between May and July and remains active through October to December. SRK-15D-07T, at an intermediate elevation, remained perennially frozen.

The active zone in Latte Creek becomes active between April and July and remains active through October to December. The period of active flow is relatively consistent between 2016 and 2018. Thermistors completed in lower portions of the Latte Creek tributary (MW15-02T, SRK15D-09T) indicate this area is permafrost free.

4.2 Hydraulic Testing

Sixty successful measurements of bedrock hydraulic conductivity (K) have been collected during field programs executed between 2013 and 2017. Testing results from unfrozen bedrock are shown in Table 4-3. Most measurements were acquired through packer testing, but airlift yield recovery tests and slug tests were also performed. Slug tests were performed on two overburden wells (MW15-03AZ and MW15-02AZ), however, the tests recovered so quickly (*i.e.,* within seconds) that they could not be interpreted.

Bedrock K values are plotted versus vertical depth below ground surface in Figure 4-6 and are color coded according to lithology. Ranges in bedrock K values for different depth intervals are also shown in a box and whisker plot in Figure 4-7 with median values summarized in Table 4-4. The hydraulic conductivity data range over several orders of magnitude with values exceeding 1E-06 m/s and others below the resolution of the testing method (red italicized numbers in Table 4-3). A broad range in K values is typical of a fractured bedrock system (Golder, 2010). A regression line though the data points (Figure 4-6) indicates a broad trend of decreasing hydraulic conductivity with depth.

Median K values decrease by an order of magnitude or more below 150 m depth and again below 250 m depth (Figure 4-7, Table 4-4).

Rock type does not appear to play a large control on hydraulic properties (Figure 4-6). Rather, structural features, which crosscut all lithologies, impart the dominant control on hydraulic conductivity. Hydraulic tests performed on pit structures (SRK, 2015), along valley traces and in the currently proposed HLF footprint (MW16-01T/WB) have been grouped together as 'structures' in Table 4-4 and Figure 4-6 and Figure 4-7. Some of these test results comprise the cluster of the higher hydraulic conductivity values between 150 m and 300 m depth (Figure 4-6). While not mapped as such, the YT-24 and Halfway Creek drainages are inferred to coincide with fault structures. Reverse circulation drillholes advanced below permafrost in these drainages returned airlift yields on the order of 30 US GPM (~1.9 L/s). Latte Creek coincides with the mapped Coffee Creek Fault.

The two boreholes advanced near the proposed HLF (MW16-01T and MW16-01WB) happened to intercept a previously identified NNW-SSE trending magnetic anomaly. Ground conditions and the hydraulic response of this feature (K values exceeding 5E-7 m/s) suggest that this is a fault structure. The median K of structures is 2E-07 m/s with tests ranging up to 275 m depth. This K value is one to two orders of magnitude higher than other bedrock tests over the same depth interval (Figure 4-7, Table 4-4).

Tetra Tech (2017) conducted packer tests on shallow, frozen bedrock in the Halfway Creek to determine foundation conditions in a proposed sediment pond location (Table 4-5). Nine out of thirteen tests had no discernible flow and were assigned maximum values based on the resolution of the test. The median K value estimated for shallow, frozen bedrock is 2E-08 m/s (Figure 4-7, Table 4-4).

Table 4-3:
Hydraulic testing results for the Coffee Gold project (unfrozen bedrock).

4.3 Water Levels and Gradients

4.3.1 Overview

A summary of groundwater level monitoring at the Coffee Gold site is provided in Table 4-6. Groundwater level monitoring started in the fall of 2013 with the inception of the VWPs installed by EBA TT. Readings from these installations were collected sporadically until dedicated, continuously recording dataloggers were connected in the fall of 2014. Conventional monitoring wells installed by Lorax in the summer/fall of 2014 were equipped with Solinst Leveloggers. Any instrument nest equipped with a VWP from 2014 onwards has also been hardwired to a datalogger. A continuous water level record is available from most instruments on site from June 2015 onwards.

Bedrock water levels measured in June 2018 are presented in Figure 4-8. Table 4-6 summarizes magnitude of seasonal water level fluctuations between 2015 and 2019. Vertical hydraulic gradients measured at conventional wells pairs and nested VWP sensors are summarized in Table 4-7 and plotted in Figure 4-9. Horizontal hydraulic gradients measured between installations are summarized in Table 4-8. Groundwater level time series from 2015 through August 2019 are presented in Figure 4-10 to Figure 4-15 for instruments with continuously recording dataloggers. Point water level measurements collected at Westbay instruments are presented in Appendix 4-D.

Water levels are highly variable across the site with the deepest water levels (from 130 to over 220 metres below ground surface) measured in ridge areas and flowing artesian conditions often measured in the drainages. However, the presence of permafrost and faults/structures can create unexpected hydrogeological conditions. For instance, artesian water levels are measured near the height of land in the Halfway Creek drainage while downward hydraulic gradients are observed near Latte Creek.

The transient water level data show distinct responses to seasonal recharge. The first type is a broad sinusoidal response to seasonal recharge with a single water level maximum per annum. The maxima appear as smooth to slightly sharp peaks in the hydrograph record. Seasonal maxima and minima may vary annually in both magnitude and timing on account of the variable climate. As discussed in Section 2.1, it is inferred that more precipitation was available to recharge the groundwater system in 2013, 2015 and 2018 while 2014 and 2017 are considered drier years. As expected, higher seasonal maxima are experienced in wetter years. This type of response is more frequently observed in the Coffee groundwater record as compared to the second type of transient water level response.

Notes:
m asl = metres above sea level, m bgs = metres below ground surface, m = metres; NR = no reading; na = not applicable; '-' = instrument not installed
1. MW = monitoring well; OW = overburden well; WB = Westbay system; T/VWP = thermistor/vibrating wire piezometer
2. Westbay system port number, not all ports are presented.
3. Period of record as indicated with the following additional notes: (a) Sporadic measurements beginning in September 2014, semi-continuous readings beginning June 2015; (b) Between Feb 2015 and June 2015 semi-continuous readings were not recorded; (c) Manual measurements collected 4-times annually; (d) After April 2017 semi-continuous readings are sporadic; (e) Between mid-Nov 2017 and early-May 2018 semi-continuous readings were not recorded; (f) Manual measurements beginning August 2013; semi-continuous readings beginning September 2014; (g) Manual measurements beginning October 2013; semi-continuous readings beginning October 2014.
4. Monitoring depth represents sand pack midpoint for conventional monitoring wells, zone midpoint for Westbay system installation, vertical depth below ground surface for VWP sensor.
5. Negative (-ve) water level readings indicate pressure reading above ground surface elevation (artesian conditions).
6. Calculated annual water level fluctuation. Values denoted with ** may not capture full magnitude of changes.
7. Sinusoidal – one maximum per year, generally smooth hydrograph, flashy – responsive to short term rainfall events.

Table 4-7:
Maximum and minumum vertical hydraulic gradients measured at selected installations across the Coffee Gold Project.

Notes:
m asl = metres above sea level; m bgs = metres below ground surface; m = metres
1. Monitoring point depth indicates the VWP sensor depth in vertical metres below ground surface, the Westbay port depth, or conventional monitoring well screen midpoint, as applicable.
2. Positive values indicate downward gradient, negative values indicate upward gradient.
3. The minimum and maximum vertical gradient is calculated from the data record following water level stabilization after MW or datalogger installation through August 2019.
4. Slow recovery after sampling at MW14-05B precludes calculation of minimum vertical gradients.
5. MW14-02A typically demonstrates artesian conditions between late summer (Aug/Sept) and early winter (Dec). Gradient calculation during this period is not representative.

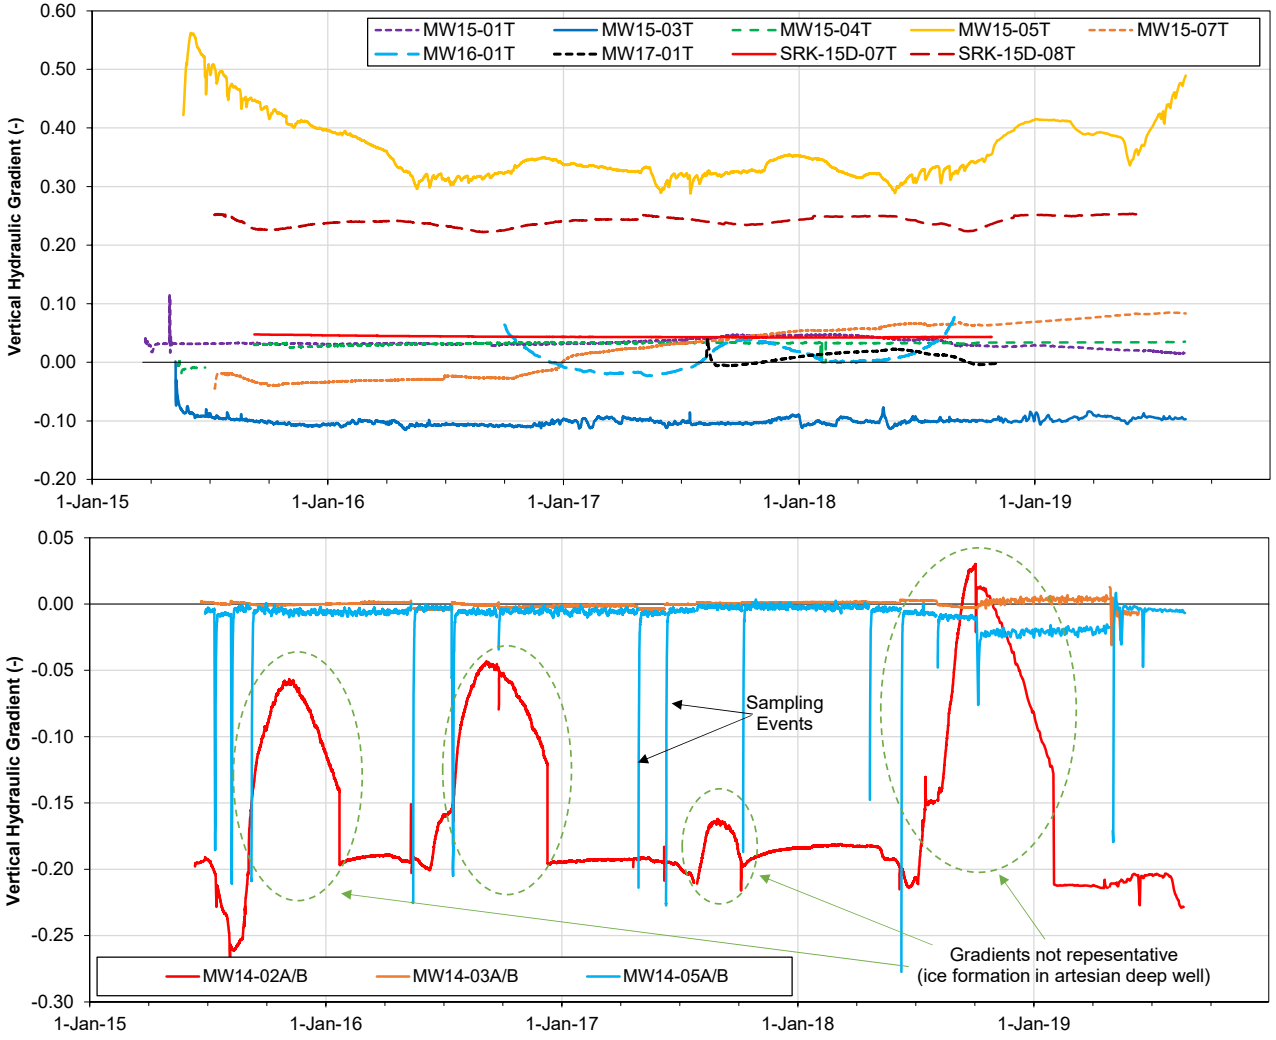

Figure 4-9: Vertical gradient time series for VWPs (upper pane) and conventional monitoring wells (bottom pane). Downward gradients are positive.

Notes:
1. Where two or more monitoring depth intervals are available at an installation, the measurement from the shallower installation is used to calculate the gradient.
2. The minimum and maximum gradient for each well pair is selected from the calculated hydraulic gradient between the locations using a daily average water level value from all days in the data record when both locations had at least one recorded water level reading.

The second type of transient water level response observed is flashier and tracks more closely with the surface water signature. Hydrograph maxima may occur more that once annually, coinciding with a freshet peak with late summer rainfall feeding a second maximum. This type groundwater level response is registered at selected wells completed near creek channels.

Some transient water level responses do not fit either type described above – they may remain flat, continuously climb or represent a hybrid of the two response types. These are discussed on a case by case basis in the discussion of the individual catchments below.

4.3.2 Halfway Creek

There are several installations located within the Halfway Creek catchment (Figure 4-8). Water level time series for higher elevations stations (MW14-05A/B, MW17-01T, MW16-01T and MW14-03A/B) are shown in Figure 4-10 while lower elevation installations (SRK15D-08AT, MW15-04T, MW15-03T) are shown in Figure 4-11. Measured discharge at hydrometric station HC-6.8 (HC-2.5) is shown for comparison. Note that hydrometric and surface water quality monitoring stations underwent a name change in 2019. Current station names are referenced, followed by the former station name in parentheses.

A combination of water level responses is displayed at stations near the proposed Kona pit (MW14-05A/B, MW17-01T) and HLF footprint (MW16-01T) (Figure 4-10). Water levels at MW14-05A/B track closely together and have continuously climbed between 2015 and 2019, gaining several meters over this period. A very subdued seasonal fluctuation is observed in the trend, but annual minima and maxima are difficult to extract given the overwhelming increasing trend. Vertical gradients are minimal.

MW17-01T is ~200 m north of MW14-05A/B and was established to confirm depth of permafrost in this area. The early part of the data record appears influenced by drilling, but a seasonal pattern emerges whereby minima occur in the late spring and maxima occur in the fall. Vertical gradients at MW17-01T are also small, ranging between slightly upward (<1%) to downward (~4%). Maximum water levels are 125 m bgs and 110 m bgs at MW14-05A/B and MW17-01T, respectively. The water level at MW17-01T is several meters below the base of permafrost.

MW16-01T is about 1.5 km southeast of MW17-0T and is located essentially along contour. Surprisingly, artesian water levels were encountered at this instrument. The installation crosses a suspected fault in the area and groundwater pressures are confined by 60 m of permafrost. The resulting water level data trend falls into the first type discussed previously (*i.e.,* broadly sinusoidal). The shallow sensor (97.5 m bgs) registers a larger seasonal fluctuation than the deeper sensor (131 m bgs) (Table 4-6). Despite artesian conditions, vertical gradients are frequently downwards between the two sensors (Figure 4-9).

Conventional monitoring wells MW14-03A/B also screen groundwater confined by permafrost. An ice lens observed in core while drilling MW14-03A/B suggests permafrost is present to at least 62 metres depth; however, it does not appear to extend to the saturated zone as the wells remain unfrozen (water levels are ~130 metres below ground surface). The shallow and deep monitoring wells report minimal vertical hydraulic gradients. The hydrographs are of the broad sinusoidal type, with annual maxima occurring in November/ December, while minima occur in the summer. Variations in annual recharge are reflected by the hydrographs, with the smallest annual fluctuation (<1.5 m) occurring in 2017 and the largest (>6 m) occurring in 2018 (Table 4-6).

SRK-15D-08AT is located at high elevation near the trace of the Halfway Creek channel (Figure 4-8). Strong artesian pressures of several meters above ground surface have registered at the shallow sensor (104 m bgs) while the deeper sensor (149 m bgs) is seasonally artesian. The hydraulic gradient is strongly and consistently downward (~22% to 25%) throughout the year. This may suggest that a permeable feature is under-draining the area. This area is confined by 60 to 80 meters of permafrost. The groundwater level hydrographs are of the broad sinusoidal type, with annual minima and maxima occurring consistently in the spring and fall, respectively.

MW15-04T, located near surface water station HC-6.8 (HC-2.5), has a flashy groundwater level hydrograph that more rapidly responds to recharge events (Figure 4-11). Annual minima occur in the winter while one to two annual maxima occur in conjunction with freshet and/or summer rainfall. This location is confined by ~ 30 m of permafrost and groundwater levels are largely artesian throughout the data record. Resting flow rates measured at the Westbay hole advanced from the same drill pad were on the order of 30 to 40 US GPM (1.9 L/s to 2.5 L/s). Groundwater levels measured by the shallow (38.8 m bgs) and deep (51.6 m bgs) sensors track closely together. Hydraulic gradients measured between the two sensors are consistent and slightly downward (<5%).

MW15-03T is the lowest elevation groundwater station in Halfway Creek (Figure 4-8) and is inferred to be on the fringe of permafrost coverage. A lineament, inferred to be a fault, cross-sects Halfway Creek in this area. Groundwater level and groundwater quality data (Section 5) indicate that MW15-03T intersects a hydrogeologically distinct area. Unlike the two instruments further upstream (MW15-04T, SRK15D-08AT), there is a strong upward hydraulic gradient (10%) between the VWP sensors at 94.7 m bgs and 48.8 m bgs. The deeper sensor measures artesian pressures, while the shallow sensor is seasonally artesian. The water level measured in the shallow overburden well (MW15-03AZ) is lower than that measured in bedrock. The water levels at MW15-03T/AZ track differently than MW15-04T, annual maxima occur during the winter with a short and muted response to freshet and summer rainfall.

