1 INTRODUCTION

1.1 INTRODUCTION TO THE ENVIRONMENTAL ASSESSMENT REPORT

The Anvil Range Mine Complex, located in Faro, Yukon, operated from 1969 to 1998 inclusive of several temporary closures. Mining and milling operations permanently ceased in early 1998 shortly after the owner, Anvil Range Mining Corporation ("Anvil Range"), filed for creditor protection under the Companies' Creditor Arrangement Act. Deloitte & Touche Inc. was appointed Interim Receiver ("Interim Receiver") of Anvil Range pursuant to an order ("Interim Receivership Order") of the Ontario Court (General Division) ("the Court") (now the Superior Court of Justice) in April 1998.

The site is managed by the Court Appointed Interim Receiver, Deloitte & Touche Inc.

Steps to renew a

licence include CEAA and licence application The Interim Receiver has overseen the management of the property under the terms of the water licences in addition to the Interim Receiver's mandate to receive, preserve, protect and realize upon Anvil Range's assets. The Interim Receiver has worked with the Department of Indian Affairs and Northern Development ("DIAND"), the Yukon Territorial Government ("YTG"), the Town of Faro, the Ross River Dena Council, and other stakeholders to manage environmental programs that are required to protect the receiving environment.

The mine complex is currently regulated under two water licences, which specify the terms and conditions under which the licence holder (i.e. Anvil Range) can discharge water into the natural environment. The Faro mine site operates under licence QZ95-003 (formerly IN89-001) and the Vangorda Plateau mine site operates under licence IN89-002. The water licences were granted by the Yukon Territory Water Board under the Yukon Waters Act. Both licences will expire December 31, 2003.

The Interim Receivership Order grants the Interim Receiver the authority to "apply for any permits, licences, approvals or permissions on behalf of [Anvil Range] as may be required by any government or regulatory authority". In order to ensure that regulatory licencing that allows for the continued performance of necessary environmental protection activities, remains in place, the Interim Receiver filed documents, in May 2002, to initiate the process for application to the Yukon Territory Water Board for a single integrated licence for the mine complex for the period from January 1, 2004 to December 31, 2008 (5 years).

Two overall steps are involved in the renewal and integration of the water licences:

1. A review process under the Canadian Environmental Assessment Act ("CEAA") which is required, in part, due to the disbursement of federal funds for the maintenance of this property. The review is focussed on the activities described in an Environmental Assessment Report ("EAR") that is submitted by the proponent following guidelines provided by DIAND; and

The CEAA process was initiated with a Project Description submitted in May 2002

This Environmental Assessment Report (EAR) is presented in three volumes plus a standalone EAR summary document and a companion document being the new mechanism for development of a closure plan 2. An application to the Yukon Territory Water Board for a water licence renewal.

To initiate the CEAA process, the Interim Receiver submitted a Project Description in May 2002 that described the proposed activities for the proposed licence period. A Project Description Supplement was submitted in September 2002 in response to questions raised regarding the Project Description. At that time, preparation of a Final Closure and Reclamation Plan ("FCRP") for the mine complex was included into the Interim Receiver's scope of work.

Guidelines for preparation of the EAR were issued by DIAND in March 2003. The final scope of the project, as described in the Guidelines focussed solely on care and maintenance activities and excluded the development of a Final Closure Plan. This change was based on the announcement by DIAND in January 2003 that the development of a FCRP would be undertaken by the closure Project Team that would be formed for this specific purpose.

This EAR has been prepared to comply with the Guidelines provided by DIAND and to provide the information necessary to enable a screening decision per the CEAA.

The EAR is a three volume document:

- 1. Volume I provides a description of the existing facilities, a description of the proposed activities and a description of the adpative management program.
- 2. Volume II describes the current environmental conditions at the mine site.
- 3. Volume III describes the impacts of the proposed activities on the existing conditions at the mine site.

A general reference between the information requested in the Guidelines and location of that information in the EAR is provided in the table below. A detailed conformity table is appended to each volume (Appendix A).

Information Reference Locations

Guideline Reference	EAR Reference
2.0 Executive Summary	Volume I
2.1 Project Summary	Volume I
2.2 Project Description	Volume I
2.3 Environmental Setting	Volume II
3.0 Environmental Effect Assessment	Volume III

The three-volume EAR is summarized in a standalone summary document, which provides a summary of the information and conclusions of the EAR.

While closure planning is not a specific, integral part of the Environmental Assessment Report, a document titled Anvil Range Mine Complex: Closure Planning Project Management, designed to address the planning process for the

> Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 1-2

final closure of the site, will be submitted by the closure Project Team at a later date.

1.2 INTRODUCTION TO VOLUME II – DESCRIPTION OF THE EXISTING ENVIRONMENT

1.2.1 OVERVIEW

The context that overarches both the selection of the proposed care and maintenance activities and the development of the environmental assessment (and the assessment framework) is that the Anvil Range property exists as a property resulting from former mining and milling activities. This property has recognized environmental liabilities. The proposed care and maintenance activities and the timeframe of the proposed licence were selected to allow the property to be maintained while allowing sufficient time for a FCRP to be developed. As such, the assessment framework described below was developed on the basis that the proponent of the proposed project (the Interim Receiver) is not proposing to start a new mine in the next five years, nor to close the property in the next licence term. As mentioned in the introduction to the EAR, closure planning is the responsibility of the government and will be addressed in a subsequent document entitled "Anvil Range Mine Complex: Closure Planning Project Management".

The premises described above drove the development of the following environmental assessment framework:

- The **spatial boundaries** of the assessment follow standard environmental assessment methodology. The effects assessment is based on two spatial scales: a local scale, the local study area; and at a regional scale, the regional study area.
- The temporal boundary for the project, scoped as a care and maintenance project in the March 11 2002 Guidelines from DIAND Environment Directorate, is defined as the five-year timeframe from 2004 to 2008. The effects assessment for the project is based on this timeframe and compares the project to conditions existing during the 1998 to 2002 care and maintenance timeframe. This point of comparison was chosen because a comparison to pre-mining condition would be a hypothetical one and would not reflect the reality that this site currently exists and that care and maintenance activities are on-going. The assessment of care and maintenance effects on the environment is therefore aimed at determining whether the proposed care and maintenance activities are adequate for the next five years and can maintain the property in a state comparable to that achieved over the 1998-2002 timeframe, where the site monitoring information demonstrated that regulatory limits were consistently achieved (as per the water licence).

The implication of the chosen environmental assessment framework is that effects being evaluated are relative rather than absolute in nature. As such, the proposed care and maintenance activities should, by definition, result in a neutral impact on the environment in comparison to 1998-2002.

The information presented in Volume II of the EAR (Description of Existing Environment) is primarily intended to support the determination of environmental effects according to the framework described above. These effects are presented in Volume III (Environmental Effects Assessment).

In addition, the information presented in Volume II was designed to support additional objectives. It is the understanding of the Interim Receiver that the Responsible Authorities, as well as other interested parties, may review the information available around pre-mining, historical and existing conditions with the intent of understanding the impacts of the property itself on the environment in comparison to the pre-mining conditions. It is the understanding of the Interim Receiver that the driver behind this broadened review focus is to underscore the need for closure planning and implementation, by referencing closure planning and implementation as required additional mitigation for this project. As mentioned above, this additional mitigation (closure planning) is the responsibility of the closure Project Team.

As such, the information presented in Volume II was researched and presented with the following objectives in mind:

- 1. respect the requirements of the March 11, 2003 Guidelines issued by the DIAND Environment Directorate.
- 2. support the assessment of effects related to the proposed care and maintenance activities for 2004-2008 in comparison to those occurring the 1998-2002 time frame.
- 3. support the additional review objectives that reviewers of this document may have (as described above).

The information, as it is available, that may be needed to support the third objective is included in both Volume II of the EAR, as well as in Volume II of the original Project Description filed with the then DIAND Environment Directorate in May 2002. This information includes data about pre-mining, historical and existing conditions, as well as site-characterization as it is currently understood. The bulk of the information that could be required for this type of review, if undertaken by the reviewers, is found in Volume II of the original Project Description (May 2002). The present Volume II of the Environmental Assessment Report, as mentioned above, is primarily intended to support the assessment of effects relating to care and maintenance activities in relation to 1998-2002. However, this volume also provides additional historical or site characterization information that would have been either researched or collected in the summer of 2002 that was not included in Volume II of the original Project

The May 2002 Baseline report may be taken as a general reference for the information presented in this report

> Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 1-4

Description (May 2002). A "road map" to this information is described in the next section.

1.2.2 INFLUENCE OF PAST MINING ACTIVITIES ON THE DESCRIPTION OF THE EXISTING ENVIRONMENT

The amassed environmental information, as described both in this volume and in the 2002 Baseline Report, clearly indicates that past (i.e. pre-1998) mining activities have had a demonstrable impact on the aquatic and terrestrial receiving environments. Furthermore, in some cases, the environmental information demonstrates that some of the mine facilities that were operated or created prior to 1998 (such as the Rose Creek Tailings Facility, for example) continue to have an ongoing impact on the receiving environments.

These historical (i.e. pre-1998) environmental impacts can be summarized as:

Air Quality: There is no scientific baseline data on historical air quality but traditional knowledge, experience at similar projects and indirect evidence from other studies indicate that effects would have occurred due to mine operating activities. (Volume II Section 2.1.3)

Streamflow in the Receiving Environment: Construction and operation of mine facilities, diversion and interception of surface water and discharge of water from treatment systems substantially altered streamflow in the receiving environment. (*Volume II Section 2.5.2; 2002 Baseline Report Section 4.2.4*)

Surface Water Quality in the Receiving Environment: Runoff from rock dumps, the plantsite, roads and other developed areas, groundwater discharge to surface in some areas, discharge of (generally compliant) water from water treatment systems and spills and other unforeseen events have resulted in degraded water quality in Rose and Vangorda Creeks as compared to upstream reference locations and general guidelines. (Volume II Section 2.5.4; 2002 Baseline Report Sections 4.2.6 and 4.2.8) A preliminary contaminant loading model has been developed that identifies contaminant source areas. (Volume II Section 3.3; 2002 Baseline Report Appendix A)

Groundwater Flow in the Receiving Environment: Interception of subsurface flow in pits and ditches, changes to groundwater recharge and discharge areas (either increasing or decreasing rates) and active pumping to surface for water supply altered groundwater flow patterns substantially within the immediate mine area (*Volume II Section 2.5.3; 2002 Baseline Report Section 4.2.5*)

Groundwater Quality in the Receiving Environment: Seepage to ground from mine facilities such as rock dumps and tailings impoundments has had a negative impact on groundwater quality in the immediate mine area. (Volume II Section 2.5.5; 2002 Baseline Report Sections 4.2.7 and 4.2.9) Comprehensive investigations into groundwater quality in the Rose Creek Valley aquifer have been carried out in 2001 and 2002. (Volume II Sections 2.5.5 and 3.4; 2002 Baseline Report Section 4.2.7)

Fish Habitat Integrity: Construction of mine facilities such as the Fresh Water Supply Dam, the Rose Creek Diversion Canal and the North Fork Rock Drain substantially altered the fish habitat in Rose Creek. Fish habitat in Vangorda

🗖 Gartner Lee

Creek has not been similarly altered because the habitat is restricted to the lower reaches downstream of mine facilities. (Volume II Section 2.5.2; 2002 Baseline Report Section 4.2.4)

Fish Population Health: There is no scientific baseline data on historical fish health or quality, however traditional knowledge, experience at similar projects and indirect evidence from other studies indicate that effects would have occurred due to mine operating activities. (*Volume II Section 2.1.3*)

Wildlife Habitat Integrity: Construction of mine facilities altered or removed wildlife habitat from use by occupying the land. Further, While there is (Volume II Section 2.7.4; 2002 Baseline Report Section 4.3)

Wildlife Population Health: There is no scientific baseline data on historical wildlife health, however traditional knowledge, experience at similar projects and indirect evidence from other studies indicate that effects may have occurred due to mine operating activities. Nonetheless, the information indicates that the local population of Fannin Sheep remained healthy throughout the mine operating period. (*Volume II Sections 2.7.4 and 2.9; 2002 Baseline Report Section 4.3*)

The proposed care and maintenance activities, as described in Volume 1 of this report, are aimed at mitigating in a short-term context the impacts related to past mining activities. In addition, the proposed care and maintenance activities includes 1) monitoring of effects, and 2) an Adaptive Management Plan that provides a response framework that will be implemented if issue-specific triggers are activated.

Future mitigation of environmental effects related to past mining activities will be the focus of the FCRP that is to be developed by the closure Project Team.