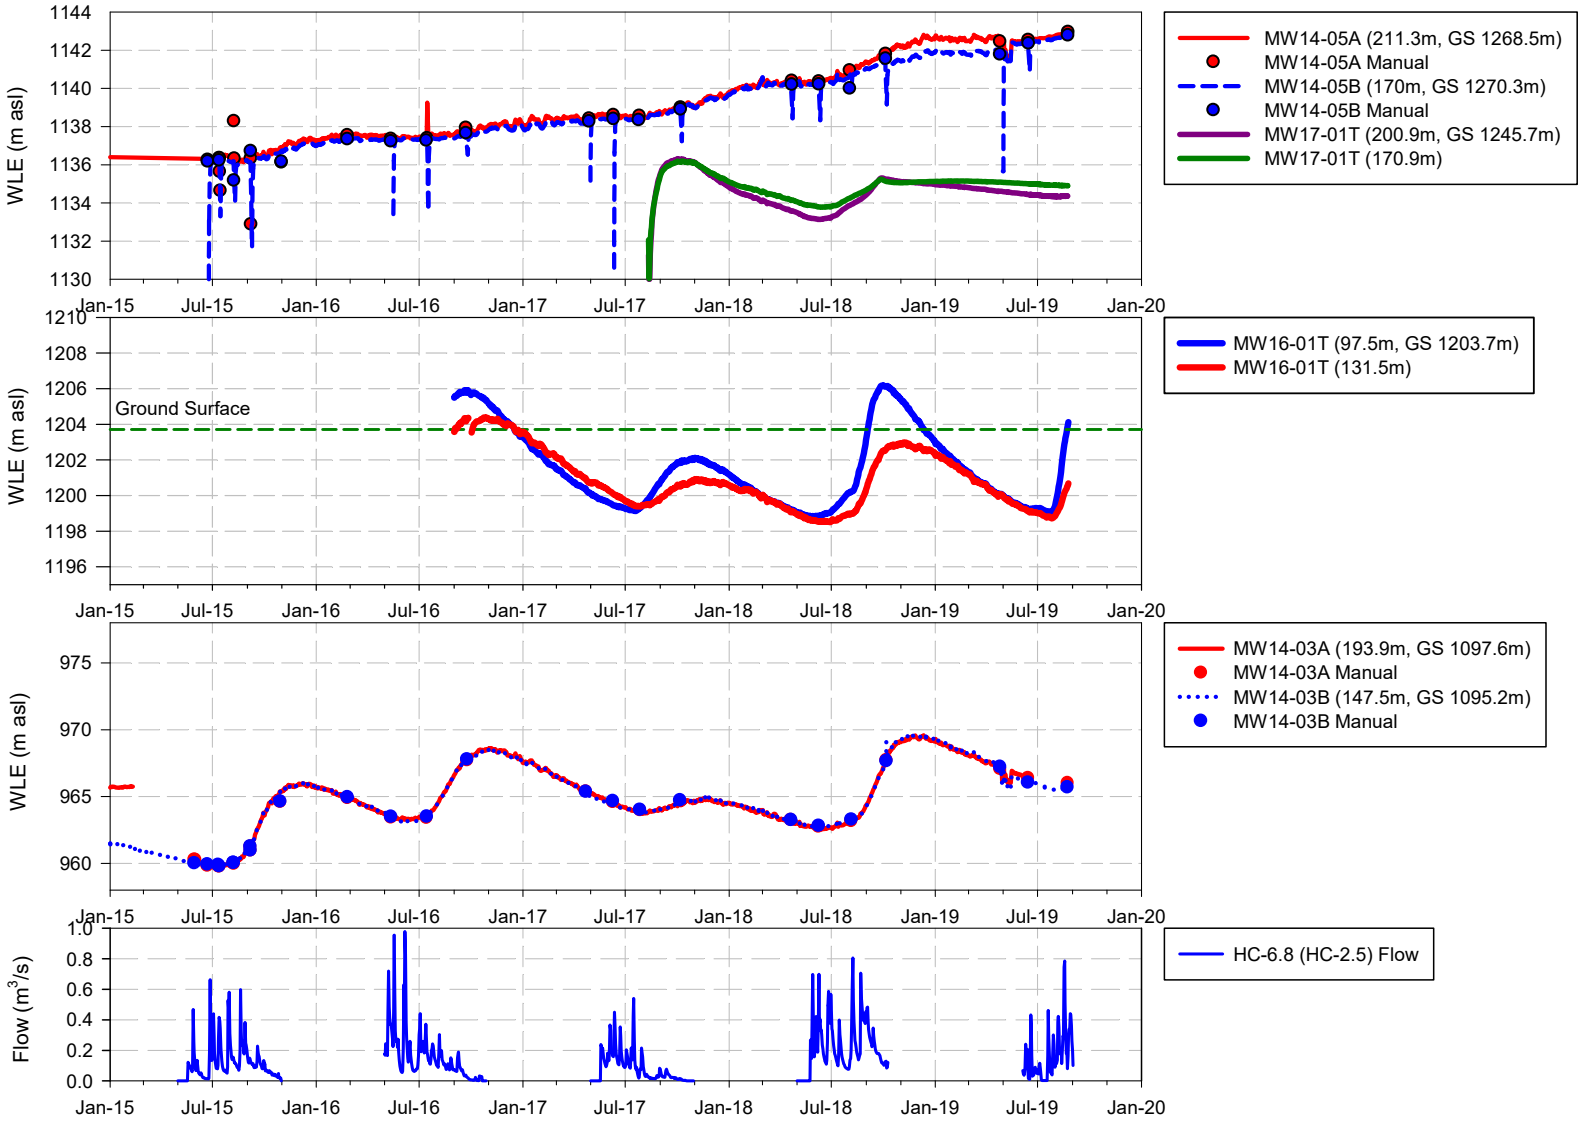

Figure 4-10: Groundwater level hydrographs measured in Halfway Creek catchment at MW14-05A/B, MW17-01T, MW16-01T and MW14-03A/B.

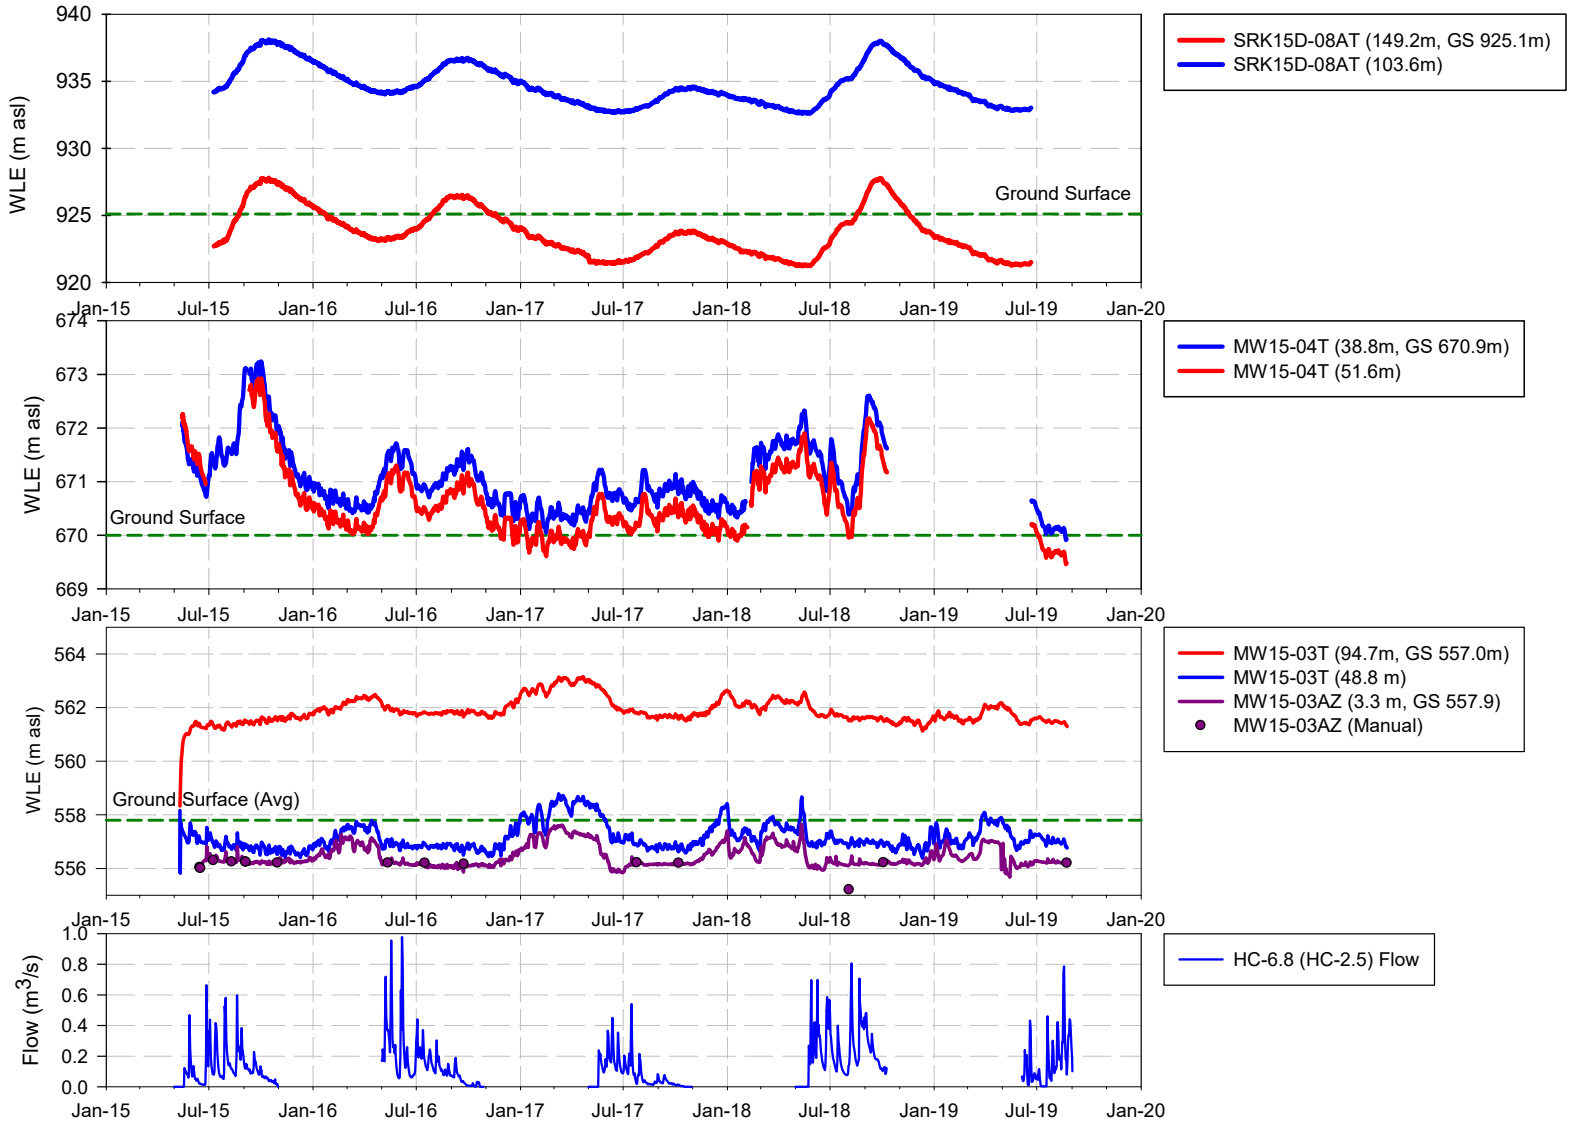

Figure 4-11: Groundwater level hydrographs measured in Halfway Creek catchment at SRK-15D-08AT, MW15-04T, MW15-03T/AZ.

MW15-06WB is a standalone, high elevation installation at the north end of the proposed Supremo pit complex that characterizes groundwater draining north and northwest towards Halfway Creek. Time series of water level point measurements from this installation are shown in Figure 4-12. This area has the deepest water levels (>215 m bgs) on site. Bedrock ~252 metres below ground surface appears to be draining more readily, as vertical hydraulic gradients are towards this zone (65% downward from an upper port at 241 m, and 15% upward from a lower port at 287 m). The shallowest water level measured at this location is nearly 50 m below the base of permafrost which is inferred to be ~170 m thick based on the thermal profile measured at MW14-04T.

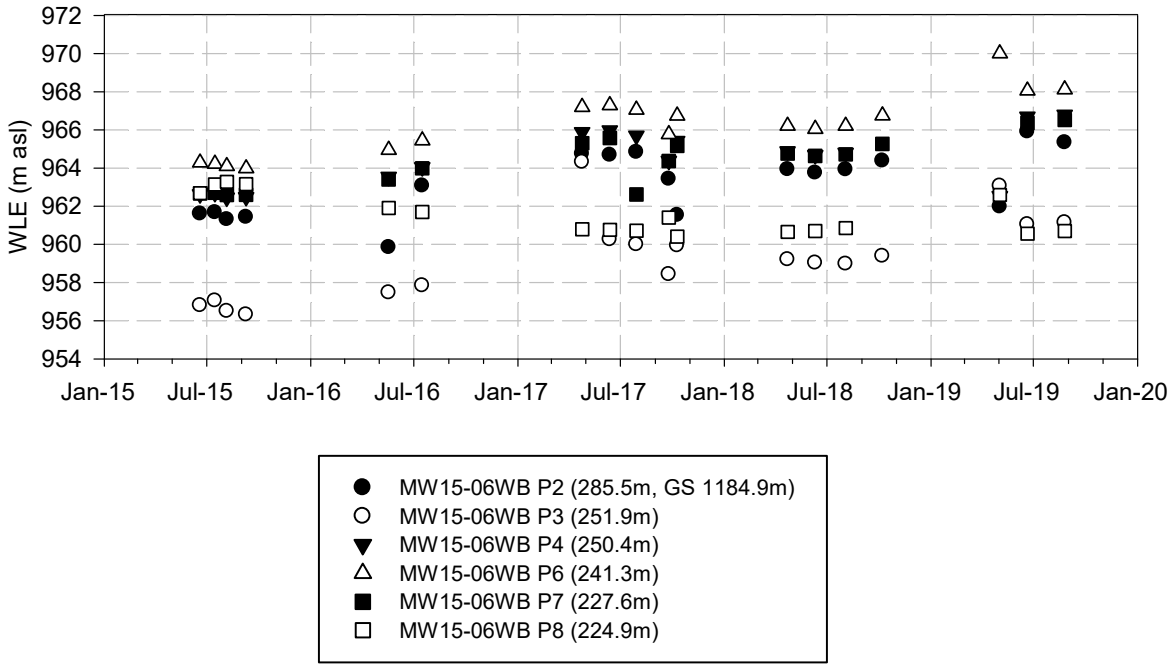

Figure 4-12: Point measurements of water levels measured at MW15-06WB.

4.3.3 YT-24

Groundwater level data from three VWP installations along the YT-24 drainage is presented in Figure 4-13. Measured discharge at hydrometric station YT24-0.1 (formerly YT-24) is shown for comparison. Thermal data collected from these instruments indicates that groundwater is confined by permafrost in this drainage, with higher confining pressures experienced farther downstream. The groundwater level hydrographs are distinct at each of the installations.

The installation at MW15-07T, at the headwaters of YT-24, has two deep water level sensors at 239 m bgs and 267.8 m bgs. Permafrost depth is between 140 to 150 m and

confines water levels that range between 120 m bgs and 138 m bgs. The water level hydrographs are broadly sinusoidal, with annual maxima occurring in November or December and annual minima occurring in June or July. Upward hydraulic gradients (<5%) were measured at this station prior to 2017 but have remained consistently downward since then. The hydrograph clearly demonstrates the below average recharge in 2017.

SRK-15D-07T is located less than one kilometre downstream from MW15-07T. The data from this installation are suspicious as no seasonal fluctuation is reported; however, the magnitude of computed water levels is reasonable. Water levels are 50 to 60 m bgs and are confined by permafrost, which extends to ~85 m bgs.

MW15-01T is located about one kilometre downstream from SRK-15D-07T. Similar to the other installations in this drainage, water levels are confined by permafrost. Permafrost extends to 70 m depth while water levels at their deepest were 36 m bgs. Since inception of the instrument, water levels have steadily increased whilst showing a seasonal variation. Annual maxima occur in the fall while minima occur in the spring. Recharge in 2018 caused the most pronounce fluctuation in water levels (>5 m). Vertical hydraulic gradients are consistently and modestly downwards (~1%). The active zone well completed near this installation, MW15-01AZ, intercepted water at some point in June/July 2015, which froze the logger in place. Unfrozen water was not observed in the well during subsequent visits.

4.3.4 Latte Creek Tributary

The Latte Creek Tributary drainage is instrumented in its upper reaches with a conventional monitoring well pair (MW14-02A/B) on the north fork and VWP CFD0351 on the west fork. Both locations demonstrate a strong response to seasonal recharge (Figure 4-14). Seasonal water level fluctuations measured at CFD0351 have exceeded 30 metres and are the largest recorded across the site (Figure 4-13, Table 4-6). The water level hydrograph is broadly sinusoidal with seasonal maxima occurring in September or October. CFD0351 is not equipped with a thermistor string and permafrost conditions are not constrained. The current permafrost map has it located on the margin, but outside of permafrost coverage (Figure 4-5). Water levels at the single VWP sensor range from 111 m bgs to 153.5 m bgs.

Groundwater is confined by a lens of permafrost at conventional well pair MW14-02A/B (Figure 4-5). While no thermistor data is available for this location, a plug of ice typically forms in the wells over winter which has estimated thickness of >30 metres. Groundwater levels in the deeper “A” well (190 m bgs) are flowing artesian in the summer/fall until the well freezes in over the winter. Hydrograph minima occur in the spring. Groundwater levels in the shallower “B” well (148 m bgs) approach ground surface but are not flowing artesian (with exception to the fall of 2018). The full magnitude of seasonal water level fluctuations is captured for the shallow well and ranges between 5 m and 19 m over the

last few years, with the smallest annual fluctuation occurring in 2017. Vertical hydraulic gradients are strongly upward (>20%) for representative portions of the hydrograph record.

CFD0324 is located downgradient of CFD0351 and MW14-02A/B. The water level hydrograph at this VWP is broadly sinusoidal and subdued compared to water level records of the upgradient stations. Seasonal fluctuations at this VWP are on the order of five metres with annual maxima occurring in September or October. A similar water level record is observed at SRK-15D-09T, located about 1.1 km south of CFD0324 along the trace of the Latte Creek Tributary.

4.3.5 Latte Creek

There are three hydrogeological installations along Latte Creek (Figure 4-8). The highest elevation station, MW14-07T, was established in September 2014. The thermistor string installed in this hole indicates a permafrost depth of approximately 60 metres. The water level recorded at the single VWP is flowing artesian and consistently several metres above ground (Figure 4-15). While there have been interruptions in data collection at this station, the record indicates that annual maxima occur in the early fall.

MW15-05T is located ~600 metres downgradient of MW14-07T. Groundwater at MW15-05T is confined by ~47 m of permafrost, with water levels at the two sensors ranging from 20 m to 40 m bgs. The hydrographs are similar between the shallow (55 m) and deep (81 m) sensors, but the deeper sensor has a slightly noisier *(i.e.,* more responsive) signal. Water levels at both sensors climb in unison in late spring and remain high through early/mid fall. Some minor flashiness arises from summer rainfall. Annual minima occur in the winter. The vertical hydraulic gradient is consistently and strongly downward (~30%) which suggests that a fault is under-draining groundwater. This 'under-draining' also produces a horizontal hydraulic gradient between MW14-07T and MW15-05T that exceeds the topographic gradient (~19% versus 14%) (Table 4-8).

MW15-02T is located at the confluence of Latte Creek Tributary with Latte Creek and is the lowest elevation groundwater installation in Latte Creek catchment. The area is devoid of permafrost. The groundwater hydrograph recorded by the single VWP sensor at MW15-02T shows little if any seasonal fluctuations. Groundwater pressure measured at the adjacent Westbay installation (MW15-02WB, Appendix 4D) indicate an upward gradient in very shallow bedrock (between 9 and 14 m bgs), while a strong downward gradient (~24%) is measured across deeper bedrock (32 and 61 m bgs). The downward gradient in deeper bedrock may suggest a hydraulically significant feature at depth under-draining the area, consistent with observations at MW15-05T. The horizontal hydraulic gradient between SRK-15D-09T and MW15-02T slightly exceeds the average topographic gradient (10%) along the Latte Tributary, while the gradient between MW15-05T and MW15-02T is consistent with topography along Latte Creek (Table 4-8).

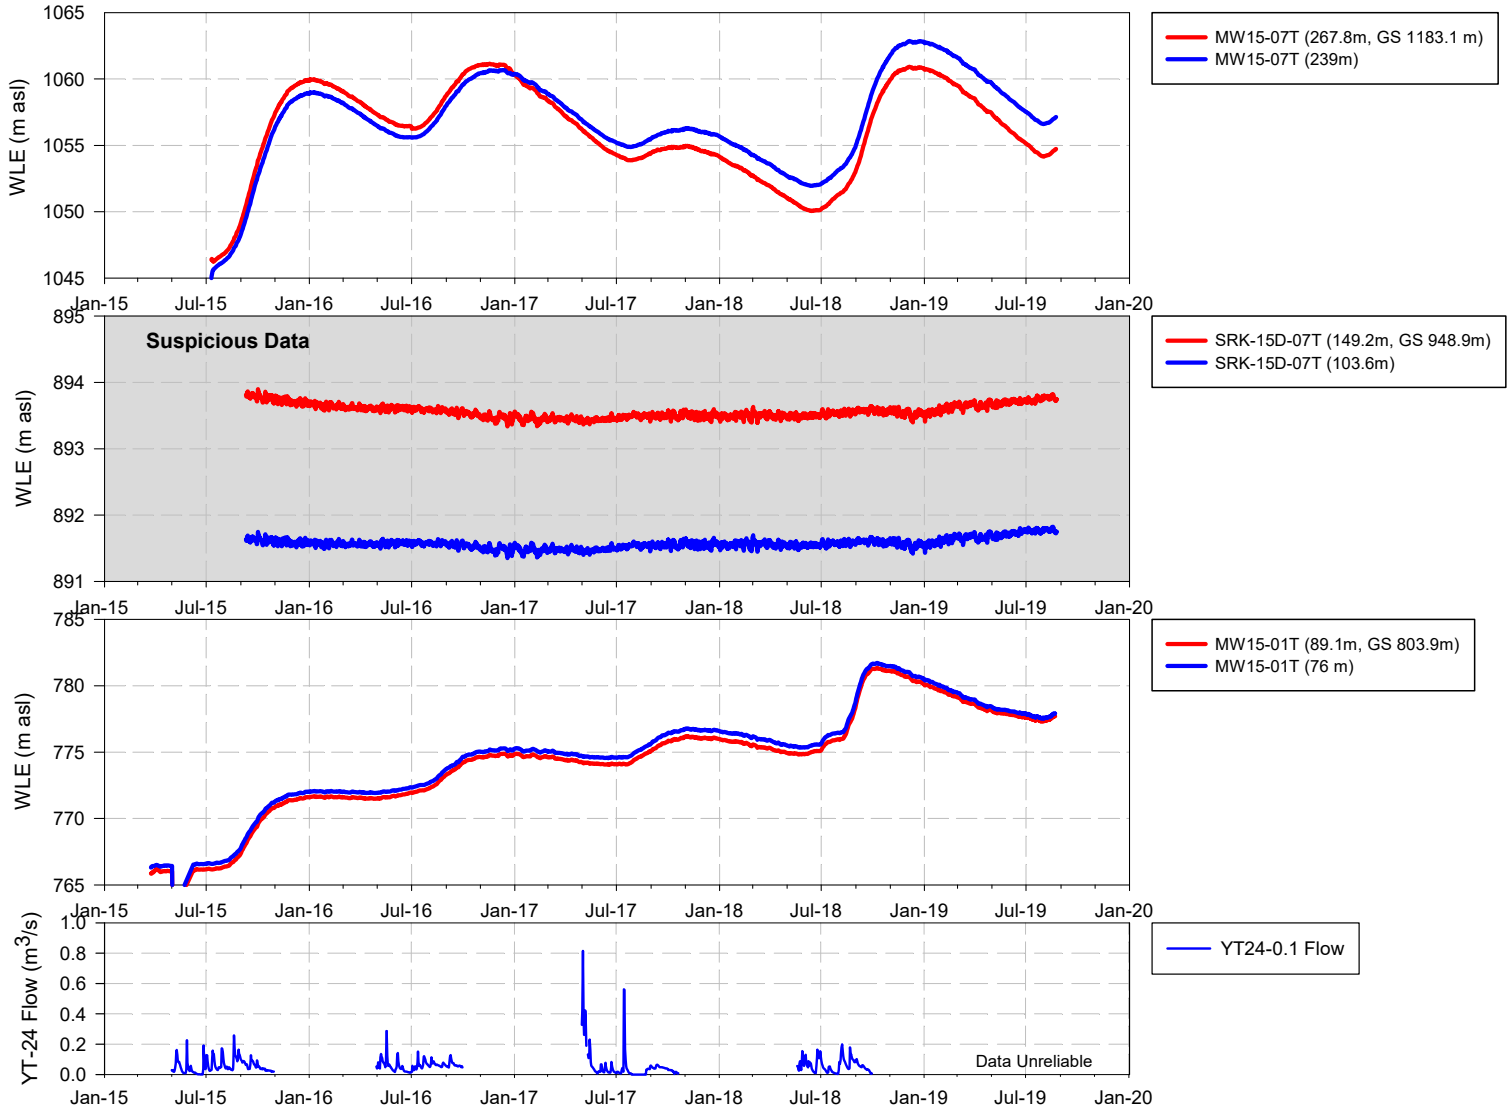

Figure 4-13: Groundwater level hydrographs measured in YT-24 catchment at MW15-07T, SRK-15D-07T and MW15-01T.

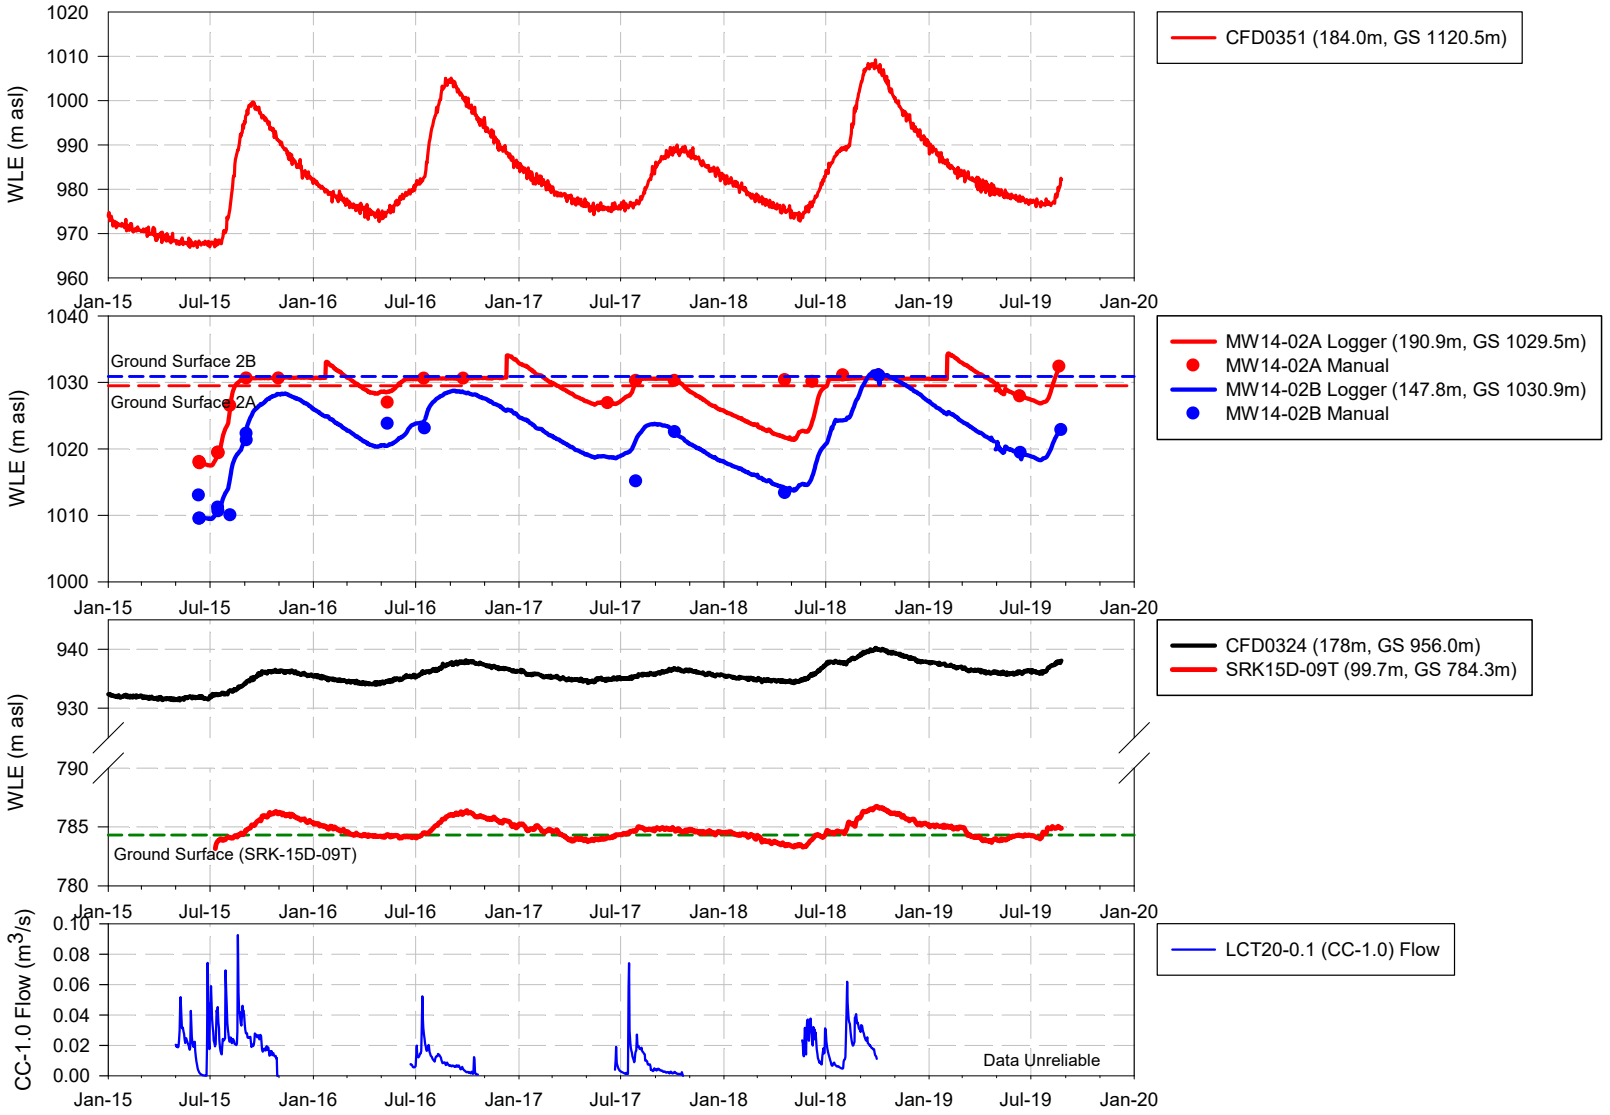

Figure 4-14: Groundwater level hydrographs measured in Latte Creek tributary drainage at CFD0351, MW14-02A/B, CFD0324 and SRK15D-09T.

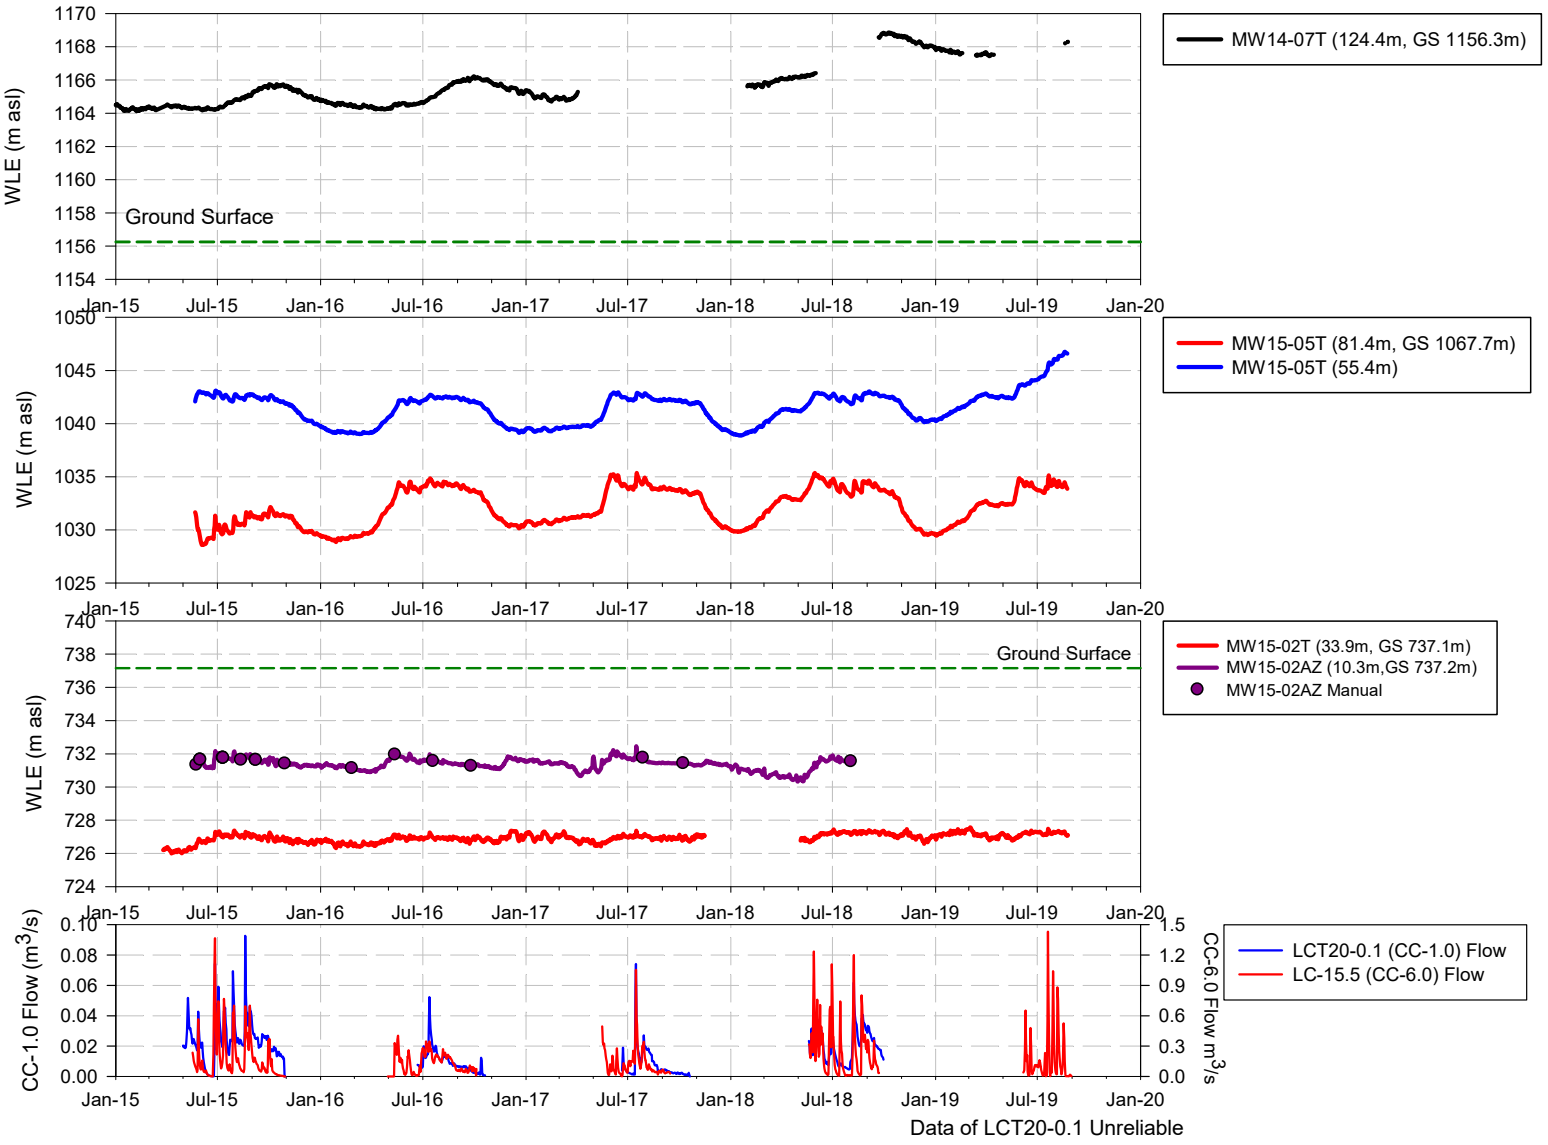

Figure 4-15: Groundwater level hydrographs measured in Latte Creek catchment at MW14-07T, MW15-05T and MW15-02T/AZ.

The shallow well installed adjacent to MW15-02T, MW15-02AZ, screens several metres of a cobbly/bouldery package of colluvial sediments classified by AECOM (2012) as a poorly drained apron of colluvial complex (xzsC1a:p). The water level at this monitoring well is within a few meters of ground surface and experiences annual maxima in the summer and minima in the spring.

4.4 Baseflow

Baseflow represents the portion of streamflow that is derived from groundwater discharge. While baseflow occurs throughout the year, it is typically most easily characterized during the winter low flow period, when runoff and interflow (shallow subsurface flow) are at their minimum. In the case of the groundwater system at the Coffee Gold Project, interflow also encompasses active zone flow.

Characterization of the baseflow regime at the Project presents numerous challenges. Accurate measurement of winter streamflow is challenging in drainages at the site on account of extensive icing that forms in local channels over the winter months. This icing, sometimes termed aufeis, is the result of shallow groundwater discharge and/or baseflow in the stream channel freezing. This ice impedes subsequent flow, which is forced on top of the existing ice cover, where it freezes. This process repeats continuously throughout the winter, and results in laminated ice layers that have been measured close to 1.5 m in thickness and greater than 50 m in width in channels at the Project. Liquid flow is thus either not present, or occurs between these laminae, and at the edges of the stream channel. It is these flows that are measured during the winter. Aufeis also acts as a storage reservoir for winter baseflows and can store up to a third of the cumulative annual baseflow in sub-Arctic watersheds (Yoshikawa et al., 2007). This stored baseflow is released during the freshet and early summer period.

Based on site data alone, winter low flows are expected to range from 0 to 0.7 L/s/km^2 (Lorax, 2019). Low flow conditions can occur intermittently during the summer and early autumn across the Project site, with unit yields during early summer often approaching those measured during the winter months. Low flows measured in June 2015 at valley bottom stations (~1 L/s/km^2) formed a critical input to the site-wide groundwater model calibration (Lorax, 2016).