1.2.3 INTEGRATION OF TRADITIONAL KNOWLEDGE

1.2.3.1 Overview

The CEAA and the project specific Information Guidelines require that First Nations traditional knowledge is to be integrated into the EA. The existing body of traditional knowledge related to the Faro mine complex was supplemented, for this EA report, by additional knowledge gathering interviews. The pre-existing body of information consists of two sets of interviews, described below, as well as previously conducted studies described in Volume II, Section 2.9.2.1. Per Sections 1.2.3.1 and 1.2.3.2. below, this information is included in Volume II, Description of the Existing Environment, and in Volume III, Environmental Effects Assessment. In addition, consultation was undertaken during the environmental assessment process regarding the proposed care and maintenance activities. The consultation activities, the identified issues and their integration into the proposed project are described in Volume 3, Section 3 (First Nations and Public Consultation).

A series of interviews were conducted by anthropologist Sheila Greer with selected elders of the Ross River Dena community in December of 1999 to

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 1-6

confirm if the findings of the Weinstein study were still considered valid and to record any additional information regarding land use (Greer 2000).

During the week of March 24, 2003, further interviews were conducted with Ross River Dena members to document current traditional use patterns in the study area, as well as traditional knowledge related to environmental concerns that might be related to the mine. These interview sessions also sought permission to use or share with a wider audience, through the EA process, earlier documented use of and traditional knowledge regarding the Faro mine area, particularly that recorded by Greer in 1999.

The 2003 interviews were conducted by Doris Dreyer, in her capacity as a researcher for the RRDC, and Testloa George Smith, RRDC member and researcher. Anthropologist Sheila Greer assisted with the initial three interview sessions, with Ms. Dreyer and Mr. Smith carrying out the balance of the interviews. An Information Sharing Protocol outlining the terms by which any traditional knowledge data assembled by the project would be shared was put in place in order for the interview work to proceed. As well, both Ms. Greer and Ms. Dreyer signed letters of confidentiality acknowledging that the knowledge and information they were collecting was privileged and the property of the Ross River Dena Council.

The traditional knowledge available for consideration in this assessment includes (1) a report titled Ross River Dena Traditional Use Study for the Faro Mine Water License Application (2004 to 2008) prepared by Doris Dreyer and Testloa George Smith (excluding transcripts or interview notes); (2) one of the 1999 interviews conducted by Ms. Greer, for which permission to share the knowledge released was granted on March 26, 2003; and (3) that which Ms. Greer heard during the interviews she participated in on March 25^{th} & 26^{th} . In these sessions the interview participants indicated their willingness to have the information they were providing (and had provided in the case of one of the 1999 interview) shared with a wider audience. Note that, as per the terms of the Information Sharing Protocol, the individuals who provided the information are not identified, and that in respect of the protocol, Ms. Greer did not take notes during these sessions.

1.2.3.2 Description of the Existing Environment

Traditional knowledge has been incorporated into the Description of the Existing Environment described in Volume 2 of this report, as it became available.

The discussion of wildlife communities in the study area resulting from the 2003 interviews provided information regarding wildlife health and movements related to activities at the mine site.

Additionally, the 2002 preliminary study of effects in the terrestrial environment was motivated, in part, by issues raised by the community of Ross River regarding the potential effects of wind blown contaminants on wildlife and

vegetation. The follow up studies that are proposed for 2003 to 2005 (described in Section 10, Volume I) are a direct continuation of this collection of scientific data that is required to produce a mitigation plan (as proposed to be completed by the end of 2005).

1.2.3.3 Effects Assessment

The accumulated traditional knowledge was considered along with scientific data in the selection of VECC's and indicators, in the assessment of effects and significance and in the proposed follow up studies. This is described in Volume 3, Environmental Effects Assessment.

1.2.4 LOCAL AND REGIONAL STUDY AREAS

The LSA extends from the background water quality sites upstream of each mine to the first monitoring point downstream of where the effluent stream enters receiving waters

RSA's have been defined for the environmental and social components where an impact assessment is completed The local study area (LSA) is based on the physical and hydrologic footprint of both mine sites, including the Haul Road (Figure 2), as this is the area of immediate influence on the environment as a result of care and maintenance activities and the area of interest as per the water licences. The LSA extends from the site-specific background water quality sites upstream of each mine to the first monitoring point downstream of where the effluent stream specified in the existing water licence enters receiving waters.

The LSA includes Faro Creek and the North and South Forks of Rose Creek and extends downstream to Site X14, where effluent discharged from Sites X5 and X13 mixes with Rose Creek downstream of the Faro mine site (Figure 3). As well, the LSA extends from the background water quality site (V1) on Vangorda Creek upstream of the Vangorda mine site, to the main stem of Vangorda Creek downstream of the mine, just upstream of the confluence with the West Fork (Figure 3). All water from the major project activities reports to this site. This LSA will apply to all discipline components.

A regional study area ("RSA") is defined to incorporate data outside of the project footprint that may be important to the determination of direct effects on an environmental component and to allow for examination of potential cumulative effects where project effects extend beyond the study area boundary. The boundaries of a RSA are established based on geographical or social boundaries as well as the "zone of influence" beyond which the effects of a care and maintenance activity have diminished to an acceptable or trivial state. As the geographical or social boundary and the zone of influence will vary depending on the environmental component (e.g. wildlife, fish, water quality), RSAs have been defined for the environmental and social components where an impact assessment is completed (in Volume III), as outlined in Table 1. Each study area is discussed in more detail in the component section of Section 2.

Table 1.Component Regional Study Areas

1.2.5 TEMPORAL BOUNDARIES

The current environmental and social conditions are those that have occurred during the care and maintenance phase (1998-2002) The environmental effects assessment is to be based on existing environmental and social conditions. As these conditions have changed substantially from premine development through mine operations to the existing care and maintenance status, the existing environmental and social conditions are considered to be those that have occurred during the care and maintenance phase between 1998 and 2002.

The description of the existing environment that is provided in this volume includes a discussion, where appropriate, of the historical (pre-1998) and existing (1998 to 2002) conditions for each environmental and social component. In this context, data collected prior to 1998 is considered historical and is presented in a summary format to provide context for a more detailed description of the existing conditions (1998 and 2002). In some cases such as hydrology and vegetation where the available information is descriptive rather than a series of discrete study points, changes to the natural environment that resulted from mine development and operation are discussed as a historical context and the available information is then discussed under existing conditions.

ENVIRONMENTAL AND SOCIAL SETTING 2

2.1 METEOROLOGY

2.1.1 METEOROLOGICAL DATA SOURCES

Meteorological data that is applicable for the local study area of the Anvil Range The data was collected Mine Complex has been collected since 1967. The station locations, information from the Anvil Range station and the Rose collected at each one and the period of collection record is outlined below in Table 2.

Table 2. **Climate Stations**

2.1.2 METEOROLOGY DATA

2.1.2.1 Temperature

The Anvil (Environment Canada) climate station was located at an elevation of 1158 mASL at the mine site. The station is no longer operable but temperatures were recorded from 1967 to 1980 (RGC 1996). The mean monthly temperatures are shown in Figure 6, and listed in Table 3 below.

Parameter	Jan	Feb	Mar	Apr	May	June	July	Aug	Sept	Oct	Nov	Dec	Year
Daily Max. Temp. (°C)	-15.1	-8.3	-5.3	2.2	9.3	16.0	17.5	15.2	9.6	1.6	-7.0	-12.6	1.9
Daily Min. Temp (°C)	-24.9	-18.8	-17.3	-8.7	-1.8	3.0	5.0	3.3	-0.9	-8.1	-16.7	-22.4	-9.0
Daily Temp. (°C)	-19.8	-13.9	-11.2	-3.2	4.0	9.9	11.5	9.5	4.6	-3.1	-11.6	-17.5	-3.4

Table 3. Mean Monthly Temperatures (°C) at Anvil Climate Station (1967-1980)

Mean and extreme temperatures The 1967 to 1980 temperature normals for the Anvil station show a mean annual temperature of -3.4° C. July is the warmest month, with a mean daily temperature of 11.5°C, and January is the coldest month, with a mean daily temperature of -19.8° C. Over the period of record, temperature extremes of 29.4 and -46.1° C have been measured.

2.1.2.2 Precipitation

Mean, maximum and minimum precipitation The mean annual precipitation at the Faro airport station is 304.7 mm, according to the 1978-2001 period of record (BGC, 2002). This total comprises roughly equal proportions of rainfall and snowfall as water equivalent. The mean monthly distribution of precipitation is plotted in Figure 7 and is listed in Table 4 below. The driest and wettest months are typically April and July, respectively, over the period of record. The greatest monthly precipitation measured over the period of record was 116.2 mm in August 2000.

Month	Mean (mm)
January	14.3
February	12.1
March	10.5
April	7.2
May	24.3
June	35.8
July	58.9
August	46.8
September	38.2
October	24.9
November	17.2
December	14.6
Annual Total	304.7

Table 4. Monthly Mean Precipitation (mm) at FaroAirport, Yukon (1978-2001)

2.1.2.3 Snowpack

Location, elevation, snow accumulation and density snow pack The Rose Creek snow course at the site was operated by DIAND from 1975 to 1985. The snow course was located near and at a similar elevation (1080 m) as the Rose Creek Tailings Facility. The accumulation of snow at this location typically begins in October, and the snow has generally melted by the end of April, although in 1985 it persisted into May. At maximum snowpack in March or April the density of the snowpack is about 200 kg/m³.

2.1.2.4 Wind

The prevailing wind direction is from the southeast. Using wind data measured at the Faro airport, and weather balloon data from the Whitehorse station, wind speeds at the Faro Mine Site and Vangorda Mine Site (at Mt Mye shelf and Grum Rock Dump) were estimated. Wind data from the Faro airport indicates that the prevailing wind direction is from the southeast, following the Tintina Trench. Table 5 and Figure 8 (RGC 1996) show the long-term monthly mean wind speed data collected at the Faro airport. The wind data was collected from an anemometer on a 10m tower near the airport terminal. The data is measured at each hour of the day, 365 days of the year. (dates not provided).

Month	Mean (m/s)	
January	1.4	
February	1.7	
March	2.2	
April	2.6	
May	2.7	
June	2.7	
July	2.6	
August	2.1

October	2.2	
November	1.7	
December	1.5	

Table 5. Long-term Monthly Mean of Wind Speed (m/s) at the Faro Airport

2.1.2.5 Lake Evaporation and Evapotranspiration

Evaporation was arbitrarily selected to represent conditions at the mine and evapotranspiration rates were adopted from the highest elevation station. Lake evaporation refers to evaporation from a free-water surface. The rate of lake evaporation was estimated from meteorological data using a computer program known as WREVAP which was developed by the National Hydrology Research Institute (Morton 1985). Since no trend in lake evaporation with elevation was evident, the calculated lake evaporation at the Whitehorse Airport was arbitrarily selected to represent conditions at the mine site. The average lake evaporation was determined to be 490 mm.

Evapotranspiration refers to evaporation from a land surface including transpiration from plants, and appears to decrease with increasing elevation. The rate of evapotranspiration was also estimated from meteorological data using a computer program known as WREVAP, developed by the National Hydrology Research Institute. As the best estimate, the calculated evapotranspiration values of 190 mm per annum, or 38% of lake evaporation, at the highest elevation station, Whitehorse Airport, were adopted for the mine site. Insufficient information is available, however, to extrapolate this trend to the mine site with more than a low degree of certainty.

2.1.3 AIR QUALITY

2.1.3.1 Historical Air Quality

All of the activities
associated with mining
and milling were
sources of air
emissionsThere is no historical monitoring data available to characterize either background
air quality or air quality during mining operations.Mining, milling and all of the associated activities were a source of air emissionsMining, milling and all of the associated activities were a source of air emissions
throughout the operating period from 1969 to 1998. In general these sources can
be characterized as follows:

Source	Characteristics
Mobile sources including mining machinery and transport vehicles	 Source of NOx, CO₂/CO and particulate emissions from internal combustion engines Fugitive dust emissions from site preparation and construction activities (overburden stripping, road and impoundment construction) Fugitive dust emissions from roadways during transport of ore and concentrate Fugitive dust associated with ore and concentrate handling and transport
Open pit and rock dumps	• Source of wind-blown particulate emissions with characteristics similar to waste minerals (parent rock)
Milling operations	 Fugitive dust emissions from ore crushing operations – characteristics similar to ore body Fugitive dust emissions from concentrate drying and handling operations – high Pb and Zn concentration Stationary sources of combustion gases (NOx, CO₂/CO and particulate) associated primarily with boilers
Tailings impoundments	Source of wind-blown particulate – characteristics generally similar to ore body and entriched in Pb and Zn relative to natural conditions

No data is available on the magnitude of atmospheric emission sources, or on ambient contamination levels inside mill buildings There were no licences for atmospheric emissions from the mine and there is no historical data available on the magnitude of these sources. Source controls were employed to minimize dust emissions from significant sources. For example, a baghouse was employed to control dust emissions from the ore crushing operation and a wet scrubber was used on the discharge from the concentrate dryer. Although these controls would have reduced emission levels, there is no performance data available and no record of stack surveys being conducted. The main stationary combustion source (mill boilers) were initially fired with coal and later converted to oil. Waste oil generated on the mine site was used to supplement fuel requirement and processed in the boilers. There were no emission controls employed on the boiler stacks.