5. Groundwater Quality Results

Newmont™
COFFEE

5. Groundwater Quality Results

Groundwater quality in the Project area is discussed in terms of major ion chemistry with reference to physical parameters (field pH, field SC) followed by oxidation-reduction (redox) conditions and trace element geochemistry. In addition, groundwater characterization by use of isotopic analyses of hydrogen, oxygen and carbon is presented. Where analytical results are reported as non-detectable, the reportable detection limit (RDL) values are conservatively used for graphing purposes. The groundwater quality is discussed in relation to the principal lithology at the screened interval of each monitoring well: overburden, gneiss, granite, breccia and schist (Figure 2-2, Table 3-2, Table 3-3). Borehole and well completion logs can be referenced in Appendix 3-A. Groundwater quality data is tabulated in Appendix 5-A, with a statistical summary of the data (count, minimum, mean, median, maximum and the number of analyses below the RDL) provided in Appendix 5-B. The laboratory certificates of analysis for samples collected by Lorax between 2016 and 2019 are included in Appendix 5-C. The laboratory certificates of analysis for groundwater samples collected by Lorax between 2014 and 2015 are included in Lorax (2017c).

A quality assurance/quality control (QA/QC) assessment was performed on the 2016 to 2019 groundwater quality data set and is provided in Appendix 5-D. As described in Lorax (2017c), several samples were deemed to have been influenced by artifacts of drilling and monitoring well installation: MW14-03A, MW14-03B, MW14-05A, and MW14-05B in October 2014, and MW15-06WB in June 2015. All four samples collected at MW14-05B in 2015 (June, July, August, September) were deemed to have been influenced by artifacts of drilling and well installation based on the examination of 2016 to 2019 groundwater quality data (Appendix 5-D). As a result, water quality data for these samples is not considered to be representative of formation groundwater and has been omitted from the discussion below. Outside of the issues listed above, the QA/QC analysis indicates a robust groundwater quality dataset has been collected and is suitable for interpretation.

Time series plots of field-measured physical parameters, and concentrations of major cations and anions, redox-sensitive parameters, and trace elements are presented in Appendix 5-E. When plotted, the lowest RDL is shown for reference.

The results of groundwater, surface water, and aufeis stable isotope and radioisotope analyses in the Project area are summarized and discussed in this report. The isotope data is tabulated, and a detailed analysis and discussion of the groundwater isotopic data is provided in Appendix 5-F.

5.1 Major Ions

The relationship of major ion charge equivalents in the Project groundwater is presented in a tri-linear Piper plot (Figure 5-1) which identifies wells of similar screened lithology by colour. Time

series plots of field-measured physical parameters grouped by lithology are presented in separate figures in Appendix 5-E (Figure 5-E-1 to Figure 5-E-4). Absolute concentrations of major cations (Ca, Mg, Na, K) and major anions (HCO_3, SO_4, Cl) are similarly plotted in Appendix 5-E (Figure 5-E-5 to Figure 5-E-8 and Figure 5-E-9 to Figure 5-E-12, respectively). Field-measured pH and SC are referenced and discussed with major ion chemistry. Field-measured DO and ORP, as well as sulphide (S^{2-}), included on the time-series plots with major anions, are discussed with redox geochemistry in Section 5.2.

Major ion concentrations, in addition to field-pH and field-SC measurements from the most recent groundwater sampling events are tabulated in Table 5-1, with the highest concentration for each parameter across the Project area highlighted yellow. Parameters that display trends (*i.e.*, increasing or decreasing concentrations) are flagged in Table 5-1.

Groundwater at the Project is predominantly circum-neutral (pH 6 to 8), with most samples characterized by pH 6.5 to 8 (Appendix 5-E). Groundwater wells show variable influence from weathering of sulphide minerals and/or dissolution of sulphate minerals, either from the deposits or other disseminated mineralization across the Project area. This is evidenced by low to substantial sulphate (SO_4) concentrations which range from 7 to 1120 mg/L and variable salinity with field-SC ranging from 28 to 2390 µS/cm (Appendix 5-E).

5.1.1 Overburden

Groundwater in overburden wells (orange symbols in Figure 5-1) is calcium-bicarbonate-type (Ca-HCO_3), irrespective of the type of deposit screened (colluvium, colluvium/bedrock interface). MW15-02AZ and MW15-03AZ have similar proportions of dissolved calcium (Ca), magnesium (Mg) and sodium (Na), with the spread in the data points largely reflecting variable sulphate (SO_4) content. As a result, the groundwater at MW15-02AZ is classified as Ca-HCO_3-type with significant SO_4 influence, while that at MW15-03AZ is Ca-HCO_3-type. Calcium is the dominant cation in the overburden groundwater, which, along with significantly lower major ion concentrations and specific conductance at MW15-03AZ (128 to 322 µS/cm) relative to MW15-02AZ (437 to 874 µS/cm) suggests that groundwater in the shallow overburden at MW15-03AZ is fresher. Groundwater pH is predominantly circum-neutral at MW15-02AZ (field pH 7.3 to 8.0) and MW15-03AZ (field pH 6.6 to 7.8, except 8.9 on Oct. 7, 2017).

A single groundwater sample was collected at MW15-05AZ (Sept. 2015), which is also classified as Ca-HCO_3-type. However, in contrast to groundwater at MW15-02AZ which has significant SO_4 influence (~41 to 49%) and MW15-03AZ with moderate SO_4 influence (~21 to 34%), the groundwater at MW15-05AZ is characterized by very low SO_4 content (~5%). In addition, the chloride (Cl) content in MW15-05AZ groundwater is elevated (~ 7%) in relation to other Project area groundwater which typically has Cl contents <1%. The field pH at MW15-05AZ is slightly acidic (pH 5.8) and the lowest measured in the Project area. Field measured specific conductance is also low (28 µS/cm) indicating very fresh water.

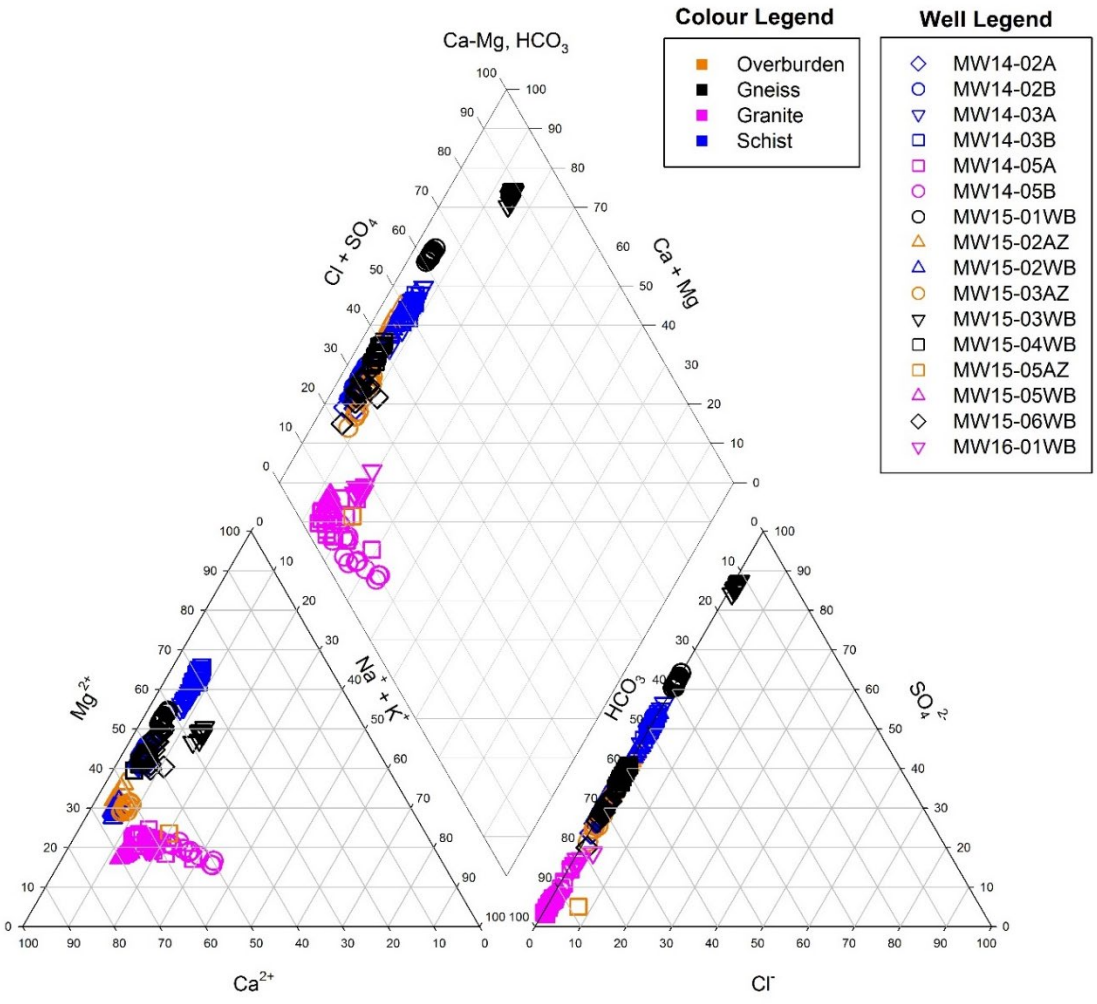

Figure 5-1: Piper Plot of Project Groundwater Quality Data (2014 - 2019).

5.1.2 Gneiss

Monitoring wells screened in gneiss are located on the north side of the Project area (black symbols in Figure 5-1). Groundwater sampled from these wells presents a wide range of hydrogeochemical compositions that range from Ca-HCO_3-type to mixed-magnesium-calcium-sodium-sulphate-type (Mg-Ca-Na-SO_4).

The groundwater compositions downstream from the proposed Supremo Pit at MW15-06WB and along Halfway Creek at MW15-04WB cluster on the Piper plot. Groundwater at MW15-06WB is predominantly mixed-magnesium-calcium-bicarbonate type (Mg-Ca-HCO_3), but ranges from Ca-HCO_3-type with significant Mg influence to magnesium-bicarbonate-type (Mg-HCO_3-type) with significant Ca influence, while groundwater at MW15-04WB is predominantly Ca-HCO_3-type with significant Mg. The groundwater at both wells has similar major ion proportions and concentrations, in addition to specific conductance which ranges from 474 to

762 µS/cm at MW15-06WB and 418 to 745 µS/cm at MW15-04WB. Field pH at these wells is typically circum-neutral, ranging from pH 7.2 to 8.2 at MW15-06WB and pH 5.5 to 8.3 at MW15-04WB.

The groundwater downstream from the proposed Supremo Pit at MW15-01WB along YT-24 and at MW15-03WB along Halfway Creek (downstream from MW15-04WB) is characterized by elevated SO_4, suggesting the oxidation of sulphide minerals. Groundwater at MW15-01WB is classified as magnesium-sulphate-type (Mg-SO_4) with significant Ca influence, while groundwater at MW15-03WB is predominantly Mg-Ca-Na-SO_4-type and represents an end-member composition in the Project area (Figure 5-1). Groundwater SO_4 concentrations and proportions at both wells are the greatest in the Project area, with higher values observed at MW15-03WB. In addition, Cl concentrations and proportions were consistently greatest at MW15-03WB. The groundwater at MW15-03WB and MW15-01WB is the most saline in the Project area, with elevated specific conductance values ranging from 1437 to 2080 µS/cm and 1156 to 2390 µS/cm, respectively. Field pH is predominantly circum-neutral at MW15-03WB (pH 7.0 to 8.3) and MW15-01WB (pH 6.1 to 7.9).

5.1.3 Granite

Monitoring wells screened in granite (pink symbols in Figure 5-1) are located in the proposed Kona Pit footprint (MW14-05A and MW14-05B), adjacent to the proposed HLF in the upper Halfway Creek catchment (MW16-01WB), and adjacent to Latte Creek downstream from the proposed HLF (MW15-05WB). Groundwater sampled from these wells is Ca-HCO_3-type.

The groundwater at MW15-05WB and MW16-01WB is Ca-HCO_3-type and is characterized by uniform compositions at each well. Both wells have similar major ion proportions, with comparable to slightly higher concentrations observed at MW15-05WB. Groundwater at both wells is fresh, with slightly higher field-measured specific conductance at MW15-05WB (162 to 402 µS/cm) compared to MW16-01WB (140 to 247 µS/cm). Field pH is predominantly circum-neutral at MW16-01WB (pH 5.9 to 7.4) and MW15-05WB (pH 5.5 to 8.1).

Monitoring wells MW14-05A and MW14-05B present among the most variable hydrogeochemical compositions in the Project area. Groundwater is Ca-HCO_3-type at both wells, with that at MW14-05B showing greater Na proportions and concentrations than at MW14-05A. Both wells present a shift to lower Na proportions and concentrations throughout the data record, with a greater decrease observed at MW14-05B. Groundwater at MW14-05B and MW14-05A has comparable salinity with specific conductance values of 359 to 519 µS/cm and 329 to 475 µS/cm, respectively; however, the data record shows opposing trends with field-SC increasing slightly at MW14-05A and decreasing slightly at MW14-05B. The field pH at both wells is typically circum-neutral with similar values at MW14-05A (pH 6.5 to 8.3) and MW14-05B (pH 6.7 to 7.5).

5.1.4 Schist

Monitoring wells screened in schist are distributed on the north and south sides of the Project in the vicinity and downstream from the proposed Latte Pit and southern Supremo pit area (dark blue symbols in Figure 5-1). MW14-03A and MW14-03B are upgradient and adjacent to the proposed Latte Pit on the north side of the Project. MW14-02A and MW14-02B are situated upgradient and within the proposed southern Supremo Pit area, while MW15-02WB is downgradient of the proposed Latte Pit and southern Supremo Pit area. Although MW14-02A is screened across hydrothermally altered rock (crackle breccia), it is mainly biotite schist and therefore has been grouped with wells screened in schist. Groundwater at these monitoring wells ranges from Ca-HCO_3 to Mg-SO_4-type.

Groundwater at both MW14-03A and MW14-03B is predominantly Mg-SO_4-type with significant HCO_3 influence, with three to four samples collected at each well classified as magnesium-bicarbonate-type (Mg-HCO_3) with significant SO_4 influence. The groundwater compositions at both wells are similar and cluster on the Piper plot, with a slightly greater range observed at MW14-03A due to more variable SO_4 proportions. Major ion concentrations at both wells are generally uniform and comparable. The groundwater at MW14-03B (1604 to 1884 µS/cm) is slightly more saline than at MW14-03A (1376 to 1700 µS/cm). Field pH is circum-neutral at both wells with values of pH 6.7 to 8.1 at MW14-03A and pH 6.9 to 7.5 at MW14-03B.

Monitoring well pair MW14-02B and MW14-02A is characterized by similar groundwater composition, with uniform major ion proportions and concentrations at each well. Groundwater composition at MW14-02B ranges from Ca-HCO_3-type with significant Mg influence to mixed-calcium-magnesium-bicarbonate-type (Ca-Mg-HCO_3), while that at MW14-02A is Ca-HCO_3-type with significant Mg influence. Field-measured specific conductance is relatively low at both wells, with more saline groundwater at MW14-02B (317 to 521 µS/cm) than at MW14-02A (204 to 400 µS/cm). Groundwater at both wells is circum-neutral, with wider range of field pH values observed at MW14-02A (pH 6.1 to 8.3) compared to MW14-02B (pH 7.2 to 8.0).

The hydrogeochemical composition of groundwater at MW15-02WB clusters with MW14-03A and MW14-03B on the Piper plot (Figure 5-1). MW15-02WB ranges from Ca-HCO_3-type water with significant SO_4 influence to calcium-sulphate-type (Ca-SO_4) water with significant HCO_3 influence. The spread in the groundwater composition reflects the variable SO_4 content. Groundwater at MW15-02WB has circum-neutral field pH (7.1 to 7.7) and is moderately saline with specific conductance values between 480 and 941 µS/cm.

5.2 Oxidation-Reduction Geochemistry

Redox conditions within a groundwater system can be assessed based on the presence and concentration of oxidized and reduced inorganic compounds in groundwater samples. Bacteria utilize oxidants (electron acceptors) in order of their energy yield as follows: dissolved oxygen (DO, O_2), nitrate (NO_3^{2-}), manganese (Mn^{4+})-oxides, ferric iron (Fe^{3+})-oxides, sulfate (SO_4^{2-}) and carbon dioxide (CO_2). Therefore, in the order of increasing reduced conditions, key indicators of suboxia can include:

- absence of O_2;
- removal of NO_3 and/or nitrite (NO_2) (associated with NO_3 reduction);
- elevated (>0.5 mg/L) concentrations of ammonia (NH_3); NH_3 is unstable in the presence of O_2;
- elevated (>1 mg/L) concentrations of dissolved Mn^{2+} and/or Fe^{2+} at circum-neutral pH, which implies the reductive dissolution of Mn^{4+}-oxide and Fe^{3+}-oxide phases, respectively; and,
- presence of dissolved sulphide species (S^{2-}, HS^- and H_2S; hereafter referred to as S^{2-}) reflecting SO_4 reduction.

Of these, the presence of elevated dissolved Fe^{2+} and/or the presence of detectable dissolved S^{2-} provide the most robust indicators of suboxia, given that the presence of these parameters is incompatible with that of O_2. Where groundwater was characterized by low concentrations of redox indicator parameters, the relative concentrations of parameters and/or presence or absence of specific parameters was used to assess redox conditions.

Oxidation-reduction potential (ORP), in units of millivolts (mV), is a field-measured parameter and provides a qualitative assessment of the general redox conditions only. Strongly negative ORP values are associated with suboxic conditions whereas positive values are associated with oxic conditions. Field measurements of ORP and DO are considered informative, but less reliable than analytical results for NO_3, NO_2, NH_3, dissolved Mn and Fe, and S^{2-}. Field readings of DO and ORP are tabulated in Appendix 5-A and presented in time series plots in Appendix 5-E (Figure 5-E-1 to Figure 5-E-4). Analytical results for NO_3, NH_3, dissolved Mn, dissolved Fe, and S^{2-} are presented in Appendix 5-A, with time series plots in Appendix 5-E (Figure 5-E-9 to Figure 5-E-16). Note that total sulphide was initially reported, with a switch to dissolved sulphide in 2018 (Table 3-8). As a result, the time series plots for S^{2-} show total concentrations (Sept. 2014 to Jun. 2018) and dissolved concentrations (Aug. 2018 to Aug. 2019), except for April 2018 when total or dissolved concentrations are graphed depending on available analyses at each location. The general presence/absence of redox sensitive parameters is summarized in Table 5-2, along with classification of the groundwater by location.