Occupational health and safety sampling was conducted, generally inside mill buildings. However, there is no data available on ambient contaminant levels.

Changes in the source of emissions are generally associated with changes in mining activities Changes in the source of emissions would have occurred throughout the life of the mine. These would generally be associated with changes in mining activities and the excavation of the various pits over time. In addition, the location of tailings disposal also changed. For example, open pit mining shifted from the Faro open pit to the Grum and Vangorda open pits in 1992. The tailings disposal location was also changed at this time from the Rose Creek Tailings Facility to the Faro Main Pit. The Rose Creek Tailings Facility would likely become a more significant source of fugitive (wind-blown) emissions following the cessation of active tailings deposition in each of the three impoundments. In recent years, fugitive (wind-blown) emissions are visible primarily from the Intermediate Impoundment and this would likely have become more significant after the cessation of active tailings deposition in 1992.

2.1.3.2 Existing Air Quality

The contribution to ambient air quality from activities on the site post mine closure have not been assessed When active mining was terminated in 1998, operational atmospheric emission sources would have been eliminated. This would include all mill sources (crushing and concentrate production and boiler operation) and mine sources (ore removal). Activities on the site are currently restricted to care and maintenance of the tailings impoundments and transfer and treatment of water. These activities do not have the potential to generate significant atmospheric emissions. However, the open pits, rock dumps and tailings impoundments will continue to be a potential source of fugitive dust through wind erosion. No ambient air monitoring has been conducted during the 1998 to 2002 care and maintenance phase and the contribution of these sources to ambient air quality have not been assessed.

2.2 TERRAIN

2.2.1 PHYSIOGRAPHY

The Faro area physiography is divided into three areas: Tintina Trench, Swim Basin uplands areas, and the Anvil Range mountains The physiography of the Faro area can be broadly divided into three main areas (Bond 2001) and these are illustrated on Figure 9:

1. The broad, linear southeast-northwest trending Tintina Trench. The Trench is the dominant structural feature of the area and is occupied by the northward flowing Pelly River. The Pelly River floodplain has an elevation of approximately 600 mASL.

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-5

Gartner Lee

- 2. The upland areas of the Swim Basin (not shown) and the Vangorda Plateau. The bulk of the mine facilities are located on the Plateau. The Plateau generally parallels the Tintina Trench and is drained by the Vangorda Creek watershed to the south and Rose Creek to the northwest. The Plateau ranges in elevation from 1,000 to 1,400 mASL. A ridge of hills and mountains divide the Plateau from the Tintina Trench, most significant of these is Sheep Mountain to the southeast and Faro Peak to the northwest.
- 3. The third physiographic region is the Anvil Range mountains. The Anvil Range is located to the northeast of the Vangorda Plateau and rises to a series of peaks over 2000 mASL. The Range is characterized by steep, U-shaped alpine valleys terminating in cirques, and shattered rock and felsenmeer above 1770 m. Major summits in the Anvil range include Mount Mye, east of the Grum and Vangorda open pits and Mount Aho, north of the Faro Main Pit.

2.2.2 SURFICIAL GEOLOGY

Most of the Faro area landforms are attributed to the McConnell glaciation

The surficial material mainly consists of bedrock, and associated colluvium, glacial till, and glaciofluvial outwash sands and gravels The landforms and surficial deposits of the Vangorda Plateau have been shaped and are attributable to the last ice age which is estimated to have existed in the Yukon between 35,000 and 10,000 years ago. The southern Yukon was covered by at least four Cordilleran (i.e. mountain) ice sheets. These glaciations, from oldest to the youngest, are named the Nansen, the Kalza, the Reid and the McConnell (Bond 2001). The landforms of the Faro area are for the most part attributed to the youngest of the Yukon glaciations, the McConnell.

Significant surficial material in the study area consists of bedrock and associated colluvium, glacial till, and glaciofluvial outwash sands and gravels (Figure 10). Glaciolacustarine, modern alluvial and organic deposits, are found sporadically but are not discussed in detail herein. The following discussion of surficial materials is derived from the *Quaternary geology and till geochemistry of the Anvil district, central Yukon Territory* (Bond 2001):

Bedrock – bedrock and/or frost shattered bedrock (felsenmeer) is frequently found at surface in the alpine areas of the Anvil Range. Elsewhere, mountain slopes are covered in thin veneer of colluvium (materials derived from slope movement processes) derived from the local bedrock. Glacial deposits are relatively absent above 1,500 m, although meltwater channels were identified as high as 1,700 m. Solifluction is common above the tree line.

Morainal Deposits (Till) – glacial till is poorly sorted deposits of clay, silt, sand, gravel and angular boulders which is deposited directly from glacial ice. A thick blanket of till is found covering the Vangorda Plateau. In some locations where pre-glacial valley existed, the till deposits can be over 100 m thick (e.g. Grum valley). Generally till deposits thin to a veneer (<1 m) along the valley walls and are generally absent above 1,500 m. Till also commonly underlies glaciofluvial deposits in areas of former meltwater drainage. The area surrounding the Grum and Vangorda Deposits is characterized by a thick till blanket overlying bedrock.

MEC Ltd. identified six major landforms: morainal; glaciofluvial; organic; alpine colluvial; steepland colluvial; and alluvial **Glaciofluvial Deposits** – during the retreat of the glaciers, melting water derived from the decaying ice transported and deposited sand and gravel in the valley bottoms and associated lateral meltwater channels. These deposits are typically stratified to crudely stratified deposits varying from sand with some silt to cobble gravels. These materials are found as significant valley fills as in the Rose Creek valley, as kame terraces at the mouth of alpine valleys or as glacial terraces and complexes associated with the Vangorda Creek valley and the Tintina Trench. Glaciofluvial deposits host the Rose Creek aquifer which underlies the Faro Mine tailings facility. The Faro townsite is located on a major glaciofluvial (and glaciolacustarine) terrace with a well developed stagnant ice (i.e. hummocky terrain) glacial fluvial complex to the northwest of the townsite. The valley bottom glaciofluvial deposits are frequently covered by silts, sands and gravel derived from contemporary stream.

2.3 GEOLOGY

2.3.1 REGIONAL GEOLOGY

The lower part of the Anvil District geological sequence is the most important with respect to the ore bodies and is represented by the Mt. Mye and Vangorda Formations

The Mt. Mye Formation is represented by schists and the Vangorda Formation is represented by calcareous phyllites. The geology of the Anvil District has been described in detail in RGC 1996. A regional geology map, repeated from RGC 1996, is provided in Figure 11.

The stratigraphy of the Anvil District consists of regionally metamorphosed sedimentary bedrock, ranging in age from late Precambrian to Permian (approximately 900 to 250 million years ago). The degree of metamorphism ranges from moderate (schist) to low (phyllite). The lower part of the sequence, Silurian aged and earlier, as represented primarily by the Mt. Mye and Vangorda Formations, is the most important with respect to the Anvil Range ore bodies. During the Cretaceous, the meta-sediments were intruded by the Anvil Batholith, a granitic pluton that varies in composition from granite to granodiorite to quartz monzonite. A higher degree of metamorphism is generally observed near the Anvil Batholith contact. The meta-sediment rocks dip northeast and southwest, away from the Batholith.

The Mt. Mye Formation is represented by schists, with the dominant rock type being grey, non-calcareous, weakly carbonaceous phyllite with lesser interlayered black carbonaceous phyllite and schists. Mafic meta-igneous rocks, now amphibolites, are present locally but are volumetrically minor. A white, calc-silicate and marble marker horizon occurs about 500 to 700 m below the top of the Mt. Mye Formation, which has a structural thickness of at least 2,000 m (the base is not exposed).

The Vangorda Formation is represented by light to medium grey to greenish-grey calcareous phyllites. At higher metamorphic grade (amphibolite facies), the calcareous phyllite is transformed to calc-silicate rocks. Major interbanded units in the Vangorda Formation include meta-igneous greenstone, which is more common near the top of the Formation, and carbonaceous pelite. The Vangorda Formation varies from 0.5 to 2 km in apparent thickness.

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-7

Deloitte & Touche

Five ore deposits have been identified.

Five ore deposits have been identified in the Anvil Range area: Faro, Grum, Vangorda, Grizzly (previously DY) and Swim. Mining is complete (depletion of known economic reserves) in Faro and Vangorda deposits, partially complete in Grum and has not occurred in Grizzly or Swim. The three deposits at which mining has taken place are described below.

2.3.2 FARO ORE BODY

Rocks of the Faro Mine site were metamorphosed in the amphibolite facies of regional metamorphism. The result is that schists are more important at Faro than elsewhere, and the calc-silicate gneiss, a rock type not seen at other sites, is widespread as the major rock of the Vangorda Formation. The increased metamorphism generally tended to coarsen mineral grain sizes, including sulphide minerals.

The ore body consists of a stratiform zinc-leadsilver massive sulphide deposit, offset by faults with two main deposits, Zones 1 and 3 and a satellite deposit, Zone 2 Deformation is so complex and flattening into the metamorphic foliation is so pronounced at the Faro site that the geology appears to be a simple layer cake of stratigraphy. The ore-body is concordant to formational boundaries and is stratigraphically approximately 75 m below the top of the Mt. Mye Formation. It consists of a gently dipping, stratiform zinc-lead-silver massive sulphide deposit, offset by faults. The main deposit (Zones 1 and 3) was approximately 1.5 km long, 500 m wide and averaged 46 m thick. The satellite Zone 2 deposit was approximately 300 m long, 180 m wide and average 24 m thick.

The main ore body was composed of two zones (Zones 1 and 3) vertically offset by a normal fault as illustrated on Figure 12. This northeast trending fault, the Faro fault, is sub-vertical and bisects the main ore-body. The east block is down dropped approximately 50 m. A diorite dyke is intruded along the fault zone. The satellite Zone 2 ore body was geologically part of the same sulphide lens but was separated by normal fault offset. The Big-Indian – North Fork fault system separates Zone 2 from Zone 3. This fault set consists of several strands with a throw of roughly 75 m, west block down.

The Zone 2 Pit was one of the few areas where the Faro deposit was exposed on surface. Thus, a weathered mantle was present over part of the deposit. The Zone 2 ore body was at the edge of the overall Faro deposit and was rich in ribbon banded quartzite ore. Massive sulphide was limited and the ore grade was low compared to Zone 1 and 3 in the Main Pit. Anvil Batholith instrusives were found along the northeast side of the Zone 2 ore body.

2.3.3 VANGORDA ORE BODY

The Vangorda deposit has unusual orebody characteristics. The Vangorda deposit was a small deposit for this area and had a number of characteristics that made it unusual. These included:

- 1. Shallow depth and a greater degree of weathering;
- 2. Abundance of foot wall sulphides; and

3. Degree of development of strongly altered phyllites.

The Vangorda deposit was relatively close to the ground surface and was more affected by weathering than the other ore deposits of the district. The thickest part of the ore body occurred below a ridge of highly compacted till east of Vangorda Creek.

The Vangorda deposit consisted of one major sulphide horizon located about 50 to 120 m beneath the basal carbonaceous member of the Vangorda Formation. The host rocks for the deposit were dominantly non-calcareous phyllites. A number of thin horizons occurred above the sulphide horizon. These horizons were too thin or of too low a grade to be economically mineable, with the exception of the south-east end of the deposit where the ore horizons were shallow (resulting in a low stripping ratios). The deposit itself contains the same sulphide rock types as the other deposits in the Anvil District.

A major fault is found at the northwest end of the Vangorda Pit as illustrated in Figure 13. This fault truncated the ore body and juxtaposed the black graphitic phyllite of the basal member of the Vangorda Formation against the ore body.

2.3.4 GRUM ORE BODY

Characteristics unique to the Grum deposit	 The Grum Deposit, with mineable reserves of approximately 25 million tonne has a number of characteristics that make it unique. These include: 1. The high proportion of disseminated sulphide ore types compared to massivores; 2. The generally weak alteration overprint.; and 3. The complex, large scale, fold structure. 		
	The deposit was covered by up to 100 m of till and glaciofluvial silt, sand and gravel. The material fills a buried channel trending north-south through the southeast pit area. No notable weathering features are present at Grum as were observed at Vangorda.		
<i>Quartoze ore types form 50% of the Grum orebody reserves</i>	The Grum deposit consists of three to five highly contorted layers of massive and disseminated sulphide mineralization within a 150 m thick section of phyllite. The most important mineralized horizon occurs just beneath the basal carbonaceous member of the Vangorda Formation. There are thin low-grade horizons with the Vangorda Formation and more important horizons in the upper part of the Mt. Mye Formation. A unique feature of the geology of the Grum ore body is the presence of quartoze ore types, which formed up to 50% of the reserves. The other ore types are similar to the other deposits.		
The Vangorda Formation and the Mt. Mye formation are composed of phyllites	The Vangorda Formation at the Grum Deposit consists primarily of soft calcareous phyllites. They are not as strongly altered as at the Vangorda Deposit and are strongly calcareous. The Mt. Mye Formation at the Grum Deposit also		

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-9

The Vangorda deposit consists of one major sulphide horizon and there is a major fault at the northwest end of the Pit

consists of phyllites, which are non-calcareous and less distinctly banded than those of the Vangorda Formation.