Table 5-2:
Summary of Groundwater Redox Classification[1]

Lithology	Well ID	NO_3	NO_2	NH_3	Mn	Fe	S^{2-}	DO [2]	ORP [2]	Classification
Overburden	MW15-02AZ	✓	ND	✓ (low)	✓ (low)	✓ (low)	Mostly ND	✓	Mostly +ve	Oxic
	MW15-03AZ	✓	ND	✓ (low)	✓ (low)	✓ (low)	Mostly ND	✓	Mostly +ve	Oxic
	MW15-05AZ	✓ (low)	ND	✓	✓	✓	ND	✓	+ve	Mildly to moderately reducing
Gneiss	MW15-01WB	Mostly ND	ND	✓	✓	✓	Mix of ND and ✓	-	-	Moderately reducing
	MW15-03WB	ND (except 2 rounds)	ND (except 1 round)	✓	✓	✓	Mix of ND and ✓	-	-	Moderately to strongly reducing
	MW15-04WB	✓	✓	✓	✓	✓ (low)	Mostly ND	-	-	Oxic to mildly reducing
	MW15-06WB	Mostly ND	ND	✓	✓	✓	✓	-	-	Mildly to moderately reducing
Granite	MW14-05A	Mostly ND	Mostly ND	✓	✓	✓	✓	✓ (low)	Mostly -ve	Moderately to strongly reducing
	MW14-05B	Mostly ND	Mostly ND	✓	✓	✓	✓	✓ (low)	-ve	Moderately to strongly reducing
	MW15-05WB	ND	ND	Mix of ND and ✓	✓ (low)	✓ (low)	ND	-	-	Mildly reducing
	MW16-01WB	Mostly ND	Mix of ND and ✓	Mix of ND and ✓	✓	✓	Mix of ND and ✓	-	-	Moderately reducing
Schist	MW14-02A	✓	ND	Mix of ND and ✓	✓ (low)	Mix of ND and ✓	Mostly ND	✓	Mostly +ve	Oxic
	MW14-02B	✓	ND	Mix of ND and ✓	✓	Mix of ND and ✓	Mostly ND	✓	Mostly +ve	Oxic to mildly reducing
	MW14-03A	ND (except 2 rounds)	ND	✓	✓	✓	✓	✓ (low)	-ve	Moderately to strongly reducing
	MW14-03B	ND (except 2 rounds)	ND (except 1 round)	✓ (low)	✓	✓	Mostly ✓ (low)	✓ (low)	Mostly -ve	Mildly to moderately reducing
	MW15-02WB	Mix of ND and ✓	ND	Mix of ND and ✓	✓	✓	Mostly ND	-	-	Varies betwen oxic and midly to moderately reducing

Notes:
✓ = detect; -ve = negative; +ve = positive; ND = non-detect; " – " = not used for interpretation purposes
1. Redox parameter concentrations ≤ 2 times the reportable detection limit (RPD) are considered to be non-detect for the purpose of assessing groundwater redox conditions.
2. Field DO and ORP readings are not used to assess redox conditions at the Westbay installations, as these parameters were measured in a calibration cup or graduated cylinder and are consequently not considered to be representative.

Field DO and ORP measurements collected from Westbay installations are not considered to be necessarily representative of formation conditions since measurements were collected in a graduated cylinder or calibration cup (*i.e.*, not isolated from atmospheric conditions). Consequently, the field DO and ORP readings are not used for interpretation purposes and the assessment of redox conditions at MW15-01WB to MW15-06WB and MW16-01WB relies solely on groundwater analytical data (Table 5-2).

5.2.1 Overburden

Groundwater sampled from overburden wells ranged from oxic to moderately suboxic.

Shallow groundwater at MW15-02AZ was oxic. NO_3 was consistently measured at concentrations between 0.23 and 0.63 mg/L, along with low concentrations of dissolved Mn and Fe (<94 and <16 µg/L, respectively). NH_3 was measurable at low levels (<0.005 to 0.025 mg/L) in most samples. The consistent presence of NO_3, along with moderate DO (4.4 to 8.8 mg/L) readings and predominantly positive ORP measurements indicate oxygenated groundwater.

The groundwater at MW15-03AZ was predominantly oxic. NO_3 was consistently measurable in groundwater, with concentrations typically ranging between 0.1 and 0.45 mg/L. DO readings were low (0.3 to 2.9 mg/L), while ORP measurements were typically positive (6 to 136 mV). Low levels of NH_3 and dissolved Mn, and very low dissolved Fe were measured in most samples. The presence of NO_3, DO and positive ORP indicate predominantly oxic conditions.

The single groundwater sample collected at MW15-05AZ in September 2015 is classified as mildly to moderately reducing based on the analytical results. Substantial levels of DO (7.9 mg/L) and positive ORP (98 mV) suggest oxygenated water, with NO_3 (0.01 mg/L) only measured slightly above its detection limit. Measurable NH_3 (0.6 mg/L), dissolved Mn (0.6 mg/L) and Fe (0.9 mg/L) concentrations are indicative of mildly to moderately reducing groundwater.

5.2.2 Gneiss

Monitoring wells screened in gneiss are situated on the north side of the Project in the Halfway Creek (MW15-06WB, MW15-04WB and MW15-03WB) and YT-24 (MW15-01WB) drainages. Redox conditions at these wells range from oxic to strongly suboxic.

Groundwater at MW15-06WB is suboxic. Dissolved Fe concentrations were low in July and August 2015 (0.057 and 0.074 mg/L, respectively), and increased about one order of magnitude in September 2015 (0.85 mg/L), typically ranging between 0.6 and 1.1 mg/L thereafter. The consistent presence of dissolved Mn (2.4 to 6.4 mg/L) and Fe, along with negligible to low NO_3 (<0.002 to 0.025 mg/L) levels, low concentrations of NH_3 (<0.005 to 0.23 mg/L), and variable S^{2-} (0.002 to 0.05 mg/L) concentrations indicate the predominance of suboxic conditions. The elevated dissolved Mn concentrations relative to dissolved Fe in the groundwater at MW15-06WB suggest mildly to moderately reducing conditions.

MW15-04WB is oxic to mildly suboxic. NO_3 and dissolved Mn were consistently measured at MW15-04WB, with NO_2 and NH_3 measured in most samples. NO_3 concentrations were highest, ranging from 0.07 to 0.5 mg/L, while NO_2, NH_3 and dissolved Mn levels were generally lower. Sulphide was typically absent (<2.3 times RDL) in the groundwater, while dissolved Fe concentrations were very low (<44 µg/L). The consistent presence of NO_3 indicates oxic conditions, while low levels of NO_2, NH_3 and dissolved Mn indicate mildly reducing conditions.

Monitoring well MW15-03WB is classified as suboxic and moderately to strongly reducing. NO_3 was typically absent (<2 times RDL), while low levels of NH_3 (<0.005 to 0.08 mg/L, except 0.9 mg/L in July 2015) and dissolved Mn (74 to 104 µg/L) were consistently measured. Dissolved Fe concentrations were very low between June and August 2015 (6 to 11 µg/L) and increased significantly from September 2015 (569 µg/L) to April 2017 (1420 µg/L), decreasing thereafter until August 2019 (357 µg/L). Sulphide concentrations were negligible (<2.8 times RDL) from June 2015 to April 2017, increasing more than one order of magnitude between June 2017 and 2019 (0.05 to 0.19 mg/L). Elevated Fe concentrations in relation to the other redox parameters suggest moderately reducing conditions, while the apparent decrease in Fe concentrations in conjunction with measurable and increasing S^{2-} levels between June 2017 and August 2019 suggest a shift to more strongly reducing conditions.

The groundwater at MW15-01WB is anoxic and moderately reducing. Dissolved Mn was consistently measurable in groundwater at concentrations ranging from 0.3 to 0.5 mg/L, along with low levels of NH_3 (<0.005 to 0.06 mg/L). NO_3 was measured sporadically at concentrations close to its RDL (<0.002 to 0.02 mg/L), while S^{2-} was absent (<2 times RDL) in almost half of the groundwater samples collected at MW15-01WB. Dissolved Fe concentrations were very low between June and August 2015 (0.003 to 0.025 mg/L), and increased significantly in September 2015, typically ranging between 0.6 and 2.0 mg/L thereafter. The elevated Fe concentrations in relation to Mn levels, along with low levels of NH_3 and absence of S^{2-} in almost half of the samples suggest that groundwater at MW15-01WB is moderately reducing.

The first two to three groundwater samples collected at MW15-01WB, MW15-03WB, and MW15-06WB were characterized by low dissolved Fe concentrations which increased significantly by up to 1 to 2 orders of magnitude in the next sample collected at each location. The initially depressed Fe levels are suspected of being artifacts of reverse circulation drilling which likely injected air into the formation thereby affecting the groundwater redox conditions.

5.2.3 Granite

Groundwater redox conditions at monitoring wells screened in granite were mildly to strongly anoxic.

Monitoring well pair MW14-05A and MW14-05B had elevated dissolved Mn, Fe and S^{2-}concentrations indicating moderately to strongly reducing conditions. NH_3 levels in both wells were generally close to the RDL (0.005 mg/L). Field DO was low at MW14-05A (typically <2 mg/L) and MW14-05B (typically <3 mg/L), while ORP readings were negative in both wells. Groundwater was slightly more reducing at MW14-05A which was characterized by greater dissolved Fe and S^{2-} concentrations compared to MW14-05B. In addition, field ORP readings generally were slightly more negative at MW14-05A than MW14-05B. Dissolved Fe concentrations increased throughout the data record at MW14-05B (2.6 to 6.2 mg/L) and at MW15-04A (1.9 to 12 mg/L) (Appendix 5-E).

The groundwater at MW15-05WB is classified as anoxic and mildly reducing. Very low levels of dissolved Mn (5 to 13 µg/L) and Fe (<1 to 11 µg/L) were consistently measured, along with absence of NO_3 (<2 times RDL) and S^{2-} (<2 times RDL). NH_3 was measurable (>2 times RDL) in half of the groundwater samples collected at MW15-05WB. The occasional presence of NH_3, in addition to dissolved Mn concentrations that were typically greater than Fe concentrations suggest mildly reducing conditions at MW15-05WB.

Westbay installation MW16-01WB is characterized by moderately reducing conditions. Dissolved Mn (1.3 to 1.4 mg/L) and Fe (1.9 to 6.5 mg/L) were consistently measured, along with negligible NO_3 concentrations (≤ 2.5 times RDL) and sporadic measurable NH_3 concentrations (> 2 times RDL). Groundwater sampled between October 2015 and August 2018 had negligible sulphide levels (<2.5 times RDL of 0.0050 mg/L), while samples collected thereafter were characterized by increasing sulphide concentrations (0.03 to 0.09 mg/L). The elevated Fe levels indicates moderately reducing conditions, while the increasing sulphide concentrations in late 2018 and 2019 suggests a possible shift towards more strongly reducing conditions.

5.2.4 Schist

Monitoring wells screened in schist spans the entire range of redox conditions from oxic to strongly reducing.

Groundwater at monitoring well MW14-02A screened in hydrothermal breccia was oxic. NO_3 was consistently measured in groundwater between 0.14 and 0.18 mg/L, with high field DO (7.0 to 12 mg/L) and predominantly positive ORP (29 to 247 mV, except once at -61 mV), indicating oxygenated water. NH_3 was measurable (>2 times RDL) in about half the samples. Dissolved Mn (<0.08 mg/L) and Fe (<0.03 mg/L) were consistently measured at very low levels, along with absence of S^{2-} (<2.7 times RDL).

Groundwater at MW14-02B consistently had measurable levels of NO_3 (0.01 to 0.16 mg/L) and dissolved Mn (0.02 to 0.91 mg/L) which along with moderate to high DO (4.7 to 9.0 mg/L) and generally positive ORP readings (15 to 209 mV) suggest oxic to mildly reducing conditions.

Measurable NH_3 (>2 times RDL) was present in less than half of the samples, while dissolved Fe (<0.01 mg/L) concentrations were generally very low. Dissolved S^{2-} was absent in all sampling events (<2.4 times RDL).

Groundwater at monitoring well pair MW14-03A and MW14-03B was anoxic. The consistent presence of NH_3, dissolved Mn, and Fe along with negligible NO_3 during all sampling rounds indicate that suboxic conditions predominated at MW14-03A and MW14-03B. The groundwater at MW14-03B is classified as mildly to moderately reducing due to higher dissolved Mn concentrations and lower concentrations of dissolved Fe and S^{2-} relative to MW14-03A which is classified as moderately to strongly reducing. At MW14-03A, observed Fe, Mn and S^{2-} trends between 2015 and 2019 suggest a shift towards more strongly reducing conditions. The average Fe concentration at MW14-03A decreased from 8.3 mg/L (2015) to 3.8 mg/L (2019), in conjunction with a slight decrease in average Mn concentrations during this period (0.8 to 0.4 mg/L) and measurable sulphide levels that remained stable until April 2019 (~0.1 mg/L) and increased slightly in June and August 2019 (0.2 and 0.5 mg/L, respectively).

MW15-02WB is characterized by variable groundwater redox conditions. Eight samples were characterized by negligible NO_3 concentrations (≤2.1 times RDL), while the remaining 10 samples had measurable NO_3 (0.08 to 0.33 mg/L). Low levels of NH_3 were present in most samples, while S^{2-} was absent (<2.3x RDL). Dissolved Mn and Fe were consistently measurable in the groundwater at MW15-02WB; however, concentrations ranged up to one to two orders of magnitude. Samples with NO_3, typically had lower Mn (2 to 71 µg/L) and Fe (3 to 162 µg/L) concentrations compared to Mn (87 to 111 µg/L) and Fe (4 to 377 µg/L) levels in samples with negligible NO_3. The groundwater redox condition at MW15-02WB varies between oxic groundwater with NO_3 and low levels of dissolved Mn and Fe, and mildly to moderately reducing groundwater with negligible NO_3 and higher Mn and Fe concentrations.

5.3 Trace Elements

This section presents a review of trace element concentrations across the Project area. Groundwater data for all analysed parameters are tabulated and presented in Appendix 5-A. Selected dissolved parameters of concern (aluminum (Al), arsenic (As), antimony (Sb), cadmium (Cd), chromium (Cr), copper (Cu), cobalt (Co), mercury (Hg), molybdenum (Mo), nickel (Ni), lead (Pb), selenium (Se), silver (Ag), uranium (U) and zinc (Zn)) are presented as time series plots in Appendix 5-E (Figure 5-E-17 to Figure 5-E-32). These parameters were selected based on consideration of geochemical test results and potential for complexation with cyanide, in addition to surface water quality results across the Project area.

Selected trace element concentrations from the most recent groundwater sampling events are tabulated in Table 5-1, with the highest concentration for each parameter across the Project area

highlighted yellow. Parameters that display trends (*i.e.*, increasing or decreasing concentrations) are flagged in Table 5-1.

Dissolved Al was measured in virtually all groundwater samples. Concentrations were typically below 10 µg/L in bedrock groundwater. The highest concentrations were in overburden groundwater at MW15-03AZ (14 to 38 µg/L) and MW15-05AZ (189 µg/L). In contrast, concentrations at MW15-02AZ (1.9 to 15 µg/L) were predominantly within the range observed in bedrock wells. Dissolved Al values at MW15-04WB decreased one order of magnitude in 2015 (from 44 to 3.5 µg/L) and remained below 4 µg/L thereafter, with a similar decrease observed at MW14-03B in 2015 (Appendix 5-E).

Dissolved As was measured in all groundwater samples. Concentrations were generally low in overburden groundwater (0.43 to 2.3 µg/L) and highest in bedrock groundwater (0.12 to 2650 µg/L). Concentrations of dissolved As were below 6 µg/L in bedrock Westbay installations MW15-02WB, MW15-03WB, MW15-04WB, and MW15-05WB. The highest concentrations were measured in granite at MW14-05B (150 to 212 µg/L) and MW14-05A (1480 to 2650 µg/L), with a slight increase observed at MW14-05A between 2018 and 2019. A significant increase in As concentrations was observed at MW15-06WB between 2015 and 2019 (10 to 123 µg/L) (Appendix 5-E).

Concentrations of dissolved Sb were generally below 1 µg/L in overburden and bedrock groundwater, except at MW14-02B, MW15-04WB, and MW15-06WB. Dissolved Sb was highest at MW14-02B (3.3 to 12 µg/L), MW15-04WB (1.1 to 3.0 µg/L), and MW15-06WB (0.3 to 3.8 µg/L.

Dissolved Cd concentrations measured in overburden and bedrock groundwater were predominantly between <0.0050 and 0.06 µg/L, except at MW15-02AZ and MW15-04WB. Concentrations at MW15-02AZ were generally close to or below the RDL (range of <0.005 to 0.125 µg/L), while concentrations at MW15-04WB were consistently measurable (0.01 to 0.1 µg/L). MW14-05A, MW15-01WB and MW15-03WB had multiple samples with results below RDLs that were raised (0.010, 0.025 µg/L), and consequently may appear elevated in relation to other samples or wells in the plots in Appendix E (Figure 5-E-18, Figure 5-E-19).

Dissolved Cr was low in overburden and bedrock groundwater, with concentrations ranging from below RDL (0.1µg/L) to 2.7 µg/L. Concentrations were generally close to or below the RDL at most wells, with the highest concentrations consistently observed at MW14-02A (0.45 to 0.65 µg/L), MW14-02B (<0.1 to 2.7 µg/L) and MW14-05B (<0.1 to 0.7 µg/L).

Concentrations of dissolved Cu were generally highest in overburden groundwater (0.57 to 2.0 µg/L). Bedrock groundwater concentrations ranged from below RDL (0.05 µg/L) to 2.8 µg/L. Concentrations in bedrock groundwater were highest in schist at MW14-03B (0.2 to 2.8 µg/L) and MW15-02WB (0.1 to 2.6 µg/L), and in gneiss at MW15-04WB (0.5 to 2.3 µg/L).

Dissolved Co concentrations were generally higher in bedrock groundwater than in overburden groundwater. Concentrations of dissolved Co in overburden groundwater were generally below 0.25 µg/L, except at MW15-05AZ (2.5 µg/L). Dissolved Co levels were highest in schist at MW14-03A (1.3 to 2.5 µg/L) and MW14-03B (3.4 to 7.6 µg/L), with a slow decreasing trend observed at MW14-03B between 2015 and 2019. A slight decrease in concentrations was also observed at MW14-05A (1.2 to 0.2 µg/L) between 2015 and 2017.

Dissolved Hg concentrations were close to or below the RDL (0.002 µg/L) in most overburden and bedrock groundwater samples. Monitoring wells with measurable dissolved Hg were typically characterized by concentrations <0.01 µg/L, except MW14-03B (<0.002 to 0.033 µg/L) and MW15-06WB (0.0041 to 0.095 µg/L) where the highest concentrations were detected; however, concentrations at MW15-06WB appear to have stabilized below 0.01 µg/L between 2017 and 2019.