Grum deposit faults There are several important faults at the Grum Deposit. The largest displacements occur on moderately dipping structures that truncate the deposit at both its northwest and southeast ends but do not crop out in the pit. A steeply north-west dipping fault set down drops the deposit about 60 m on the northwest. A myriad of smaller steeply dipping faults has also been mapped both underground and in the pit. Figure 14 illustrates geology for the ultimate design Grum Pit, which is larger than the existing excavation.

2.3.5 ROSE VALLEY GEOLOGY

The mine is situated within an area of discontinuous permafrost The mine area is situated within an area of discontinuous permafrost. At the mine site, north facing slopes and areas with older forest cover are more likely to contain permafrost. Permafrost ground, with varying degrees of ground ice content, was encountered during the construction of the Cross Valley Dam and the Rose Creek Diversion Channel. Felsenmeer is formed near the top of high hills due to frost action effects on exposed bedrock.

The surficial geology of the Rose Creek valley generally consists of colluvial, fluvial and morainal deposits forming a discontinuous cover over the bedrock. On the valley sides, bedrock is discontinuously covered with a veneer of morainal and colluvial deposits that increases in thickness towards Rose Creek. A complex assemblage of fan and outwash sand and gravels, dissected by stream channel and lacustrine materials fill Rose Creek Valley. Terraces and fans are prominent on the north side of the valley, where they, in part, underlie the existing tailings area.

Bedrock underlying the Rose Creek Valley and bedrock in the Vangorda and Grum Pits consists of Cambrian to Ordovician rocks of the Vangorda Formation Bedrock underlying the Rose Creek valley consists primarily of the Cambrian to Ordovician rocks of the Vangorda Formation. This formation is described as a "soft silvery grey calcareous phyllite with interbands of medium crystalline grey marble" (RGC 1996). This formation has been locally intruded by granodiorites and quartz monzonites of the Anvil Batholith. Foliation in the bedrock underlying the Rose Creek valley is mapped as generally parallel with the valley axis (west northwest to east southeast and dipping shallowly to the southwest (15 to 30 degrees) (Pigage 2001). The competence of the bedrock varies but in most cases is poor. Exposures were found to be easily eroded by freeze –thaw and stream flow processes. In places, the schist is reported as being weathered up to 2 m depth (Golder 1980).

2.4 GEOLOGICAL HAZARDS AND SEISMICITY

2.4.1 GEOLOGICAL HAZARDS OVERVIEW

BGC described an assessment of hazards based on a review of geological information and an assessment of mine infrastructure Geological hazards resulting from natural conditions have the potential to significantly impact facilities and infrastructure at a mine site. An assessment of hazards at the Anvil Range Mine Complex was described by BGC based on a review of surficial and bedrock geological information coupled with an assessment of climatic and topographic conditions related to mine infrastructure locations. The assessment utilized information provided in BGC 2001, which was a qualitative risk assessment for structures situated in the Rose Creek valley.

Some potential geological hazards that may exist at the Anvil Range Mine Complex consist of the following:

- 1. Landslides, in either soil or rock.;
- 2. Falls;
- 3. Debris torrents; and
- 4. Fault movements.

Consequences of landslides, falls and debris torrents The three types of slope movements: landslides, falls and debris torrents, have essentially similar consequences. Failure debris that travels into the mine complex area may impact either a pond of water, a water channel, the access roads or some other component of the mine infrastructure such as a pipeline, dam or treatment facility. If the debris falls into a pre-existing body of water, a wave could be generated that would overtop the water retention structure (a dam or dike). If the debris falls into a channel, then the channel could be blocked, or if the volume of debris is small, the hydraulic capacity of the channel will be changed. If the debris falls on the road, then access could be blocked. Other component specific consequences (e.g. complete damage to a water treatment pipeline) are possible as well.

Fault movements, a hazard related to the seismic risk assessment for a site, consists of the rapid movement of the ground beneath one of the site structures or channels. Fault movements, if severe, could potentially result in deformations or failure of dams or other earth structures.

2.4.2 SLOPE MOVEMENT AND FALLS

Slope stability issues are confined to local failures The majority of the natural soil located in the Anvil Range Mining Complex consist of granular soils; *i.e.* locally derived tills, glacial outwash deposits and fluvial deposits. These soils are not particularly prone to slope stability hazards, except for the mechanism of river erosion and within active fluvial fans. Even in these two cases, slope stability issues will likely be confined to local failures due to oversteepening and eroding water.

Colluvial deposits could provide erratic rockfalls or local slides

The areas most likely to experience rockfalls are the exposures located above the FWSD reservoir and the Rose Creek Diversion Canal. The colluvial deposits that have been mapped at the Faro Mine are either soils that are actively moving or soils that have moved downslope into their current position. The colluvial soils should be considered to be quasi-stable or in an active state of movement. These materials are typically located on the steeper sections of the surrounding Rose Creek or Vangorda Creek valleys and could provide erratic rockfalls into the valley or local small slides.

Unless in very weak rock masses, rockslides are controlled by the discontinuities within the rock mass. Most rock slopes failures can be classified as either: planar failures, wedge failures, toppling failures or circular failures. The initiation of failures would be dependent upon site-specific geological controls (foliation planes, joints, etc.) and the orientation and height of exposed surfaces.

For rock falls to occur, there needs to be exposed rock faces, steep slopes on the exposed faces and adverse geological controls. The areas of the Faro Mine site that are the most likely candidates for exposure to rock fall hazards are the exposures located above the Fresh Water Supply Dam ("FWSD") Reservoir (which is scheduled for removal by March 2004 as described in Volume 1) and the Rose Creek Diversion Canal. The steepness of the overall slopes in the area of the Anvil Range Complex range up to 30 degrees (based on Figure 10). Some local oversteepening in the area surrounding the creeks and rivers is likely. In addition, the exposed rock slopes are likely locally steeper than the general overall slope angles.

Earthquake loading should also be considered as part of any slope stability assessment. Earthquakes can have two main effects on the stability of the slopes; increased horizontal force in the slope that decreases the stability and liquefaction of soil within the slope or at the foundation. As noted for soil slides, the addition of earthquake loading will adversely affect the stability of rock slopes.

2.4.3 DEBRIS FLOWS

This may occur in the upper reaches of the surrounding mountains along some headwaters of the creeks. Debris flows consist of a spatially continuous movement where the soil/rock moves as a viscous liquid. This type of failure may occur in the upper reaches of the surrounding mountains and feed soil and rock into the Anvil Range Mine Complex. This type of failure would require steep slopes and debris within the steep area. It is envisioned that only in the high altitudes along some headwaters of the creeks that this type of failure could occur.

2.4.4 FAULT MOVEMENTS

The hazards include impacts to structures and slopes and rock slides. Faults occur throughout the Anvil Range Complex site area. A major regional fault is the Tintina Trench, located close to the study area. The major geological hazard related to faults is related to fault movements that induce earthquakes. If the fault is located in the immediate vicinity, then the direct movements of the fault can impact structures and slopes. The secondary geological hazard related to faults is in the local control of slides within the rock mass. The rockmass,

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-12

located at a fault zone, can generally be recognized by a zone of intense shearing, fracturing and brittleness of the rock. These factors combine to potentially form the boundaries of rock slides or falls.

Known faults within the Mine complex include the Rose Creek Fault, Vangorda Fault, Blind Creek Fault, and the Tie Fault.

2.4.5 SEISMICITY

Earthquakes can produce both ground ruptures and seismic shaking of the ground, depending upon the magnitude (M) of the earthquake, the distance from the epicenter and the local site-specific conditions. Both of these resultant occurrences have potential impacts on engineered structures, such as dams and other water diversion structures. Before any impact analyses can be undertaken on the various engineered structures, it is necessary to estimate the level of seismic shaking that a structure may undergo. This task is generally referred to as a seismic hazard assessment. Peak ground acceleration (PGA) values resulting from seismic events are stated as a percentage of gravity (g).

A number of studies of seismicity relevant to the Faro mine complex have been conducted over the life of the mine.

There are three approaches to seismic risk assessment that result in different site acceleration estimates Vick (1983) noted that there are three main approaches to seismic risk assessment that will likely result in different estimates of potential site acceleration values:

- 1. Historical seismicity approach examination and summary of the historic earthquake record proximal to the site in question.
- 2. Probabilistic approach refinement of the historical approach where the historical record is the basis of a probabilistic analyses to determine a unique probability of occurrence for each possible level of seismic acceleration.
- 3. Deterministic approach where an estimate of the maximum seismic acceleration is based on an assessment of available geological data without regard for past historic events. The geological data is used to determine the nearest fault and then to estimate the magnitude of the earthquake that would result on this fault. This approach is commonly applied in areas where active earthquake-generating faults exist. Generally, the acceleration estimated by this method is termed as "maximum" or "maximum credible".

A range of PGA's have been used for designing various facilities at the Anvil Range Mine Complex. In the "Abandonment Plan for Faro Mine Tailings" report, dated September 1981, Klohn Leonoff (Klohn) estimated PGA values based on two different approaches as follows:

- 1. 0.07g for a 475 year return period;
- 2. 0.10g for a 900 year return period;
- 3. 0.32g for a 10,000 year return period; and
- 4. 0.40g for Maximum Credible Earthquake (MCE).

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-13

Deloitte & Touche

It was recommended that the MCE be used as the closure design criteria

Statistical and historical analyses were used to estimate the MCE Klohn noted that the closure design criteria would be much different than the values used for an operating mine. Therefore, Klohn recommended that the MCE be used for the design criteria. The data available at that time was limited and a conservative approach was taken.

Based on the historical movement rates within the Tintina Trench, Klohn estimated that an earthquake with a magnitude of M6.5 could occur. Using an empirical formula that included the distance from the site to the location of the earthquake, a peak ground acceleration of 0.40g was estimated. Using the same methodology and an estimated M6.0 earthquake within the local faults of the Rose Creek Valley, a peak ground acceleration of 0.36 g was estimated for the site facilities.

Statistical analysis was also performed by Klohn, based on earthquake analysis provided by GSC Pacific Geoscience Centre (PGC). The 10,000-year event resulted in a peak ground acceleration of 0.32 g. The analysis was also performed to estimate the 475-year return period earthquake, which was determined to be 0.07g. The report noted that one method used to estimate the MCE was by doubling the magnitude of the 475-year event and that this would result in an MCE of 0.14 g.

In a Dome Petroleum memo dated September 1984, based on information supplied by the PGC, the seismic risk for the Faro area was calculated to be 0.063g for a 475-year return period and 0.08g for the 1,000-year return period event.

In a report dated March 1986, "Report on design and proposed construction, Rose Creek Water Reservoir Dam Raising" Kilborn Engineering performed pseudo-static analysis on the proposed dam raise. It was noted that the analysis was performed using a "conservative design earthquake" value of 0.15g. No quantification of the method used to determine this earthquake loading was made, nor was the return period for this earthquake mentioned.

In a report dated February 1989, Appendix I of the report entitled "1988 Performance Monitoring and Additional work on the Down Valley Tailings project: Faro Mine", Golder Associates Ltd. used a PGA value of 0.08g (475year return period) as part of an analysis of the geotechnical stability of the FWSD. It was noted that the earthquake parameters used for this analysis of the FWSD were based on the values employed in the 1980 design of the Down Valley Tailings containment project. The design earthquakes for that project were a PGA of 0.052 g (100-year return period) and 0.097g (200-year return period). The determination of these design earthquakes were based on a statistical analysis of historical earthquakes, based on data provided from the Pacific Geoscience Centre.

In a report dated November 1996, Appendix A of the report "Anvil Range Mining Complex – Integrated Comprehensive Abandonment Plan (ICAP)"

Various studies have been conducted to estimate the PGA and seismic risk.

Robertson Geoconsultants had an assessment of the seismic ground motions for the Faro area performed. This was based on historical data and the assumption that earthquake loading would be transmitted through rock. The PGA was estimated as follows:

- 1. 0.05g for a 475 year return period; and
- 2. 0.13g for a 10,000 year return period event.

The Robertson report noted that "there is no evidence of more recent displacement along the Tintina Fault and the fault is not included as an earthquake source zone in either the H or R zonations given in the GSC report, i.e. the fault is not considered active and no maximum magnitude has been defined for the fault. Thus, it is unrealistic to consider a deterministic estimate of seismic ground motions at Faro in which an earthquake is assumed to occur on the Tintina." This suggests the Klohn value for the MCE is larger than can be generated by the existing tectonic conditions.