Dissolved Mo was consistently measured in overburden and bedrock groundwater. Groundwater concentrations were lowest in the overburden (0.25 to 0.53 µg/L). In contrast, concentrations in bedrock groundwater ranged from 0.83 to 29 µg/L in the conventional monitoring wells and 0.31 to 199 µg/L in the Westbay installations. The highest concentrations were observed at MW15-06WB (28 to 199 µg/L), with a significant increase in 2015, followed by slowly decreasing concentrations thereafter. Concentration decreases were also observed at MW14-03A (2015 to 2017), and MW14-02B, MW14-03B and MW14-05B (2015 to 2019) (Appendix 5-E).

Concentrations of dissolved Ni in groundwater were generally below 5 µg/L, except at MW14-02B and MW14-03B. Dissolved Ni concentrations were highest and most variable at MW14-02B (1.2 to 15 µg/L) and MW14-03B (9.9 to 22 µg/L); however, concentrations decreased at both wells between 2015 and 2019.

Dissolved Pb concentrations were low in the overburden and bedrock groundwater. Concentrations were lowest in the overburden (<0.005 to 0.033 µg/L) and more variable in bedrock, ranging from <0.005 µg/L to 1.6 µg/L.

Dissolved Se was generally low in overburden and bedrock groundwater, with concentrations ranging from below RDL (0.04 µg/L) to 1.1 µg/L. The May 2015 sample collected at MW15-02AZ and the April 2018 sample collected at MW15-03WB had the highest Se concentrations of any overburden and bedrock wells at 1.1 µg/L. All other overburden and bedrock groundwater samples were consistently below 0.6 µg/L.

Concentrations of dissolved Ag were generally below the RDL (0.0050 µg/L) in overburden and bedrock groundwater. Dissolved Ag levels were highest at specific wells in schist (MW14-03A, MW14-03B) and gneiss (MW15-03WB, MW15-06WB). All wells with measurable dissolved Ag were typically characterized by concentrations below 0.015 µg/L. MW14-05A, MW15-01WB and MW15-03WB had multiple samples with results below RDLs that were raised (0.010, 0.025 µg/L),

and consequently appear elevated in relation to other samples or wells in the plots in Appendix E (Figure 5-E-30, Figure 5-E-31).

Concentrations of dissolved U were consistently elevated (>15 µg/L) at most wells, except for MW14-05A, MW14-05B, MW15-03WB, MW15-05AZ, and MW16-01WB. Dissolved U levels were highest in gneiss at MW15-01WB (526 to 589 µg/L), MW15-04WB (107 to 176 µg/L) and MW15-06WB (5.7 to 103 µg/L). Concentrations at MW15-03WB, the only other well screened in gneiss, were significantly lower (5.7 to 9.1 µg/L). Dissolved U levels were lowest in the overburden groundwater (0.90 to 35 µg/L) and in granite (1.2 to 33 µg/L) at MW14-05A, MW14-05B and MW16-01WB. A decreasing concentration trend is apparent throughout the data record at MW14-05A (33 to 4 µg/L) and to a lesser extent at MW14-05B (~7 to <2 µg/L), while a slight but steady increase was observed at MW14-03B (~40 to 58 µg/L) between 2015 and 2019 (Appendix 5-E).

Dissolved Zn was typically measured across the Project area with higher and more variable concentrations at Westbay installations screened in the bedrock. Dissolved Zn levels were lowest in the overburden (<0.1 to 8.6 µg/L), followed by bedrock groundwater in conventional wells (<0.1 to 34 µg/L). Groundwater concentrations in the Westbay installations ranged from 4.9 to 253 µg/L in 2015 and from <0.5 to 64 µg/L between 2016 and 2019.

5.4 Isotopes

Groundwater, surface water and aufeis samples were collected from the Project area between 2014 and 2019 for the analysis of stable isotopes (^{2}H, ^{18}O, ^{13}C) and radioisotopes (^{3}H, ^{14}C) (Table 3-9). Water stable isotopes of hydrogen (^{2}H) and oxygen (^{18}O) are used to assess groundwater sources and recharge history, while the radioisotopes tritium (^{3}H) and radiocarbon (^{14}C) are used to estimate groundwater age (*i.e.*, mean residence time), which is an indication of how long water is circulating within a groundwater system. A summary of the key findings is presented herein, with a detailed discussion of the isotopic data and results provided in Appendix 5-F. The 2014 to 2019 stable isotope and radioisotope data are tabulated in Appendix 5-F.

Tritium (^{3}H) and radiocarbon (^{14}C) measurements in samples were used to estimate the fractions of young and paleo groundwaters (F_{young} and F_{paleo}, respectively) in a given groundwater sample based on the method proposed by Jasechko (2016a). In this method, young groundwater is defined as any groundwater that recharged since 1953 (*i.e.*, before the onset of large-scale thermonuclear bomb testing). Paleo groundwater refers to any groundwater that recharged prior to the end of the last major Earth glaciation, approximately 11,700 years ago. A summary of this method, as well as details of the calculations involved are presented in Appendix 5-F.

5.4.1 Stable Isotopes

The stable isotope compositions of groundwater, surface water, and aufeis samples collected in the Project area generally plot along an array of similar slopes to the local meteoric water line (LMWL) (Figure 5-2). The data plot slightly above the LMWL, which may reflect a slight difference in the source of water vapour that generates precipitation in the Project area in comparison to precipitation in Dawson City and Mayo (Lapp, 2015; IAEA, 2020) which was used to develop the LMWL. The range of estimated isotopic compositions for annual precipitation, rain-dominated precipitation (May-Oct.), and snow-dominated precipitation (Nov.-Apr.) in the Project area are defined by purple, red, and blue shading in Figure 5-2, respectively. These ranges were calculated using isotope and precipitation data from Mayo (IAEA, 2020) and correcting for elevations encountered at the Project site (see Appendix 5-F).

Overall, groundwaters collected from the Project site are isotopically heavier than the estimated value for mean annual precipitation and plot closer to the isotopic composition of rain-dominated precipitation (May to October) than that of snow-dominated precipitation falling between November and April (Figure 5-2). This observation suggests that groundwater recharge at the Project site is more heavily driven by infiltration of rain than by snowmelt, and is consistent with a greater proportion of annual precipitation falling as rain (~70 %) and a smaller contribution from snow (~30 %) at an elevation of 975 m asl (Lorax, 2019). Similar results have been obtained in a groundwater stable isotope study in the nearby Ogilvie River Watershed, north of Dawson City, Yukon (Baranova, 2017). Surface waters are shifted towards an isotopically heavier range of values in comparison to groundwater. This may simply reflect surface water samples that were predominantly collected between late April and October, when their water budget included greater input from summer precipitation, which is expected to be isotopically heavier than the mean annual precipitation and groundwater discharge (Figure 5-2).

There is considerable overlap in the stable isotope composition of groundwater at most monitoring wells, except for MW15-03WB (Figure 5-3). The water sampled at this location consistently has lower $\delta^{18}O$ and $\delta^{2}H$ values in comparison to other monitoring wells. This isotopically lighter signature at MW15-03WB is indicative of a colder recharge environment, which could be due to higher elevation precipitation or precipitation that fell during colder geological periods. For example, during the late-Pleistocene (50,000 to 20,000 years ago), $\delta^{18}O$ in precipitation was likely ~1 to 2 ‰ lower than during the Holocene (11,700 years ago to present time) due to a colder climate in extratropical areas (Jasechko, 2016b). In contrast, MW15-03AZ, which is screened in the active zone in the Halfway Creek valley, is characterized by isotopically heavier water, which indicates greater contribution of summer precipitation in the active zone flow system.

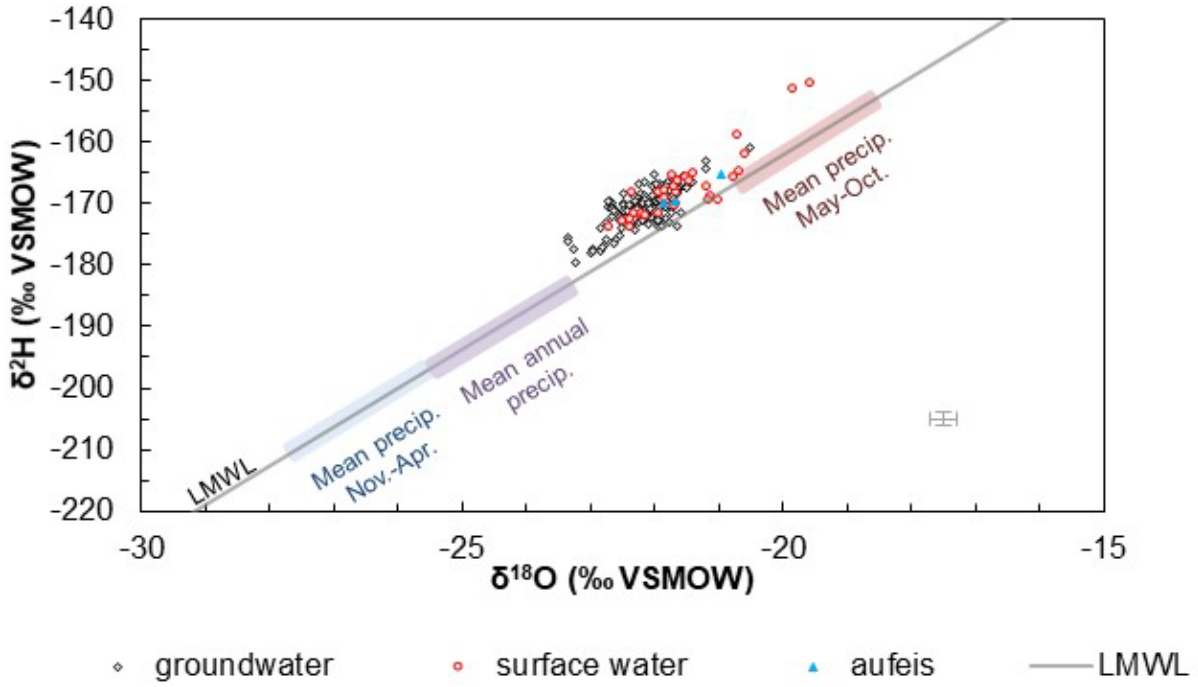

Figure 5-2: Isotopic composition of groundwater, surface water and aufeis at the Project site.

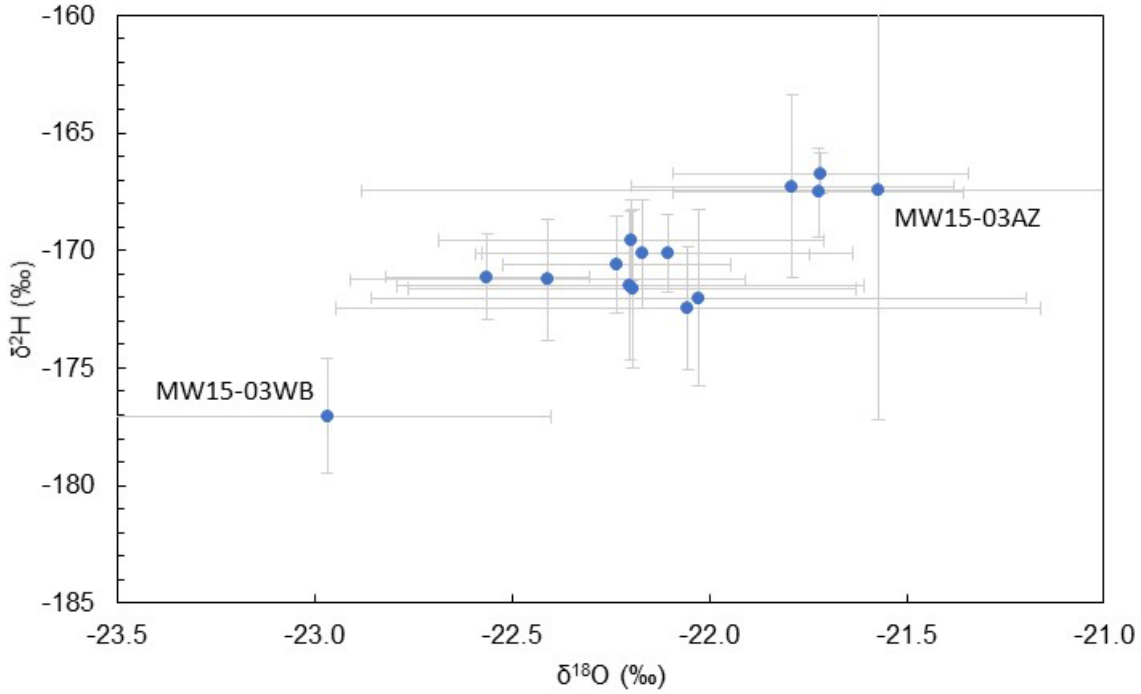

Figure 5-3: Mean stable isotope composition of groundwater at each monitoring well in the Project area (2014-2019). Error bars are ± 2 standard deviations.

5.4.2 Tritium and Radicarbon

The Pearson and Hanshaw (1970) method for correcting radiocarbon age relies on assumptions of $\delta^{13}C$ of the recharge environment, which depends on factors including soil vegetation type and soil porewater pH (at the time of recharge). These factors cannot truly be known, and as a result $\delta^{13}C$ is commonly estimated (Clark and Fritz, 1997). For the interpretation of radiocarbon ages presented in this memorandum, a groundwater recharge pH of 7.0 and a soil $\delta^{13}C$ value of -23 ‰ (typical of C3-plant based ecosystems; Clark and Fritz, 1997) are assumed, which correspond to a $\delta^{13}C_{recharge}$ value of -17.3 ‰ (Table 5-3). It is worth mentioning that under a slightly lower soil pH (*e.g.*, pH 6.0), $\delta^{13}C$ of recharge under these conditions would change to -21.5 ‰, and the reported radiocarbon ages would be offset by approximately 1,000 to 2,000 years. The uncertainty inherent in this method should be considered when interpreting the calculated ^{14}C ages (Table 5-3).

Calculations of F_{young} and F_{paleo} are prone to large uncertainties given the large range in possible ^{3}H and ^{14}C concentrations since 1953 and over the last 60,000 years, respectively, as well as assumptions that must be made regarding $\delta^{13}C$ of recharge and DIC concentrations. Therefore, the results are interpreted using mean fractions of young and paleo waters in a qualitative manner.

Tritium and radioisotope data indicate that the majority of groundwater in high-elevation and sub-permafrost monitoring wells is at least 70 years old and may be thousands of years in age (Table 5-3). This includes groundwater from high-elevation monitoring wells in granite (MW14-05A, MW14-05B, MW16-01WB, MW15-05WB) and sub-permafrost north-facing terrain in gneiss (MW15-06WB, MW15-01WB). All these wells have little to no tritium and F_{young} values ≤0.1, indicating that they are predominantly composed of water older than ~70 years (Figure 5-4, Figure 5-5). Calculated radiocarbon ages for these wells range from 6,500 to 22,400 years and F_{paleo} values range from 0.5 to 1, suggesting much longer residence times for sub-permafrost groundwater at high elevations at the Project site (Figure 5-6, Figure 5-7). The long groundwater residence times beneath permafrost in granite are supported by observations of low bedrock hydraulic conductivity at MW14-05A and MW14-05B which is ≤ $1x10^{-9}$ m/s and very slow well recharge rates observed during groundwater sampling.

In contrast, a large component of young groundwater with ages on the order of a few decades predominates along south-facing slopes above Latte Creek where permafrost is sparse (*i.e.*, MW14-02A, MW14-02B). Groundwater at MW14-02B and MW14-02A is tritiated (*i.e.,* contains tritium, with 5.4 and 7.2 tritium units (TU), respectively) and has F_{young} values greater than 0.6 (Table 5-3). A more active groundwater circulation pattern at these locations is consistent with higher hydraulic conductivity in the vicinity of MW14-02B, which ranges from $1x10^{-7}$ to $5x10^{-9}$ m/s. There is nevertheless a component of older groundwater that also appears to contribute to the water sampled at these locations, given calculated radiocarbon ages greater than 8,000 years and F_{paleo} values of 0.7 (Table 5-3). Groundwater mixing can account for this combination of young and old groundwater at MW14-02A and MW14-02B. The younger groundwater system in this area also appears in valley wells in Latte Creek at MW15-02AZ and MW15-02WB, which are

tritiated (9.4 and 6.6 TU, respectively) and have F_{young} values of 1.0 and 0.7, respectively. These results indicate that permafrost-free and more rapid groundwater circulation on the south-facing slope above Latte Creek may be a major input to groundwater contributions in the Latte Creek valley.

Along the Halfway Creek valley, groundwater in overburden at MW15-03AZ is likely on the order of a few decades old, based on an elevated tritium content (7.9 TU) which is indicative of more rapid groundwater circulation. However, a large range in groundwater ages is apparent in bedrock groundwater along Halfway Creek. MW15-04WB contains elevated tritium (6 TU) indicating it is mostly comprised of water several decades in age. In contrast, groundwater at MW15-03WB is tritium-free (< 0.8 TU), has a calculated radiocarbon age of 13,500 years, and an F_{paleo} value of 1.0, suggesting that it is likely several thousand years old (Table 5-3). Groundwater at MW15-03WB also has the lowest $\delta^{18}O$ value (Figure 5-3), which could be consistent with paleo-groundwater that recharged during the Pleistocene when meteoric $\delta^{18}O$ values were approximately 1 to 2 ‰ lower than present-day (Jasechko, 2016b). MW15-03WB is artesian and is installed in a valley bottom, and its location is along an inferred lineament (Huscroft, 2002) which may act as a conduit for long-residence time flow with upwelling groundwater (based on strong upward hydraulic gradients measured by MW15-03T). The unique $\delta^{18}O$ value is consistent with distinct groundwater quality at MW15-03WB, given its end-member major ion composition for the Project site, as well as elevated salinity and SO_4 concentrations in relation to other bedrock wells, and low dissolved uranium concentrations compared to other wells screened in gneiss and located upstream along Halfway Creek.

COFFEE

6. Groundwater System Conceptual Model

Figure 6-1 illustrates a conceptual hydrogeological cross-section along section line A-A' which transects Latte Creek, the Supremo Pit complex, and Halfway Creek (Figure 4-5, Figure 4-8). The cross-section shows baseline water levels, hydraulic conductivity measurements, borehole airlift yields (where applicable), permafrost distribution, as well as water quality and isotope results. The lateral extents of permafrost are derived from Tetra Tech (2017), with permafrost thickness inferred from field measurements and the elevation trend shown in Figure 4-4.

Ground temperature data from thermistors, as well as observations from drilling and groundwater monitoring indicate that permafrost is discontinuous but extensive across the project area (Figure 4-5). Permafrost is inferred to be of very low hydraulic conductivity (Woo, 2012; Kane *et al.* 2013; Walrood *et al.*, 2012). Permafrost is of hydrogeological significance as it is considered to behave like an aquiclude or an aquitard and can confine sub-permafrost groundwater such that it exhibits artesian conditions (Woo, 2012).

Overall, permafrost extends to greatest depths in ridge areas and appears to reduce in thickness towards areas of lower elevation (Figure 4-4). The north-facing slopes tend to have thicker and more prevalent permafrost than south-facing slopes. The thickest permafrost at site (~168 m) is encountered near the north end of the proposed Supremo pit at MW14-04T (Figure 4-5). South facing slopes are largely permafrost-free. Supra-permafrost groundwater flow occurs in the active zone. At the Coffee mine, the active zone is conceptualized as a highly heterogeneous zone that is variable in timing and duration, both spatially and temporally (Table 4-2).

Hydraulic testing at the project site has been completed on multiple lithologies located within pit footprint areas and farther afield (Table 4-3). The hydraulic conductivity (K) data are typical of a fractured bedrock system with values ranging over several orders of magnitude (Figure 4-6). Structural features that crosscut all lithologies impart the dominant control on hydraulic conductivity with lesser influence from lithology. Most of the elevated K values at depth are attributed to hydraulic tests that targeted geologic structures intersecting the proposed pits (SRK, 2015). Major creek traces (*i.e.*, Latte Creek, Latte Tributary, Halfway Creek, YT-24) are conceptualized to represent permeable fault structures as indicated by high airlift yields encountered during drilling and other hydraulic tests yielding elevated K values (Figure 6-1).

Groundwater levels across the Coffee project are highly variable with respect to depth to water level, vertical and horizontal hydraulic gradients, and the timing and magnitude of hydrograph fluctuations. This variability speaks to the complexity of a groundwater system in an area of topographic relief influenced by faulting and discontinuous permafrost.

Groundwater levels are relatively deep in ridge areas (~130 to 220 m bgs; Figure 6-1), although flowing artesian conditions are also encountered at moderate to high elevations in the southwestern project area (MW16-01T, MW14-07T) and the south facing slopes of the Latte Creek Tributary (MW14-02A). At monitoring locations where permafrost depth is accurately known, groundwater pressures generally exceed the base of permafrost, demonstrating confined conditions. Notable exceptions are at MW15-06WB and MW17-01T (Figure 6-1), where the water table is inferred to be at least 50 m and 20 m below the base of permafrost, respectively. Artesian groundwater pressures are reported at many lower elevation installations in both permafrost and permafrost-free areas, including the Halfway Creek drainage (MW15-04WB/MW15-04T) and Latte Creek Tributary (SRK-15D-09T) (Figure 6-1).

Water level hydrographs indicate variable response to seasonal recharge patterns, with fluctuations ranging from <1 m to over 30 m (Table 4-6). The magnitude of seasonal fluctuations is not clearly correlated to well collar elevation, nor the presence of permafrost. Continuous water level records indicate that most wells are relatively insensitive to individual rainfall events and show gradual seasonal increases in water levels that peak between late summer and winter. The timing of peak groundwater levels is highly variable across the site.

Arsenic and uranium are consistently measured in the overburden and bedrock groundwater in the Project area. Bedrock groundwater is characterized by elevated concentrations of dissolved As and U (0.12 to 2,650 µg/L and 1.2 to 589 µg/L, respectively). Arsenic levels are highest in the deeper groundwater near mineralized areas at upgradient locations in the Halfway Creek (MW14-05A, MW14-03A, MW15-06WB) and Latte Creek Tributary (MW14-02A, MW14-02B) drainages. Groundwater As concentrations are significantly lower in downgradient areas of these two drainages (MW15-04WB, MW15-02WB; Figure 6-1), indicating the attenuation of As along groundwater flow paths. This is also reflected in low concentrations of As measured in surface water at Halfway Creek (HC-6.8) and Latte Creek (LC-11.4) during winter low flow periods (Figure 6-1). In contrast, elevated U concentrations measured at these stations during the winter low flow period suggests little to no attenuation with U behaving conservatively (Figure 6-1). Uranium concentrations in Halfway Creek (HC-6.8) and Latte Creek (LC-11.4) during low flow periods are typically similar to groundwater concentrations in the nearby wells (*i.e.*, MW15-04WB, MW15-02WB; Figure 6-1).

Groundwater stable isotope compositions across the site suggest that groundwater recharge is more heavily driven by infiltration of rain than by snowmelt, while tritium and radiocarbon data suggest that permafrost exerts a strong control on groundwater residence times. At high elevations and beneath permafrost, ^{3}H and ^{14}C data suggest that groundwater is predominantly greater than 70 years in age and could be thousands of years old. In contrast, ^{3}H data suggest a more active groundwater circulation pattern along south-facing

slopes where permafrost coverage is limited such as Latte Creek, with a large component of young groundwater with residence times on the order of decades (MW14-02A, MW14-02B; Figure 6-1).

Radioisotope data (^{3}H, ^{14}C) indicate that valley bottoms include a mixture of young and old groundwaters that converge in discharge areas. Shallow overburden wells (MW15-02AZ, MW15-03AZ) are characterized by young groundwater (decades-old or less) based on elevated tritium contents. Deeper groundwater screened in valley bottoms contains components of young (decades old or less) and old (thousands of years) groundwater as evidenced by the presence of ^{3}H and long mean groundwater ages (^{14}C) (MW15-02WB, MW15-04WB; Figure 6-1). The isotopic data indicate bedrock groundwater at MW15-03WB, the farthest downgradient groundwater station on Halfway Creek, is on the order of thousands of years old and is distinct in both isotopic and geochemical composition from other groundwater sampled in Halfway Creek and across the Project.

There is very little literature on sub-permafrost groundwater ages in Yukon. However, during the early Holocene, the climate was several degrees Celsius warmer with more precipitation than present day (Grinter et al., 2019; Lecavalier et al., 2017; Kaufman et al., 2016; Clark et al., 2004). During this period, permafrost would have likely been sparse/absent in this part of Canada, thereby allowing a pulse of groundwater recharge. Later, in the mid to late-Holocene, the climate cooled and permafrost likely grew back creating confining conditions. The estimated radiocarbon ages generally agree with the timing of this permafrost regression several thousand years ago. Wells with reliable radiocarbon ages (*i.e.*, with lower TDS and DIC levels) consistently indicate a component of recharge that occurred between approximately 6,000 and 11,000 years ago.

7. Conclusions

Multiple hydrogeological and geotechnical field investigations have been advanced at the Project between 2013 and 2019. This report constitutes the synthesis of all baseline hydrogeological data up to August 2019. The investigations have revealed a complex groundwater system influenced by permafrost and fractures. The main findings of this baseline study are as follows:

- Overall, permafrost is widespread across the Project. It extends to greatest depths in ridge areas and appears to thin towards areas of lower elevation; north facing slopes tend to have thicker permafrost than south-facing slopes. The thickest permafrost (~168 metres) is encountered near the north end of the proposed Supremo pit. Permafrost in the project area is relatively warm (between 0 and -2˚C) and is coolest (-1.4°C to -1.9˚C) on north facing slopes.
- Hydraulic conductivity data range over several orders of magnitude and generally decreased with depth which is typical of a fractured bedrock system. Median K values decrease markedly at 150 m bgs and again below 250 m bgs. The median K of structures is 2E-07 m/s with tests ranging up to 275 m depth. This K value is one to two orders of magnitude higher than other bedrock tests over the same depth interval. There does not appear to be a correlation between hydraulic conductivity and lithology.
- Groundwater draining the Halfway Creek catchment is largely confined by permafrost. At high elevations in the area of the proposed Kona and Supremo pits, groundwater occurs at significant depth (130 to over 220 m bgs) and is below the base of permafrost. This is contrasted by artesian groundwater presssures confined by permafrost in the high elevation heap leach facility footprint. At lower elevations of the Halfway Creek catchment, groundwater is typically confined by permafrost and artesian conditions are frequently encountered. The lowest elevation monitoring installation in Halfway Creek, MW15-03T, is situated on the fringe of permafrost along a fault that crosscuts both Halfway Creek and YT-24. This station registers strong upward hydraulic gradients in bedrock and hydrograph maxima in the early spring, both of which are in contrast to other stations located along the creek trace.
- Groundwater is well-confined along the upper reaches of the YT-24 drainage. The piezometric surface is several to tens of metres above the base of permafrost and vertical hydraulic gradients vary in both magnitude and direction along the drainage, indicative of the complex hydrogeologic regime at the Project. Groundwater level hydrographs vary distinctly between the three stations along this

drainage with some trending upward since station initiation, others remaining flat with and without seasonal variation.

- The Latte Creek Tributary catchment has partial permafrost coverage. At the highest elevation installation in this catchment, CFD0351, groundwater is more than 100 m deep and varies seasonally by up to 35 m. Elsewhere, groundwater pressures are artesian or close to ground surface with seasonal hydrograph fluctutaions between 2 m and 20 m. Strong upward hydraulic gradients are measured in upper reaches of the drainage, while both upward and downward hydraulic gradients are measured in bedrock at the confluence with Latte Creek.
- Strong artesian groundwater pressures are measured at the headwaters of Latte Creek. Immediately downstream, the piezometric surface is above the base of permafrost, but groundwater pressures are not flowing artesian. Seasonal trends in water pressure are subdued compared to other areas, with water levels rising on the order of a few metres at some locations. Strong downward vertical gradients are observed in both upper and lower reaches of the drainage. Horizontal hydraulic gradients along the intrumented length of the drainage exceed topographic gradients, suggesting groundwater is underdrained by a broader regional fault (*i.e.,* a splay of the Coffee Creek Fault).
- Groundwater is predominantly circum-neutral (pH 6 to 8), with most groundwater between pH 6.5 and 8. Groundwater quality shows variable influence from weathering of sulphide minerals and dissolution of sulphate minerals, either from the deposits or other disseminated mineralization across the Project area. Sulphate concentrations range from low to substantial (7 to 1120 mg/L) and salinity is variable (field specific conductance readings between 28 and 2390 µS/cm).
- Major ion chemistry of overburden groundwater is calcium-bicarbonate-type. The bedrock groundwater has a wide range of major ion signatures from calcium-bicarbonate to mixed magnesium-calcium-sodium-sulphate-type water, reflecting variable influence of sulphide weathering. The groundwater in granite calcium-bicarbonate-type, but is generally more sodic (*i.e.*, contains a higher sodium proportion) than other groundwater on site.
- Groundwater redox conditions predominantly range from oxic in the overburden to anoxic and mildly to strongly reducing in bedrock wells. Exceptions include bedrock wells MW14-02A and MW14-02B which are oxic and oxic to mildly reducing, respectively, while MW15-02WB appears to vary between oxic and mildly to moderately reducing conditions.
- Dissolved arsenic and uranium were consistently measured in the overburden and bedrock groundwater during baseline monitoring. Groundwater quality in the Project area is characterized by elevated dissolved arsenic and uranium

concentrations which generally were highest in the bedrock, ranging from 0.12 to 2650 µg/L and 1.2 to 589 µg/L, respectively.

- Water quality trends observed in several bedrock monitoring wells and Westbay installations suggest that groundwater chemistry is slowly stabilizing after drilling and well installation. Groundwater major ion composition has progressively shifted towards lower sodium proportions and concentrations at MW14-05A and MW14-05B, while redox parameters show a shift to more strongly reducing conditions throughout the data record at MW14-03A, MW15-03WB and MW16-01WB. In addition, several parameters including major ion, redox and/or trace elements are characterized by concentrations that appear to be trending slowly at a few wells (*e.g.*, MW14-03A/B, MW14-05A/B, MW15-06WB).
- Groundwater stable isotope compositions across the Project are isotopically heavier than the estimated composition for mean annual precipitation, and closer to the isotopic composition of rain-dominated precipitation (May-October) than that of snow-dominated precipitation (November-April). This suggests that groundwater recharge is more heavily driven by infiltration of rain than by snowmelt, which is consistent with a greater proportion of annual precipitation occurring as rain (~70 % at an elevation of 975 m asl) in the Project area (Lorax, 2019).
- Isotopic analyses of carbon and hydrogen suggest that permafrost exerts a strong control on groundwater residence times. At high elevations and beneath permafrost, ^{3}H and ^{14}C data suggest that groundwater is predominantly greater than 70 years in age and could be thousands of years old. In contrast, along south-facing slopes where permafrost coverage is limited, such as Latte Creek around MW14-02A and MW14-02B, ^{3}H data suggest a more active groundwater circulation pattern with a large component of young groundwater with residence times on the order of decades.
- Valley bottoms include a mixture of young and old groundwaters that converge in discharge areas. Shallow wells completed in overburden (MW15-02AZ, MW15-03AZ) are characterized by young (decades-old or less) groundwater based on elevated tritium contents. Deeper Westbay installations MW15-02WB and MW15-04WB contain tritium, indicating decades-old or less groundwater ages; however, MW15-04WB also includes a component of groundwater thousands of years in age based on its radiocarbon age. Valley bedrock installation MW15-03WB screens groundwater that is likely thousands of years in age based on its ^{3}H, ^{14}C, and $\delta^{18}O$ signatures, and is distinct in both isotopic and geochemical composition from other groundwater sampled in Halfway Creek and across the Project.

1 INTRODUCTION

This report and the attached Appendices document the technical services carried out by Westbay Instruments (Westbay) under Lorax Environmental Services Ltd. P.O. No. A362-4. Westbay System completions were installed in boreholes BH2-WB, BH4-WB, BH5-WB, BH8-WB, BH10-WB and BH12-WB on a site near Coffee Creek, Yukon Territory.

This report documents the installation tasks and related QA checks.

2 PRE-INSTALLATION ACTIVITIES

All boreholes were drilled using air rotatory methods at a nominal 4.5-inch diameter (HQ-size). Permanent surface casings were installed to bedrock in each borehole. The surface casing depths are not included in this report. An exception to the above drilling method used is discussed in section 4.2, where addition drilling was conducted using a coring rig.

3 INSTALLATION

Westbay technical services representatives were on site for installation of the Westbay System completions as follows: Mr. Mark Lessard, April 29 – May 20, 2015. Mr. Andrew Bessant, May 20 – June 7, 2015, and Mr. Dave Larssen was on site June 7th-June 10th. Lorax representatives Ms. Laura Findlater, Mr. Jordi Helsen, Mr. Andrew Solod, and BGC representative Ms. Catherine Schmid were on-site to assist and supervise the work.

(Note: all depths are with respect to ground surface. Monitoring well reference elevations were not available at the time of writing).

Table 1, Summary of Westbay System Completions

Monitoring Well No.	Installation Dates 2015	Borehole Depth (m)	Depth of HQ rods (m)	MP38 Tubing Length (m)	No. Monitoring Zones
BH2-WB	May 22	82.9	56.5	82.9	2
BH4-WB	May 17-19	61.1	30	60.9	2
BH5-WB	June 6-9	293	200	294	4
BH8-WB	May 4-5	116.7	78	116.7	2
BH10-WB	May 25	65.7	10*	65.6	2
BH12-WB	May 11-14	99.7	34	99.6	3

* HQ rods removed, surface casing only.

The Westbay Systems were installed according to the procedure described below.

3.1 Preparation of Westbay System Design

Packer and zone depths and the projected depth of permafrost for each borehole were provided to Westbay by Mr. Jordi Helsen or Ms. Laura Findlater of Lorax. Well designs were created based on these depths. Each well design was used to prepare a Westbay Completion Log, which specifies the location of components in the well. These logs were reviewed and approved in the field by Mr. Helsen or Ms. Findlater prior to installation of the wells. The Westbay Completion Log as approved was used as an installation guide in the field. Field copies of the logs are in the Appendices.

A measurement port coupling was included in each primary zone to provide the capability to measure fluid pressures and collect fluid samples. Measurement port couplings were also included in QA zones to provide QA testing capabilities. A pumping port was placed above the top packer located directly above the expected base of permafrost in each completion. This pumping port was placed as part of a plan to introduce a 3:1 propylene glycol/water mixture into the steel casing adjacent to the permafrost zone.

Ms. Laura Findlater of Lorax requested that optional synthetic (PET) filters were not to be installed over the measurement port couplings.

3.2 Layout of Westbay System Components

Prior to Westbay System installation, the Westbay System components were set out on a rack near the borehole according to the sequence indicated on the Westbay Completion Log. Each component was numbered beginning with the lowermost as an aid to confirming the proper sequence of components. The appropriate Westbay System couplings were attached to the tubing sections. Magnetic location collars were attached 0.6 meters below the top of the measurement port in each primary zone.

Each component was visually inspected. Serial numbers for each packer, pumping port and measurement port coupling were recorded on the Westbay Completion Log. The well component layout was confirmed with the log before the components were lowered into each borehole.

3.3 Lowering of Westbay System Components

The Westbay System components were lowered into the boreholes by hand or rig assisted as required, through HQ drill rods (nominal 76mm ID) which were used as a temporary guide tube. Each tubing joint was tested with a minimum internal hydraulic pressure of 150 psi for one minute to confirm hydraulic seals. A record of each successful joint test and the placement of each component are noted on the Westbay Completion Log by check marks.

A 3:1 water/propylene glycol mixture supplied by Lorax was added to the Westbay completion when necessary to counter buoyancy effects while components were lowered into each borehole and for testing of joint seals during lowering.

3.4 Hydraulic Integrity Testing

After the Westbay System components were lowered into each borehole, the water inside the tubing was monitored at a depth different from the open borehole water level for a minimum period of thirty minutes to confirm hydraulic integrity of the tubing. The data from the hydraulic integrity tests are shown in Table 2 below.

Table 2, Borehole and Westbay Tubing Water Level

Well number	Borehole water level Per-Installation (ground surface)	Westbay tubing water level (below top of Westbay)
BH2-WB	24.8 m	65.14 m
BH4-WB	artesian	34.304 m
BH5-WB	215.2 m	282.9 m
BH8-WB	38.41 m	41.32 m
BH10-WB	8.2 m	20.72 m
BH12-WB	~ 1 m	34.304 m

3.5 Positioning of Westbay System Completion

After the components were lowered into the borehole, and the guide tube was removed (BH10-WB) or the guide tube was lifted into position just below the, permafrost interface and was hung permanently from the surface casing. (BH2-WB, BH4-WB, BH8-WB, BH5-WB and BH12-WB). The final position of the guide tube is illustrated on each wells Summary Completion Log in the Appendices. The Westbay System tubing was positioned as indicated on the cover page of the Summary Completion Log. Ground surface was used as zero reference for all installations. The Westbay System components were supported in this position while packer inflations were carried out.

The positioning of the Westbay System is based on the "nominal" lengths of Westbay System components. The positioning calculations do not include allowances for borehole temperature or deviation effects.

The attached figure titled “MOSDAX Transducer Position” provides information to correlate the position of MOSDAX Transducer sensors to the reference position at the top of the Measurement Port. The attached figure titled “Dimensions of Packer Seals and Monitoring Zones” outlines the calculations used to determine the packer centerline depths and zone length.

The Summary Completion Log and Table 4, shows the final “as-built” locations of key components in the well, and Table 5 shows the final “as-built” locations of all components in the well, are included in the Appendices.