In a report dated November 2001, entitled "Physical Stability Assessment of the Fresh Water Supply Dam" undertaken by BGC, the seismic loading values were as follows:

- 1. 0.063g for 475 year return period; and
- 2. 0.080g for 1,000 year return period.

Klohn Crippen, as part of a dam safety review at the Faro site in 2002, undertook a seismic hazard assessment using the computer program, EZ-FRISK[®]. Two seismo-tectonic models were used, namely the GSC-R model, which is based on historical seismicity and regional tectonics, and the GSC-H model, which is based on historical seismicity. The resulting PGA values were as follows:

- 1. 0.05g and 0.06g (GSC-R and GSC-H, respectively), for the 475 year return period;
- 2. 0.09g and 0.11g (GSC-R and GSC-H, respectively), for the 2,500 year return period;
- 3. 0.15g and 0.16g (GSC-R and GSC-H, respectively), for the 10,000 year return period;

SRK (2003) recently completed a seismic hazard assessment and arrived at the following estimates of the PGA:

- 1. 0.05g for 475 year return period; and
- 2. 0.15g for 10,000 year return period.

The deterministic analysis resulted in a much larger PGA than any of the statistical analyses. The majority of the analyses performed in order to determine the seismic design parameters for the Faro Mine were based on historical records (statistical method) and probabilistic determinations. The only deterministic estimation of the earthquake risk was performed by Klohn (1981). As listed in Table 6, the deterministic analysis resulted in a much larger PGA than any of the statistical analyses.

Study	Return Period Event				
	475	1,000	10,000	Estimated MCE (based on twice the 475 Year Event)	MCE
Klohn Leonoff (1981)	0.07g	0.10g	0.32g (probabilistic)	0.14g	0.40g (deterministic)
Dome/PGC (1984)	0.063g	0.08g		0.126g	
Golder (1989)	0.08g			0.16g	
Robertson (1996)	0.05g		0.13g	0.10g	
BGC/PGC (2001)	0.063g	0.08g		0.126g	
Klohn Crippen (2002)	0.05- 0.06g		0.15 – 0.16g		
SRK (2003)	0.05g		0.15g		

 Table 6.
 Summary of Earthquake Loadings

The above information indicates that the seismic loading design criteria have been quite variable in the 20 years that have been reviewed for the Faro area. It should be noted that the design horizontal acceleration determined for the 475year return period has been relatively consistent in this period from 0.05g to 0.08g. Using the suggestion provided in Klohn 1981 that the maximum credible earthquake (MCE) is twice the magnitude of the 475-year event, relatively consistent values emerge for the magnitude of this event, from 0.10g to 0.16g even though the single deterministic analysis resulted in a larger magnitude.

Two significant seismic events were measured at the Anvil Range Mine Site in 2002. On November 3, 2002 a magnitude 7.9 earthquake occurred approximately 120 km south of Fairbanks, Alaska. A second seismic event occurred on November 5, 2002 when a magnitude 4.6 earthquake occurred approximately 50 km south of Faro. Both events were felt by the mine staff at the mine site and it was noted that numerous aftershocks associated with both events could be felt in Faro. There were no impacts to site facilities as a result of these events. These events add to the earthquake record but they do not change the conclusions provided above in relation to earthquake return periods.

2.5 WATER RESOURCES

2.5.1 WATER RESOURCE STUDY AREA

The water resource study area includes the Rose Creek and Vangorda Creek watersheds Water resources include hydrology, hydrogeology and water quality environmental components. The water resource RSA is watershed based and includes both the Rose Creek and Vangorda Creek watersheds as shown in Figure 3. The existing conditions upon which the environmental effects

assessment is based is data available from 1998 to 2002, during care and maintenance activities. Historical information is also available and is presented under each component section below, to provide information and perspective on changes to each component, over time, as a result of mine activities.

The RSA for the Faro Mine Site is defined by all catchment areas upstream of the confluence of Rose Creek with Anvil Creek. This allowed assessment of any effects of mining activity on the Rose Creek to be assessed for impacts to Anvil Creek, the next receiving water body downstream. It also allows consideration of any effects at this point in the watershed in a cumulative effects assessment for activities in the Anvil Creek watershed and, ultimately, in the Pelly River.

The Vangorda Mine site RSA is defined by all catchment areas upstream of the confluence of Vangorda Creek with the Pelly River. This boundary allows the assessment of any mine effects on fish and fish habitat in lower Vangorda Creek. Any detectable aquatic effects at this point would need to be included in a cumulative effects assessment for activities in the Pelly River.

2.5.2 HYDROLOGY

2.5.2.1 Watershed Description

The Faro Mine site facilities are located within the Rose Creek watershed and the Vangorda Plateau Mine site is located within the Vangorda Creek watershed. Anvil Creek (including Rose Creek drainage) and Vangorda Creek are both tributaries to the Pelly River. The Rose Creek watershed is approximately 340 km^2 and flows to the 980 km² Anvil Creek watershed, which drains the southeast slopes of the Anvil Range Mountains to the Pelly River. The Faro Mine site facilities are within the Rose Creek watershed.

Vangorda Creek drains an area of approximately 90 km² via an east (mainstem) and west fork. Drainage from the south slope of Mount Mye flows into the main stem and drainage from the northwest slope flows into the west fork. The two forks join together just above the Town of Faro. The Vangorda Plateau Mine site is located within the Vangorda Creek watershed.

2.5.2.2 Historical Hydrological Changes

Initial development and on-going surface water management has changed the site hydrology Development of the complex resulted in significant changes to surface hydrology both during the initial development stages and on an ongoing basis as additional surface water management structures were constructed or existing structures were modified. These changes relate primarily to the interception and rerouting of surface flows in constructed diversion channels or the construction of surface water barriers that altered the downstream flow.

Initial construction of the Faro Mine Site (1968/1969) and subsequent activities involved construction of the facilities (listed in Table 7) that changed the surface hydrology.

Timeframe	Facility	Change to Hydrology
Initial Construction	Fresh Water Supply Dam	Introduction of manual control over winter flow rate in
	South Fork of Rose Creek	Rose Creek; delay in the release of freshet flows to Rose
	Dumphouse Dend	Creek
	Pumphouse Pond Faro Creek Diversion	Removal of water from Rose Creek to the mill
	Talo Creek Diversion	Rerouting of most flow from tributary to Rose Creek to tributary to North Fork of Rose Creek
	Original Tailings Impoundment	Addition of tailings supernatant into Rose Creek at an
		artificial (i.e. not natural) flow schedule
	Faro Main Pit	Interception of surface runoff and rerouting to various outflow pumping locations
	Mine Access Road	Consolidation of possible surface sheet flow and ground infiltration into discreet streams at culvert crossings
Mine Life	Rerouting of Faro Creek Diversion	Change of entry into North Fork of Rose Creek to current location
	North Fork of Rose Creek	Change of location of confluence with the South Fork and
	Diversion	possible change to groundwater recharge characteristics
	Groundwater recharge ponds in North Fork of Rose Creek	Possible increase of surface water losses to ground
	Upper leg of Rose Creek Diversion Canal	Rerouting of Rose Creek through a constructed channel
	Second Tailings Impoundment	Change of location of entry of tailings supernatant into Rose Creek
	North Wall Interceptor Ditch	Rerouting of water from Guardhouse Creek drainage into a constructed channel and change of entry location into Rose Creek
	Intermediate and Cross Valley Dams	Change of entry of tailings supernatant into Rose Creek and change of flow schedule to accommodate water treatment processes; local changes to surface water/groundwater interactions
	Lower leg of Rose Creek Diversion Canal	Rerouting of an additional length of Rose Creek through a constructed channel
	Rock Dumps	Changes to surface infiltration/runoff characteristics and routing of surface runoff flows
	Zone II Pit	Interception of surface runoff and rerouting to various outflow pumping locations
	Faro Main Pit as tailings disposal facility	Decrease in water (tailings supernatant) entering Rose Creek taken up as storage in Main Pit
	Faro Main Pit pumping/ recycle system	Periodic releases of high flows into Rose Creek via Cross Valley Pond

Table 7. Hydrological Changes Resulting from Construction at the Faro Mine Site

Initial construction of the Vangorda Plateau mine site (1989/1990) and subsequent activities involved construction of the facilities that changed the surface hydrology as listed in Table 8.

Timeframe	Facility	Change to Hydrology
Initial Construction	Rock Drain in North Fork Rose Creek	Delay of passage of high flow events (i.e. freshet) to Rose Creek and possible changes to local surface water/groundwater interactions
	Haul Road	Consolidation of possible surface sheet flow and infiltration to ground into discreet streams at culvert crossings
	Mine Access Road ("Grum turnoff")	Consolidation of possible surface sheet flow and infiltration to ground into discreet streams at culvert crossings
	Grum Interceptor Ditch	Rerouting of surface flows to Grum Creek around the Grum pit
	Vangorda Creek Diversion Flume	Rerouting of Vangorda Creek into a constructed channel
	Grum and Vangorda Pits	Interception of surface runoff for storage or rerouting to water treatment plant
	Vangorda Pit interceptor ditches	Rerouting of surface flows and consolidation of possible surface sheet flow into discreet streams
	Water Treatment Plant	Periodic releases of high flows into Grum Creek (pre-1995) and Vangorda Creek via the Grum Interceptor Ditch (post 1995)
Mine Life	Overburden dump, rock dumps and ore transfer pad	Changes to surface infiltration/runoff characteristics and routing of surface runoff flows
	Vangorda Rock Dump collector ditch/Little Creek Dam	Interception of surface runoff for storage or rerouting to water treatment plant
	Rerouting of Grum Interceptor Ditch to Sheep Pad Pond	Rerouting of surface flows from tributary to Grum Creek to tributary to Vangorda Creek
	Moose Pond	Rerouting of partial surface flow from Grum Creek to ground

Table 8. Hydrological Changes Resulting from Construction at the Vangorda Plateau Mine Site

2.5.2.3 Hydrologic Investigations

The majority of
hydrological
investigations have
focussed on one area
onlyHydrological investigations that have been undertaken throughout the mine life
have generally focussed on the mine sites and their immediate receiving
environments. The majority of these studies focussed on one area only, such as
the design flood for a proposed diversion channel or the minimum size of
reservoir required to provide a reliable water supply to the Faro Mill.

Streamflow monitoring Streamflow monitoring The streamflow monitoring network in the vicinity of the Anvil Range Mining Complex was increased beginning around 1990 with the installation of automatic water level recorders and by expanding the number of flow measurement stations. As well, the Yukon Territory Government added three new stations (Drury Creek, Tay River and Blind Creek) in the mine region. Drury Creek is located approximately 50 km west of the mine area. Tay River shares its catchment divide (on the north side) with Anvil Creek and Vangorda Creek, and Blind Creek shares its catchment (on the south side) with Vangorda Creek.

Two hydrological studies are most relevant to the site:

- 1. 1996 Integrated Comprehensive Abandonment Plan ("ICAP") Study (RGC 1996); and
- 2. 2002 Water Balance and Contaminant Loading Study (Gartner Lee Limited, 2002b).

Mean Annual Runoff

The ICAP study (RGC 1996) provided a comprehensive hydrological assessment of the Faro and Vangorda Plateau Mine site areas. Flows were measured using a variety of techniques (weir, bucket and stopwatch, current meter, staff gauge, and pressure transducer). The following sources of information were used in the 1996 hydrological assessment:

- Sources of information for the 1996 ICAP study
- 1. The series of Annual Reports prepared for Water Licence IN89-001 (water quality and quantity data presented and evaluated at the Faro Mine and area).
- 2. The series of Annual Reports prepared for Water Licence IN89-002 (water quality and quantity data presented and evaluated at the Vangorda Plateau development).
- 3. Streamflow records collected by the Water Survey of Canada (WSC) at 16 streamflow gauging stations.
- 4. Streamflow records collected at 3 hydrometric stations operated by the Water Resources Division of DIAND.
- 5. Records of spot flow measurements made by DIAND personnel at water quality monitoring sites throughout both Faro and Vangorda Plateau developments.
- 6. Environmental reports prepared by Steffen Robertson Kirsten (Canada) Inc. (SRK) and Laberge Environmental Services.
- 7. Unpublished data gathered by mine personnel, such as raw data extracted from the mine's automatic water level recorders.

For the 1996 hydrological assessment, data collected by the WSC and DIAND were used to characterize the minesite hydrology by employing a regional analysis technique which involved deriving empirical relationships between the measured streamflow of the regional stations and the physical characteristics of the catchments which generated the streamflow. These empirical relationships then formed the basis for estimating flows at ungauged points around the Faro and Vangorda Plateau Mine sites.

Elevation generally accounts for a large proportion of the variation in mean annual precipitation within a mountainous region; hence, mean annual runoff (MAR) was also assumed to be a function of elevation. The following sources of data were assembled to determine this relationship:

1. Nineteen pairs of MAR and median elevation data provided by the WSC and DIAND stations.

Flows were estimated at ungauged points around the mine sites

The relationship between elevation and mean annual runoff was determined

2. Four pairs of MAR and median elevation values provided by four incremental catchments monitored by the WSC.

To assemble data source 1, the streamflow records with missing data were patched, then the series of annual average discharges for each station were averaged to arrive at a preliminary estimate of MAR. Next, the preliminary MAR estimates were adjusted so they were representative of a common 30-year period from 1966 to 1995. Finally, the median elevations for all the stations were measured from topographic maps.

The second source of data was obtained from those streams in the region that are monitored by two streamflow gauging stations. The data from these paired stations were collectively used to characterize the MAR and median elevation of the intervening catchment between the stations.

Once all the data were assembled and processed, a curve was fitted to the data to develop a relationship that was believed to represent hydrological conditions for various median elevations at the mine site (Figure 15).

Extreme Flood Estimation

Flood estimates were developed in 1996 for several key points around the mine sites to provide the basis for the conceptual design of spillways and diversion channels.

Two extreme flood events were examined for each point of interest, namely the 500-year peak instantaneous flood and the Probable Maximum Flood (PMF). The former is a rare event which is expected to only be exceeded once every 500 years on average (or roughly once in 6 lifetimes). The latter event is defined as "the flood that may be expected from the most severe combination of meteorologic and hydrologic conditions that are considered to be reasonably possible in the geographical region encompassing the basin under study" (USACE 1980). The PMF for the study area has a likely return period in excess of several thousand years.

The magnitude of a 500-year peak instantaneous flood was estimated using the Rational Method. The magnitude of PMF events was estimated using the Creager Curve. Results of these analyses are presented in Table 9.

Table 9. Estimated Peak Instantaneous Flood Discharges for Various Structures

Structure	Catchment Area (km ²)	500-Year Return Period (m ³ /s)	Probable Maximum Flood (m ³ /s)
Faro Creek Diversion Channel	15.3	27	150
Intermediate Dam Spillway	221	190	840
Vangorda Creek Diversion Channel	20.1	31	180

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-21

Flood estimates provide the basis for conceptual design of spillways and diversion channels. They were examined for the 500 year peak instantaneous flood and the PMF.

2.5.2.4 Water Balance Methodology

A complete water balance for the Rose and Vangorda catchments was developed in 1996 for the Integrated Comprehensive Abandonment Plan (RGC, 1996). This work was subsequently updated in 2001 based largely on the collection of additional flow data via a set of on-site continuous data loggers.

The 1996 water balance covered the Anvil Creek and Vangorda Creek watersheds To complete the 1996 water balance, the mine complex was described as a system of elements and associated flow paths between the elements. The amount of water generated by each element and the amount of water flowing along each flow path was then quantified. The coverage of the water balance was extended over the entire watersheds of Anvil Creek and Vangorda Creek. The outlets of the subcatchments were dictated by the locations of water quality monitoring stations, tributary confluences, open pits, and dams.

A total of 36 subcatchment areas, 20 for Anvil Creek and 16 for Vangorda Creek, were identified. Table 10 provides a description of each subcatchment, together with its measured drainage area and estimated mean annual runoff for its median elevation for the period 1990 to 1995. The subcatchment areas are illustrated on Figures 16, 17 and 18.

New data obtained from the installation of new streamflow recorders helped to create a new water balance in 2002

Seasonal effects were presented The installation of several continuous streamflow recorders from 1996 to 2002 provided additional data that was combined with the results of the 1996 water balance study to create new water balances for Rose and Vangorda Creeks (GLL, 2002b). The new data collected from 1996 to 2000 included spot flow measurements around the minesite and, most importantly, three new flow recorders (pressure transducers with dataloggers) as follows:

- 1. At location R7 in the North Fork of Rose Creek, installed in 1996;
- 2. At location X14 in Rose Creek below the tailings facility, installed in 1998 as a replacement to an older, malfunctioning unit; and
- 3. At location V8 in lower Vangorda Creek, installed in 1998.

New water balances were described for the 1996 subcatchment areas (Figures 16 to 18) that were based on the actual measurements to as great a degree as practical. Flows at ungauged locations were extrapolated from gauged locations in proportion to the MAR's calculated in 1996 (Table 9). The water balance was presented in terms of two seasons (winter and fall) defined as November to April and May to October as a means of capturing seasonal effects.

Subcatchment ID No.	Subcatchment Description	Catchment Area (km2)	Median Elevation (m)	MAR for Period 1990 1995* (mm)

Table 10. Details of Subcatchments for Historical Water Balance Analysis

* MAR = mean annual runoff. The period 1990-1995 was relatively wet (approximately 10% greater than the MAR experienced in the preceding 25 years).

Streamflow Record – Rose Creek

The streamflow record for location R7 in the North Fork of Rose Creek upstream of mine activities (Figure 3) provides the most continuous recording of local flow in recent years. These data were measured by a datalogger and pressure transducer installed in September 1996.

A stage discharge curve was used to convert pressure transducer readings to equivalent flow rates

Daily flow rates were screened for anomalous readings and for the effects of ice

An early winter spike in the Rose Creek data was revealed A stage-discharge curve was developed for location R7 based on available spot flow measurements. The curve was used to convert the pressure transducer readings (height of water) to equivalent flow rates. These pressure readings were monitored by the datalogger at 45-minute intervals. To compute an accurate daily flow record, these readings were first converted into 45-minute flows and subsequently compiled into daily (24-hour) averages.

The daily flow rates at location R7 were screened for anomalous readings and, specifically, for artificial effects of ice. This was accomplished by overlaying the streamflow record for location R7 with a streamflow record operated by the Water Survey of Canada (WSC) on the Ross River at Ross River. This was a useful comparison because the WSC employs special processing techniques that account for the effect of ice on their stage measurements. Furthermore, the Ross River exhibits a similar streamflow pattern as the North Fork, as evidenced by a correlation of coincidental flow data at the two streams.

The overlay of data revealed a consistent early winter spike in the Rose Creek (R7) data that does not appear in the Ross River record. These peaks are attributed, at this time, to the effects of early freezing and ice formation and were removed from the database for Rose Creek such that the two flow records showed similar seasonal patterns. The patched R7 streamflow record was subsequently used as the primary reference for flows in the mine area.

The streamflow record at location X14 (noted on Figure 3) is recorded by a datalogger and pressure transducer. However, the data record is not as continuous as at location R7. Replacement data loggers and transducers have been installed periodically due to damage. The rating curve that is used to convert the pressure transducer readings into flow rates was applied to hourly data which was subsequently compiled into daily (24-hour) averages.

Water Balance – Rose Creek

The North Fork of Rose Creek is defined in this study as the area upstream of location X2 (noted on Figure 3). The North Fork was selected as a distinct component of Rose Creek because of the important source terms in the drainage area and because the available monitoring data was sufficient to support the assessment of these specific source terms.

The interactions between source terms to the North Fork of Rose Creek are illustrated in Figure 19. The resulting water balance is listed in Table 11. Some general comments that apply to development of the water balance are as follows:

Comments that apply to development of the water balance for the North Fork of Rose Creek.

Comments that apply to the water balance for Rose Creek at location X14.

- 1. Two seasonal periods (summer and winter) were selected in order to identify significant seasonal trends and in order to provide a flexible model for future sensitivity analyses.
- 2. The water balance was constructed beginning in winter 1995/1996 in order to correspond to the available flow data. Eleven time steps were defined to represent winter and summer seasons to winter 2000/2001.
- 3. Flows for ungauged subcatchments were extrapolated from the R7 streamflow record in proportion to the catchment areas and mean annual runoffs listed in Table 9.
- 4. The combined Faro Valley and Faro Creek diversion system was assumed to pass 76% of its flow into the North Fork of Rose Creek (i.e. leaks 24% into Faro Main Pit).
- 5. The quantity of seepage from the Zone II Pit into the North Fork of Rose Creek is based upon calculations developed for the ICAP study.
- 6. No direct seepage from the Faro Main Pit into the North Fork of Rose Creek is considered.

The water balance for Rose Creek (downstream of the Rose Creek Tailings Facility at location X14 as illustrated in Figure 3) incorporates all of the known source terms from the mine site. The interactions between source terms to Rose Creek at location X14 are illustrated in Figure 20. The resulting water balance is listed in Table 12. Some general comments that apply to development of the water balance are as follows:

- 1. Two seasonal periods (summer and winter) were selected in order to identify significant seasonal trends and in order to provide a flexible model for future sensitivity analyses.
- 2. The water balance was constructed beginning in winter 1995/1996 in order to correspond to the available flow data. Eleven time steps were defined to represent winter and summer seasons to winter 2000/2001.
- 3. Flows for ungauged subcatchments were extrapolated from the R7 streamflow record in proportion to the catchment areas and mean annual runoffs listed in Table 9.
- 4. Flow from the North Fork of Rose Creek is represented as one source term taken from Table 11.
- 5. The rate of recharge to groundwater upstream of the tailings facility and beneath the Cross Valley Pond and the rate of groundwater discharge downstream of the Cross Valley Pond are taken from the 2001 hydrogeological model described in *Rose Creek Tailings Facility, 2001 Hydrogeological and Geochemical Investigation*, Gartner Lee, 2002c.
- 6. Surface release from the Cross Valley Pond (X5) and seepage from the Cross Valley Pond (X13) are taken from Annual Environmental Reports for the

Table 11. Water Balance Calculations for North Fork Rose Creek

Notes:

1) The Faro Ck Diversion controls a total area of 16.2 km2. An estimated 24% of the yield from this catchment bypasses the diversion channel and reports to the Main Pit. 2) RGC estimated seepage from Zone II Pit to North Fork to be 18,400 m3/y with a water level in pit of 1110 m. No allowance made for overland flow from Zone II Dump to North Fork. 3) Some flow bypasses R7 and X2 in the stream alluvium. This flow was assumed to be negligible. 4) Local runoff = combination of groundwater, interflow and overland flow.

2) Influence of storage in Fresh Water Reservoir and the Rose Ck alluvium aquifer is simplified. Also, some of the mill supply was obtained from North Fork flows diverted into Pumphouse Reservoir. This diversion was not directly accounted for in this spreadsheet

3) The measured and estimated outflows from the Rose Ck Tailings Facility exceeded the estimated inflows to this facility by an average of 95 L/s over the complete simulation period. This missing inflow was assumed to originate as ditch leakage from the Rose Creek Diversion Channel. As a first approximation, this ditch leakage was assumed to not exhibit a seasonal pattern.

4) The Gartner Lee groundwater investigation (2001) estimated the groundwater flux in the Rose Creek alluvium aquifer to be about 79 L/s upstream of the tailings facility. For the purpose of this water balance,

this groundwater was assumed to originate roughly half from the North Fork and half from the South Fork. The tailings facility itself was estimated to contribute 20 L/s to the underlying aquifer, largely from the the Intermediate and Polishing Ponds (under shutdown conditions). The aquifer was estimated to discharge approximately 12 L/s to Rose Creek between the CVD and Station X14.

Sandara and

5) Some problems exist with observed X14 record. In early record, spot measurements are about 80% of computed flows. Also, erroneous peaks due to ice effects have not been removed.

Faro Mine Site for the years 1995 to 2001 as filed with the Yukon Territory Water Board.

Streamflow Record - Vangorda Creek

A datalogger and pressure transducer were installed at location V8 in lower Vangorda Creek (Figure 3) in 1999. DIAND has operated a seasonal flow gauging station in lower Vangorda Creek in previous years. The datalogger recordings were used exclusively for this study.

A stage discharge curve was developed for location V8 based on available spot flow measurements. The curve was used to convert the pressure transducer readings (height of water) to flow rates. The datalogger records the pressure data at 30-minute intervals. These raw pressure data were converted to equivalent flow rates and then averaged to compute a record of daily average flow rates. The data record contains gaps related to readings that are unusable due to unknown effects.

The daily flow rates at location V8 were assessed for anomalous readings and, specifically for artificial effects of ice. This was accomplished by overlaying the streamflow record for location V8 with the streamflow record for the Ross River at Ross River. These two streams exhibit similar seasonal flow patterns, as evidenced by a correlation between the coincidental daily flows at V8 and Ross River.

The overlay of data does not display any discrepancies in the record for location V8 for the periods where usable data was collected.

Because of the substantial gaps in the data record for location V8, the streamflow record for location R7 was subsequently used as the primary reference for flows in the Vangorda Creek catchment.