3.6 Pre-inflation Profile

Prior to inflating the packers, a pre-inflation pressure profile was carried out in the Westbay Systems to confirm the proper operation and position of measurement ports and magnetic collars. The data confirmed proper operation and position of all measurment ports (Figure 3). The data for the pre-inflation profile for each well is located in the Appendices.

3.7 Inflation of Westbay System Packers and Placement of Antifreeze Solution

The Westbay packers were inflated using a 3:1 proplyene glycol/water mixture provided by Lorax. The Westbay Model No. 6055 vented inflation tool was used for packer inflation. All the packers appear to have inflated normally. The data for inflation of each packer are provided on the Westbay Packer Inflation Records included in the Appendices.

The packers were inflated in a specific sequence as part of a plan to introduce and control an antifreeze solution in the well annulus through the permafrost zone, with the exception of BH5-WB where no glycol/water mixture was introducted as there is no fluid in the annulus between the HQ and the Westbay to flush out of the permafrost zone.

The sequence of tasks for introducing 3:1 proplyene glycol/water mixture is illustrated below:

- A set of two packers positioned inside the HQ rods immediately below the expected base of permafrost are inflated.
- The pumping port above the upper inflated packer was opened.
- A 3:1 mixture of water and propylene glycol supplied by Lorax was pumped inside the Westbay tubing, out the pumping port and into the well annulus (HQ rods). Pumping continued until a return flow of the mixture was observed from the well annulus at ground level, thus indicating that the well annulus (HQ rods) was full of the antifreeze mixture.
- The pumping port above the upper inflated packer was closed.
- The remaining Westbay packers were inflated sequentially beginning at the bottom.
- The squeeze relief venting function of the packer inflation tool was disabled to prevent accidental release of tubing fluid to the formations.

4 EXCEPTIONS TO STANDARD INSTALLATION PROCEDURES

4.1 BH8-WB Release of Antifreeze Solution

There was an unintentional release of 3:1 propylene glycol/water mixture into the annulus of the borehole during the installation process.

1. Packer inflation was completed on May 5th. It was noted by the field crew on May 6th that about 42 liters of the water-glycol mixture had been released from inside the Westbay tubing during the squeeze relief venting by the packer inflation tool.
2. The release was reported on May 6th. After discussions it was decided by Lorax to conduct purging of the individual zones to determine the effect on the native fluid chemistry. This purging was done by the Westbay representative on May 8th to May 10th.
3. We understand that chemical analysis of retrieved samples yielded no detectable glycol mixture after field analysis.
   Lorax sent other samples for more detailed analysis offsite, and these results are not known.
4. The squeeze relief venting capability of the packer inflation tool was mechanically disabled to prevent a similar release in future wells onsite.
5. As a preventive measure against future occurrences, Westbay implemented changes to the field crew mobilization procedures to more clearly document any exceptions to the standard procedures.

After preventive measures were implemented, no further occurrences of propylene glycol/water mixture release occurred during the remaining installations.

4.2 BH5-WB Installation

BH5-WB was first drilled using air rotary to a depth of 200m. On completion it was determined that no water was present in the borehole. It was decided by Lorax to continue drilling to a depth 295m using a diamond coring drill rig. HWT casing was installed to 170m. The remaining 95m to TD was cored with HQ-size wireline equipment. On completion of the coring the water level in the borehole was at surface. The water level was monitored by Lorax, and it dropped to below 200m. It was determined at this point that the plan to introduce and control an antifreeze solution in the well annulus through the permafrost zone would not be followed as there was no drilling fluids that needed to be flushed out above the permafrost packers.

The sequence of events below describes the installation process and the unintentional positioning of the Westbay System.

1. The HQ rods used as a guide tube in BH5-WB were lifted into position, 200m below ground surface and hung permanently from the HWT surface casing using a casing clamp.
2. The borehole was sounded using a tag line supplied and operated by Lorax personnel to confirm total depth (TD) of the borehole (293m). Multiple attempts at sounding where conducted by Lorax and a few different depths were recorded, (291.8m, and 287m) it was uncertain whether the hole was at depth or some material had sluffed in. The unclear readings of TD led to the adjustment of the Westbay System design, removing some tubing components from the bottom to prevent unexpected landing too high in the borehole. The standard installation procedure for landing the Westbay System on bottom were changed to an alternative standard procedure which included suspending the Westbay tubing at ground surface.
3. Lorax approved the changes and signed the installation documentation.
4. Once all Westbay System components were lowered into the borehole, two packers in the HQ guide tube were inflated to hold the Westbay System in its final designed position. These packers would provide support to Westbay System while mobilization of the drill rig off site took place. The Westbay System top section was below the top of HQ rods at the end of shift, safely protected from possible damage.
5. The following morning the Westbay System was found to have had slid down the well 7.55m from top of the HQ rods and was resting on bottom of hole (293m).
6. It was speculated onsite that ice may have formed inside the HQ rods, decreasing the capability of the two inflated packers to support the weight of the Westbay completion string.
7. An additional 7.5m of Westbay tubing were attached to the downhole tubing and the “as-is” position of the packer seals were reviewed and accepted by Lorax.
8. A pre-inflation profile and hydraulic integrity test were carried out, as a QA check to show the Westbay System to be hydraulically sealed and functioning properly.
9. Based on the successful outcome of the QA checks, Lorax approved the inflation of the Westbay System packers as positioned in the borehole.
10. All packers seemed to have inflated normally and the well is operating to designed specifications.

5 FLUID PRESSURE MEASUREMENTS

After packer inflation was completed, fluid pressures were measured at each measurement port. At that time, the in-situ formation pressures may not have recovered from the pre-installation activities and potential groundwater pressure increases in monitoring zones that may result from packer inflation. This latter effect may be more likely to occur in monitoring zones located in low-permeability geological formations. Longer term monitoring may be required to establish representative fluid pressures.

A plot of the piezometric levels in all zones in each well is shown on Figure 4 in the Appendices. The data were examined to confirm proper operation of the measurement ports and as a check on the presence of annulus seals between monitoring zones. The calculation sheets for the pressure profiles of the Westbay System are also enclosed in the Appendices.

6 OPERATOR TRAINING

Training was provided to Mr. Jordi Helson, Mr. Chris Bourque, and Ms. Laura Findlater of Lorax. The training covered the following areas:

- Operation and maintenance of Model 2531 Sampler Probe and MAGI controller in pressure profiling, sample collection.
- Cable reheading and troubleshooting.

Mr. Jordi Helson, Mr. Chris Bourque, and Ms. Laura Findlater are certified for un-supervised operation and field maintenance of this Westbay equipment.

MOSDAX Transducer Position

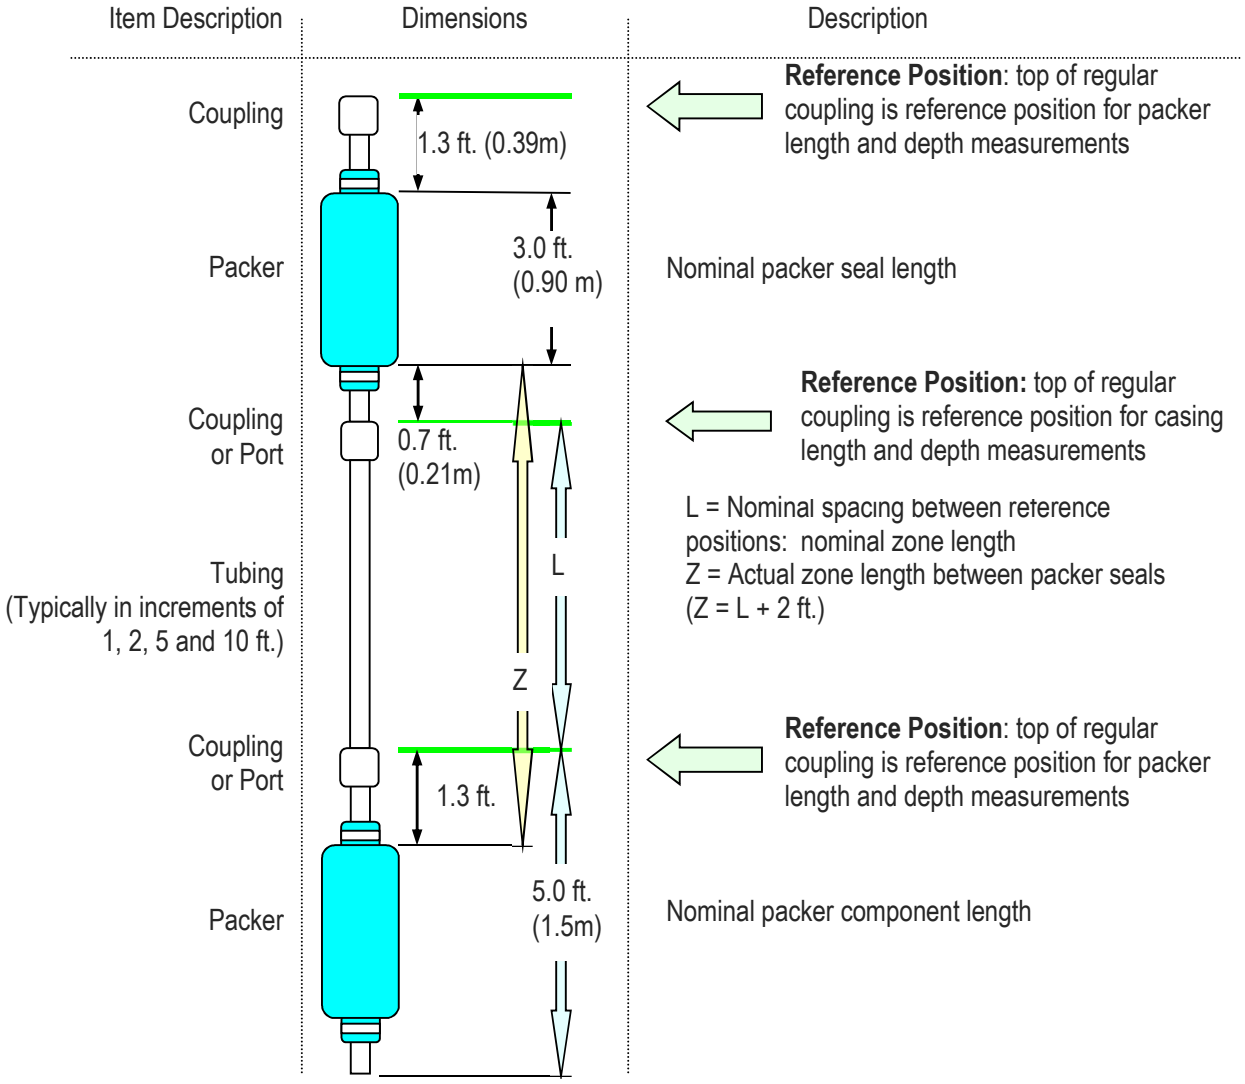
Figure 1: MOSDAX Transducer Position

Dimensions of Packer Seals and Monitoring Zones. 0238 Packers



Discussion Points:

- The top of a coupling (Regular Coupling, Measurement Port or Pumping Port) is the reference point for describing nominal depths and nominal lengths. Actual positions of packer seals and zone lengths are determined with respect to the appropriate reference positions.
- Packer Position Example: A packer with a nominal depth of 50 ft. (15.2m), will have a nominal packer seal position of 51.3 to 54.3 ft. (15.59 to 16.49m)
- Zone Length Example: A zone whose upper packer is at 50 ft. (15.2m) and bottom packer is at 70 ft. (21.3m) will have a nominal zone length of 15 ft. (4.6m) and an actual zone length (between packer seals) of 15.0+1.3+0.7 = 17.0ft. (4.6 + 0.39 + 0.2 = 5.19m)
- Information on the position of Measurement Port Valve and MOSDAX Transducer sensor, used for detailed calculation of piezometric level measurements, are described separately.

APPENDICES

APPENDIX: Monitoring Well: MW-16-01WB

1 INTRODUCTION

This report and the attached Appendix document the technical services carried out by Westbay Instruments (Westbay) under Lorax Environmental Services Ltd. P.O. No. A362-4. A Westbay System completion was installed in borehole MW-16-01WB at the Kaminak Gold site near Coffee Creek, Yukon Territory.

This report documents the installation tasks and related QA checks.

2 PRE-INSTALLATION ACTIVITIES

Borehole MW-16-01WB was drilled using an air rotatory method at a nominal 4.5-inch diameter to a depth of 120.1m. Permanent surface casing was installed to bedrock in the borehole. A string of HQ-size drill rods (nominal 76mm ID) was permanently installed to 68 meters depth before installation of the Westbay System.

3 INSTALLATION

Westbay technical services representative Mr. Mark Lessard was on site for the installation from September 30 to October 5, 2016. Lorax representatives Mr. Andrew Solod and Mr. Chris Bourque were on-site to assist and supervise the work.

Table 1, Summary of Westbay System Completion

Monitoring Well No.	Installation Dates 2016	Borehole Depth (m)	Depth of HQ rods (m)	MP38 Tubing Length (m)	No. Monitoring Zones
MW-16-01WB	Oct 1 - 3	120.1	68	118.0	4

(Note: all depths are with respect to ground surface. Monitoring well reference elevations were not available at the time of writing).

The Westbay System was installed according to the procedure described below.

3.1 Preparation of Westbay System Design

Packer locations and the projected depth of permafrost (about 60m) for the borehole were provided to Westbay by Mr. Andrew Solod of Lorax. A well design was created based on these depths. The well design was used to prepare a Westbay Completion Log, which specifies the location of components in the well. The log was reviewed and approved in the field by Mr. Solod prior to installation of the well. The Westbay Completion Log as approved was used as an installation guide in the field. A field copy of the log is in the Appendix.

A measurement port coupling was included in each primary zone to provide the capability to measure fluid pressures and to collect fluid samples. Measurement port couplings were also included in QA zones to provide QA testing capabilities. A pumping port was placed above the top packer located directly above the expected base of permafrost in the completion. This pumping port was placed as part

of a plan to introduce a 3:1 propylene glycol/water mixture into the steel casing adjacent to the permafrost zone.

Mr. Andrew Solod of Lorax requested that optional synthetic (PET) filters were not to be installed over the measurement port couplings.

3.2 Layout of Westbay System Components

Prior to Westbay System installation, the Westbay System components were set out on a rack near the borehole according to the sequence indicated on the Westbay Completion Log. Each component was numbered beginning with the lowermost as an aid to confirming the proper sequence of components. The appropriate Westbay System couplings were attached to the tubing sections. Magnetic location collars were attached 0.6 meters below the top of the measurement port in each primary zone.

Each component was visually inspected. Serial numbers for each packer, pumping port and measurement port coupling were recorded on the Westbay Completion Log. The well component layout was confirmed with the log before the components were lowered into the borehole.

3.3 Lowering of Westbay System Components

The Westbay System components were lowered into the borehole by hand, through permanent HQ drill rods (nominal 76mm ID) to 68 meters and open borehole to total depth. Each tubing joint was tested with a minimum internal hydraulic pressure of 150 psi for one minute to confirm hydraulic seals. A record of each successful joint test and the placement of each component are noted on the Westbay Completion Log by check marks.

A 3:1 water/propylene glycol mixture supplied by Lorax was added to the Westbay completion when necessary to counter buoyancy effects while components were lowered into the borehole and for testing of joint seals during lowering.

3.4 Hydraulic Integrity Testing

After the Westbay System components were lowered into the borehole, the water inside the tubing was monitored at a depth different from the open borehole water level for a minimum period of thirty minutes to confirm hydraulic integrity of the tubing. The data from the hydraulic integrity test is shown in Table 2 below.

Table 2, Borehole and Westbay Tubing Water Level

Well number	Borehole water level (ground surface)	Westbay tubing water level (below top of Westbay)
MW-16-01WB	ground level (artesian)	37.310 m

3.5 Positioning of Westbay System Completion

The final position of the guide tube is illustrated on the Summary Completion Log in the Appendix. The Westbay System tubing was positioned as indicated on the cover page of the Summary Completion

Log. Ground surface was used as zero reference for the installation. The Westbay System components were supported in this position while packer inflations were carried out.

The positioning of the Westbay System is based on the "nominal" lengths of Westbay System components. The positioning calculations do not include allowances for borehole temperature or deviation effects.

The attached figure titled “MOSDAX Transducer Position” provides information to correlate the position of MOSDAX Transducer sensors to the reference position at the top of the Measurement Port. The attached figure titled “Dimensions of Packer Seals and Monitoring Zones” outlines the calculations used to determine the packer centerline depths and zone length.

The Summary Completion Log and Table 4, shows the final “as-built” locations of key components in the well, and Table 5 shows the final “as-built” locations of all components in the well, are included in the Appendix.

3.6 Pre-inflation Profile

Prior to inflating the packers, a pre-inflation pressure profile was carried out in the Westbay System to confirm the proper operation and position of measurement ports and magnetic collars. The data confirmed proper operation and position of all measurment ports (Figure 3). The data for the pre-inflation profile for the well is located in the Appendix.

3.7 Inflation of Westbay System Packers and Placement of Antifreeze Solution

The Westbay packers were inflated using a 3:1 proplyene glycol/water mixture provided by Lorax. The Westbay Model No. 6055 vented inflation tool was used for packer inflation. All the packers appear to have inflated normally. The data for inflation of each packer are provided on the Westbay Packer Inflation Records included in the Appendix.

The packers were inflated in a specific sequence as part of a plan to introduce and control an antifreeze solution in the well annulus through the permafrost zone.

The sequence of tasks for introducing 3:1 proplyene glycol/water mixture is illustrated below:

- A set of two packers positioned inside the HQ rods immediately below the expected base of permafrost are inflated.
- The pumping port above the upper inflated packer was opened.
- A 3:1 mixture of water and propylene glycol supplied by Lorax was pumped inside the Westbay tubing, out the pumping port and into the well annulus (HQ rods). Pumping continued until a return flow of the mixture was observed from the well annulus at ground level, thus indicating that the well annulus (HQ rods) was full of the antifreeze mixture.
- The pumping port above the upper inflated packer was closed.
- The remaining Westbay packers were inflated sequentially beginning at the bottom.
- The squeeze relief venting function of the packer inflation tool was disabled to prevent accidental release of tubing fluid to the formations.

4 FLUID PRESSURE MEASUREMENTS

After packer inflation was completed, fluid pressures were measured at each measurement port. At that time, the in-situ formation pressures may not have recovered from the pre-installation activities and potential groundwater pressure increases in monitoring zones that may result from packer inflation. This latter effect may be more likely to occur in monitoring zones located in low-permeability geological formations. Longer term monitoring may be required to establish representative fluid pressures.

A plot of the piezometric levels in all zones in the well is shown on Figure 4 in the Appendix. The data were examined to confirm proper operation of the measurement ports and as a check on the presence of annulus seals between monitoring zones. The calculation sheet for the pressure profile is also enclosed in the Appendix.

MOSDAX Transducer Position