Water Balance - Vangorda Creek

The water balance for Vangorda Creek at location V8 incorporates all of the known source terms from the mine site. The interactions between source terms to Vangorda Creek at location V8 are illustrated on Figure 21. The resulting water balance is listed in Table 13. Some general comments that apply to development of the water balance are as follows:

- 1. Two seasonal periods (summer and winter) were selected in order to identify significant seasonal trends and in order to provide a flexible model for future sensitivity analyses.
- 2. The water balance was constructed beginning in winter 1997/1998 (Time Step 5 of the Rose Creek water balance) to be representative of existing conditions during the care and maintenance phase.

A stage discharge curve was used to convert the pressure transducer readings to flow rates

The daily flow rates were asses for anomalous readings and for the effects of ice

Comments that apply to the development of the Vangorda Creek water balance

0.025

0.197

 Total seepage into Vangorda Pit was estimated by subtracting i) an estimate of local runoff, ii) measured LCD flows and iii) measured Sheep Pad Pond diversions from measured annual accumulation of water in pit.
 Total seepage into Vangorda Pit was apportioned to three sources (Vangorda Creek Diversion, Vangorda NE Interceptor and Till Dump catchment) 2) Follar seepage into Varigorda Pix was apportanted to intree sources (Varigorda Creek Diversion, Varigorda Pix Interceptor and Fill Dump claccording to their respective estimated long-term yields.
 3) Leakages from LCD and Varigorda Dump Collection Ditch are crude estimates not based on data.
 4) The volume of water pumped from the LCD is significantly less than the estimated yield of the Varigorda Dump catchment. The difference may be altibuted to the filling of void space within the Varigorda Dump and/or the dump results in enhanced evaporation.

+ Outflow from Vangorda Ck Diversion + Seepage from Little Creek Dam

+ Outflow from Shrimp Creek

= Total flow at V8

5) Seepage from Grum Interceptor Ditch assumed to equal 10% of yield from Subcatchment 27.

- 3. Flows for ungauged subcatchment areas were extrapolated from the verified R7 streamflow record in proportion to the catchment areas and mean annual runoffs listed in Table 9.
- 4. Seepage losses from the Vangorda Creek Diversion Flume to the Vangorda Pit are estimated based on the observed inflow rates into the pit.
- 5. Volumes extracted from the Sheep Pad Pond to the Vangorda pit are taken from the Annual Environmental Reports for the Vangorda Plateau mine site.
- 6. Seepage rates from Little Creek Dam and from the Vangorda Rock Dump to Shrimp and Vangorda Creeks are estimated based on judgement only.

2.5.2.5 Water Balance Study Results

Observations from the 2002 water balance for the North Fork of Rose Creek, the mainstem of Rose Creek, and for the Vangorda Creek The 2002 water balance for the North Fork of Rose Creek provides the following observations for the period from November 1995 to April, 2001.

• An estimated 83% of the flow in the North Fork of Rose Creek originates from natural runoff upstream of the mine site.

The 2002 water balance for the mainstem of Rose Creek provides the following observations for the period from November 1995 to April 2001:

• Of the flow in Rose Creek below the tailings facility, an average of 55% originated from the North Fork of Rose Creek, 25% originated from the South Fork (drainage area above the tailings facility) and 9% originated from effluent released from the Cross Valley Pond (toe seepage and surface outflow).

The 2002 water balance for Vangorda Creek provides the following observations for the period from November 1997 to April 2001:

- The flow in lower Vangorda Creek originates, on average, 34% from the West Fork and 66% from the main stem (drainage including most mine facilities).
- Of the flow in the main stem, an average 54% originates from natural runoff in Vangorda Creek unaffected by mine activities (drainage area upstream of the mine site).

2.5.3 HYDROGEOLOGY

2.5.3.1 Historical Hydrogeological Changes

Mining activities have affected the local groundwater flow in several ways, including the following:

<i>Mining activities that have affected the local groundwater flow</i>	 Interception of groundwater in open pits. Increased permeability in the rock mass through blasting of open pit walls. Interception of groundwater in diversion ditches. Alterations to the Rose Valley aquifer from development and operation of the Rose Creek Tailings Impoundments. Increased infiltration through unvegetated and poorly drained areas (e.g. free dumps) as well as leakage from diversions.
The Faro Main Pit groundwater interception	The Faro Main Pit was developed on the north side of the Rose Creek valley. Much of the area was covered by a thin layer of compacted till over bedrock. The pit was excavated to a depth of approximately 365 metres below the original ground surface at its deepest point and now intercepts both shallow groundwater flow at the soil/bedrock interface and deeper groundwater flow in faults and fractures. Leakage from the Faro Creek Diversion Ditch into the pit via the northeast pit wall is known to contribute to groundwater inflows. Groundwater inflow rates are not specifically monitored and separated from surface inflows. However, mine dewatering pumping records indicate pumping rates between 40 and 55 L/s were required to keep the pit drained from 1986 to 1990 (RGC 1996).
The Faro Zone 2 Pit groundwater interception	The Faro Zone II Pit similarly intercepts both shallow and deeper groundwater flow, although at a smaller scale than the Faro Main Pit. The presence of substantial faulting in the southern area of the Main pit creates the possibility for subsurface flow of water from the Main Pit into the Zone II Pit. Annual monitoring of volumes dewatered for the Zone II Pit, as reported in annual environmental reports, indicates that seepage from the Main Pit did not increase substantially with an increase in the water level in the Main Pit. The groundwater inflows into the Zone II Pit were estimated at 13 L/s during mine operations (RGC 1996).
Vangorda Pit groundwater interception	The Vangorda Pit is located on a south side of Vangorda Creek. The overburden encountered consisted primarily of compacted glacial till up to approximately 30 metres in thickness. Groundwater inflow into the Vangorda Pit was estimated at 0.14 L/s during mine operations (RGC 1996). A net inflow of groundwater into the Vangorda Pit was also suggested by a geochemical study conducted in 2000 (SRK, 2000b) that indicated an unidentified source of alkalinity that could be attributed to groundwater influx.
Grum Pit groundwater interception	The Grum Pit is located on the north side of Vangorda Creek and was developed in a small depression in the hillside. A small lake (Doal Lake) was present prior to the development of the pit. The surficial deposits at the Grum Pit were thicker than at the other pits. A north-south trending bedrock valley was intersected in the southeast corner of the pit that was filled with approximately 100 m of glacial till over a basal layer of sand and gravel. This aquifer was dewatered by pumping wells during mine operations prior to 1997 and has subsequently flowed directly into the Grum Pit. The effect of the interception of this flow is also observed in changes observed in the degree of saturation of surface soils downgradient of the Grum Pit in the Grum Creek area. Prior to development of the Grum Pit, this area was observed to be largely saturated near surface with

some test pits reported as filling with water during excavation whereas the area is currently observed to be drier near surface (Anvil Range, pers. comm.).

Other effects of open pits may relate to the increased permeability (compared to natural bedrock) of blasted rock walls which may allow increased passage of groundwater.

Diversion ditches may alter pre-existing flows or result in groundwater recharge Diversion ditches that are seated in bedrock, or that intersect other shallow groundwater zones, will alter the pre-existing flow regime. For example, the Rose Creek Diversion Canal is interpreted to largely intercept and re-direct shallow groundwater flow from the south side of the Rose Creek Valley that previously flowed into the valley aquifer (GLL 2002c).

Alternately, diversion ditches may result in groundwater recharge (through ditch leakage). For example, the Faro Creek diversion ditch is known to leak water into the shallow aquifer above the Faro Main Pit.

A confining surface layer, additional groundwater recharge and surface ponds have effected the local groundwater flow Prior to development of the tailings impoundments, the local Rose Creek Valley hosted an unconfined aquifer that produced an estimated 3,000 to 4,000 m³ of groundwater per day (GLL 2002c). Development of the tailings impoundments introduced a confining surface layer (tailings), additional groundwater recharge (tailings slurry water) and surface ponds that have had a substantial effect on local groundwater flow. An interpretation and numerical model of the existing groundwater flow regime are described in GLL 2002c.

Some rock dumps may promote increased infiltration (groundwater recharge) compared to the original ground conditions where free dump piles or other lose materials are present.

Rock dumps may Alternately, hard packed and compacted surfaces of rock dumps may restrict groundwater recharge and promote increased surface runoff compared to the original ground conditions.

2.5.3.2 Regional Hydrogeology

Predicting groundwater flow through the rock in the Anvil Range mine sites is difficult The area surrounding the Anvil Range Mine Complex (Figure 3) is underlain by metamorphic and volcanic bedrock. The Proterozoic and Paleozoic schists and phyllites were intruded by the Anvil Batholith, which consists of granite, granodiorite and quartz monzonite. The crystalline nature of these rocks typically creates a very low primary porosity (0-10%), therefore and groundwater flow through the bedrock likely occurs along planes of weakness or deformation, such as fractures, faults or shear zones. Predicting the occurrence of groundwater and its flow direction in this type of rock is difficult at best, and there is little information available for the Anvil District.

Bedrock is overlain by various types of surficial deposits (or overburden) consisting primarily of glacial till, glaciofluvial sediments and alluvium. In topographically elevated areas, these surficial deposits are thin and irregularly

distributed. Surficial deposits are generally thickest in the valley bottoms, although significant thicknesses of till have been documented in the uplands of the Vangorda Plateau.

- Groundwater flow path, flow direction and recharge The presence, characteristics and thickness of surficial deposits are likely to be the primary control to the occurrence and flow of groundwater in the study area. Known groundwater flow occurs primarily in the overburden, or through the upper most weathered surface of the bedrock. Flow direction is controlled mainly by surficial and bedrock topography. Recharge occurs via infiltration of precipitation and the groundwater migrates downward, following topography to discharge zones into local creeks or shallow depressions. The bedrock valley sides act as recharge sites and groundwater flow progresses to the valley floors as a discharge zone. Recharge to valley aquifers may also occur locally through the beds of streams occupying the valley.
- Valley aquifers Large glaciated valleys, including the Pelly River, Rose Creek, and Blind Creek valleys, have been filled with significant thickness of glacial sediments. Where these deposits are primarily glaciofluvial sands and gravel, they represent relatively high yield aquifers. Valley aquifers are usually unconfined, with shallow depths to water and significant groundwater yields. However, if confining layers, such as glacial till or other fine-grained deposits extend across the valley floor and partially up the valley sides, confined aquifers, with significant hydraulic heads may be encountered.

2.5.4 SURFACE WATER QUALITY

2.5.4.1 Overview

The intent of this description of surface water quality is to describe the water quality conditions from 1987 - 2002. The water quality baseline for the reference areas, discharge points and receiving waters are described for the historic period of record (1987 - 1998) as narrative summaries taken from the 2002 Baseline Report. Data for the 1998-2002 period are then presented to describe the existing environmental conditions which form the baseline for the current assessment.

Water quality summaries were based only on measurable data points Interpretation of water quality data included a number of samples which had no detectable concentrations and was hampered by changes in analytical methodology and detection limit over the period of record. Although suitable statistical methods exist to account for "censored" data (those values which are below the detection limit), there is no acceptable means for statistical interpretation where the detection limit has changed over the period of record. These factors prevented statistical comparisons of data over time or between sites. Comparisons therefore relied on qualitative comparisons between sites and the weight of evidence guiding conclusions. Water quality summaries were based only on measurable data points. For all cases where "Non detects" were present, the data summaries recorded the total number of samples and the

Water quality

numbers of samples which contained detectable quantities. "Non detects" were not included in the statistical summaries.

Interpretation of effects of the mine on surface water quality were guided by a) comparisons between sites and b) comparisons of water quality against CCME (1999) Guidelines for protection of freshwater aquatic life.

Surface water quality at the Faro and Vangorda Plateau mine sites has been

characterized by samples taken at a variety of stations from 1987 to 2002. This

period of record covers mine operation, mine development (Vangorda Plateau)

and closure periods and includes data that reflect a variety of water treatment and management systems at both sites. The water quality conditions for the period

information for 2002 is provided in the annual Environmental Reports required under the existing water licences for the sites: for the Faro Site in GLL 2003a and

Surface water quality for the 1987-2001 period includes data from a total of 29

different stations for the Faro site and 21 for the Vangorda Plateau site. These

1987-2001 is presented in the May 2002 Baseline Report.

for the Vangorda Plateau Site in GLL 2003b.

2.5.4.2 Monitoring Sites

The sampling period covers mine operation, mine development, and mine closure

The surface water quality baseline includes data from 29 different locations for the Faro site and 21 for the Vangorda Plateau site

include reference locations showing no mine influence, effluent streams and seepages within the mine site itself, compliance points for effluent discharge, sites where effluent has mixed with receiving waters immediately off of the site and receiving waters downstream of the mine.

Not all of these monitoring sites provide information that is useful for environmental assessment and, therefore, data from a smaller number of selected sites were used to describe existing water quality conditions. The most important requirements are for:

- Reference water quality for comparison against potentially impacted sites;
- Effluent water quality to assess compliance and to assess loadings to the natural environment; and
- Receiving water quality to assess potential effects on water quality.

The total of 50 water quality sites was therefore reduced to 19 (10 for Faro and 9 for Vangorda Plateau) for the purposes of the environmental assessment. The stations which were omitted describe internal water on the site and specific sources of runoff or seepage. Water quality stations are described in Table 14 and located on Figure 3. A complete listing of water quality data for these locations is provided in Appendix B.

Rose Watershed / Faro Mine Site

Sites that represent reference water quality for the assessment

The number of

sampling sites was reduced to describe

the environmental

baseline

Faro Creek, upstream of the diversion (Site FDU), the North Fork of Rose Creek, upstream of the mine (R7) and Upper Guardhouse Creek (Site W10) receive surface runoff which has had no direct contact with mine activities at the Faro

site. They represent reference water quality for purposes of this environmental assessment.

Water from sites that have had contact with mining activities Water which has had contact with mining activities is treated and discharged from the site via outflow from the Cross Valley Pond (Site X5) or seepage from the Cross Valley Dam (X13). These two water streams mix with water from the Rose Creek Diversion Channel (which contains diverted clean water and water which may have interacted with mine activities) and are sampled at Sites X14 and R2, to represent the net effect of the Faro Site on water quality at the boundary of the local study area.

Receiving water quality sampling sites Receiving water quality was sampled in Rose Creek at Site R3, midway to Anvil Creek, and at R4, where Rose Creek meets Anvil Creek, the downstream boundary of the Regional Study Area. Effects on Anvil Creek were determined by comparison of water quality upstream of the confluence with Rose Creek (R6) with that after mixing of Anvil and Rose Creeks (R5).

Vangorda Watershed / Mine Site

of the assessment.

Sites that represent reference water quality for the assessment

Water from sites that have had contact with mining activities Water from the mine site, prior to discharge to off site receiving waters was characterized by measurements made at the outflow from the Sheep Pad Pond (inclusive of treated mine water, V25BSP), Grum Creek (site runoff, V2) and AEX Creek (site runoff, V6A). Water quality in Vangorda Creek upstream of the confluence with Shrimp Creek (V27) represents the net receiver of all mine activities, prior to mixing with reference water.

Vangorda Creek upstream of the mine site (Site V1) and Shrimp Creek (Site V4)

both convey surface runoff which has had no direct contact with mine activities

at the Vangorda Plateau site. They represent reference water quality for purposes

Receiving water quality sites Receiving water quality for the local study area was assessed using data from Vangorda Creek, upstream of the confluence with the West Fork (Station VGMain) and from the West Fork, upstream of its confluence with Vangorda Creek (V5). These two sites defined the downstream boundary of the Local Study Area. Water quality at the downstream boundary of the Regional Study Area was characterized by measurements made at the mouth of Vangorda Creek, upstream of its confluence with Pelly River (V8).

2.5.4.3 Rose Watershed Surface Water Quality

Reference Water Quality

Alkalinity, sulphate and zinc concentrations in the Faro area during mining operations

Reference stream water quality in the Faro area during the period of mine operations was consistently neutral to alkaline (pH 7.5 - 8.0) with low sulphate concentrations (<6 mg/L). Total zinc concentrations were also low, generally ranging from 0.007 to < 0.005 mg/L. Zinc, sulphate and alkalinity levels were

higher in the North Fork of Rose Creek than in Faro and Guardhouse Creeks during the period of mine operations.

Trace metal concentrations in reference waters indicate mineralized geology, with detectable concentrations of most trace metals (Tables 15 and 16). Trace metal levels in the reference streams for Al, As, Cd, Cr, Cu and Pb generally exceeded CCME (1999) guidelines for protection of aquatic life while levels for Ag, Fe, Hg, Ni and Zn generally did not. A total hardness of 60 mg/L was used for those metals where the CCME guidelines are hardness dependent.

Effluent Water Quality

The discharge of water from the Faro site occurs as seasonal discharge over the Cross Valley Dam (Site X5) or as seepage through the dam (Site X13). The discharge consists of treated pit water and overland runoff from the mine site, which is treated in the Intermediate Pond.

Water quality has been sampled on a regular basis since 1986 Water quality at these sites was sampled on a regular basis starting in 1986. This information was summarized from the "Anvil Range Mine Complex 2002 Baseline Environmental Information. Volume 2" Report (GLL 2002a), but additional details may be found in the annual monitoring reports that are filed with the Yukon Territory Water Board. Prior to 1992, water quality in the Cross Valley Pond was controlled primarily by the characteristics of the settled tailings supernatant from upstream deposition of mill tailings. Zinc and sulphate concentrations averaged 0.24 and 436 mg/L, respectively, and pH ranged from 6.7 to 9.6. Seepage from the pond had lower pH levels (6.1 - 7.8) and Zn levels ranged from 0.01 to 0.167 mg/L. Iron levels in the seepage averaged 2.0 mg/L.

Discharge water quality conditions from 1998 to 2002 showed high levels of Ca (180-217 mg/L, Table 17) as a result of lime treatment upstream. Sulphate levels exceeded those recorded historically (532-582 mg/L). The ponds were effective in settling solids, as TSS levels averaged 4 - 10 mg/L. A pH of 7.3 in the main discharge remained within the slightly alkaline ranges reported historically but was lower than the pH of the reference streams, suggesting some acid generation on site. Zinc concentrations in the Cross Valley Pond seepage were reduced following mine closure. They averaged 0.039 mg/L between 1998 and 2002 (Table 18), approximately 15% of the levels recorded during mine operations. Zinc increased (average = 0.334 mg/L) in the dam discharge during the care and maintenance phase, compared to 0.24 mg/L during operations, likely related to the periodic introduction of a relatively large volume of water pumped from the Faro Main pit beginning in 1998, which was ultimately released to Rose Creek as treated and compliant effluent via location X5.

Receiving Water Quality

Concentrations of Fe and Mn in the mine discharge water were elevated by several orders of magnitude over concentrations in the reference streams and the concentration of zinc at X5 (but not at X13) was elevated by one order of

magnitude (Table 18). For the other metals, concentrations were increased by approximately two-fold over reference levels, with the exception of As and Cd, which were not elevated in the mine discharge waters compared to the reference sites.

On-going metals loadings were high but discharge concentrations were within the Water Licence limits on almost all occasions for all licenced parameters

Comparison of water quality in Rose Creek with that in the discharge water showed dilution and assimilation of mine water in the receiving environment during the baseline period The existing water quality conditions at the discharge therefore reflect ongoing metals loadings to the receiving environment even though discharge concentrations were within the water licence limits on almost all occasions for all licenced parameters. Of most concern are Zn and Ag, because of a combination of high loadings and their relatively high toxicity (see CCME Guidelines in Table 15). High levels of sulphate are also discharged. These serve as a good indicator of mine discharge, but are not toxic. High levels of Fe and Mn are also discharged but these are of lower toxicity.

Water quality downstream of the mine site is influenced by the discharge of treated, compliant effluent from the Cross Valley Dam, seepage from the dam, and by mixing with water from the Rose Creek diversion channel. Prior to 1998, water quality at this site was variable: sulphate ranged from 4 - 762 mg/L, pH from 5.9 to 8.6 and Zn from 0.01 to 0.64 mg/L (average = 0.08).

During the 1998-2002 care and maintenance period, the receiving waters continued to show elevated levels of Ca, sulphate, Zn and other trace metals from the discharge of treated mine water. Comparison of water quality in Rose Creek (Tables 19 and 20) with that in the discharge water (Tables 17 and 18) showed substantial dilution and assimilation of mine water in the receiving environment. Nevertheless, receiving water quality was impaired when compared with CCME Guidelines for protection of aquatic life for Al, As, Cd, Cu, Fe, Pb and Zn at Sites X14 and R2, immediately downstream of the Cross Valley Dam. The area of concern represents approximately 100 m of stream reach immediately downstream of the Cross Valley Dam, which is functioning as a mixing zone. Ammonia levels exceeded concentrations in reference creeks (Table 19) but cool waters (maximum recorded temperature of 12°C) and moderate pH (maximum recorded pH of 8.6) limited the average concentration of the toxic, un-ionized fraction to less than the CCME Guideline of 19 ug/L.

Although metal levels downstream of the mine exceeded CCME Guidelines, some appear to reflect natural mineralization of surface water near the mine. Concentrations of Al, As, Cd, Cr, Cu, and Pb downstream of the mine were the same as, or less than, concentrations at the reference water quality sites that were not influenced by mine drainage (Table 20). Nickel concentrations were elevated above reference levels, but were below CCME guidelines. In summary, receiving water quality contained elevated concentrations of Fe, NH₃, Mn, Zn and SO₄, when compared to reference water quality and CCME Guidelines. No CCME Guidelines exist for sulphate and Mn, as these substances are of low toxicity.

The CCME Guidelines represent water quality conditions that assure indefinite survival of the most sensitive life stages of sensitive aquatic species. Most

exceedances would have occurred during discharge periods and were therefore short-term events. The water quality data do not indicate any conditions which are acutely lethal to aquatic life. This is supported by the acceptable toxicity testing reported in annual reports for the site (i.e. GLL, 2003a).

Regional Study Area Water Quality

The water quality data for the baseline period is limited in its utility for comparisons with other sites

No evidence suggests that the aquatic community in Rose Creek has been impaired by the mine discharge. The RSA downstream of the immediate receiving waters for the Faro site is described by water quality at sites R3 and R4 in Rose Creek. The existing conditions for the RSA are described by comparison of reference water quality in Anvil Creek (R6) with water quality in Anvil Creek downstream of the confluence with Rose Creek (Site R5). No water quality data were collected at these sites during the period of mine operation.

Existing water quality data in the RSA is limited: only four samples were collected for the period 1998 – 2002. This limits their utility for comparisons with other sites. Ca and SO₄ concentrations were elevated at the mouth of Rose Creek in response to mine water discharge (Table 21). Ca concentrations were double those at reference sites and SO₄ levels were higher by more than one order of magnitude. Total Suspended Solids and ammonia concentrations had decreased to background at this point.

Concentrations of Zn remained at levels of 0.05 mg/L at the mouth of Rose Creek and exceeded both reference levels and the CCME Guideline by a factor of two (Table 22). Mn concentrations declined by a factor of three along the length of Rose Creek, although they remained one order of magnitude higher than reference levels. There is no CCME Guideline for Mn and it has very low toxicity. Fe concentrations declined to background levels along Rose Creek.

In summary, at Site R4 existing water quality conditions are distinguished by elevated levels of Ca, SO_4 , Zn and Mn. Of these, Zn is the only pollutant of potential concern, based on comparison with the CCME Guideline. There is no evidence, however, to suggest that the aquatic community in Rose Creek has been impaired by the mine discharge as described in existing information for the Rose Creek aquatic environment (Section 2.6).

Anvil Creek, immediately downstream of its confluence with Rose Creek, marks the downstream extent of the Regional Study Area. Upstream of Rose Creek, Anvil Creek is characterized by moderate levels of Ca and SO₄ (Table 23), indicating a more alkaline system than the reference areas of Rose Creek. Metal concentrations (Table 24) are similar to those in the Rose Creek reference areas (Table 16). Downstream of the confluence, Mn concentrations are greater than background as a result of the inflow of Rose Creek. This is the only measurable response to the Faro Mine Site at the edge of the Regional Study Area. All other water quality indicators of the Faro Mine discharge were not measurably different from reference water quality at this point.

Rose Watershed Surface Water Quality Summary

The existing water quality for the Faro Mine Site was described by:

Summary of the Faro Mine Site water quality baseline.

- Alkaline conditions, low solids and concentrations of trace metals (except for Zn and Hg) which exceeded CCME guidelines in reference waters isolated from mine influence;
- Discharge of mine waters from Cross Valley Pond which contained Ca, Zn, SO₄, Fe, Mn at concentrations which were several orders of magnitude above reference levels and of trace metals (except for As and Cd) which exceeded reference levels by a factor of two;
- Water quality in Rose Creek immediately downstream of the Cross Valley Pond discharge which reflected discharge of high levels of Fe, NH₃, Mn, Zn and SO₄ from the mine;
- Assimilation of all mine influences except for Ca, Mn and Zn in Rose Creek upstream of Anvil Creek; and
- Mn as the only measurable mine influence in Anvil Creek downstream of its confluence with Rose Creek.

These conditions describe the existing water quality against which the proposed project activities (Project Description, Volume I) have been assessed for the 2004 -2008 time period (Environmental Effects Assessment, Volume III).

2.5.4.4 Vangorda Watershed Surface Water Quality

Reference Water Quality

Alkalinity, sulphate and zinc concentrations in Vangorda and Shrimp Creeks during mine operations.	Reference stream water quality in Vangorda and Shrimp Creeks during the period of mine operations was consistently neutral to alkaline (pH 6.7 to 8.6). Sulphate concentrations were lower at location V1 in upper Vangorda Creek (1-26 mg/L) than at location V4 in Shrimp Creek (7-134 mg/L). This has been attributed to the presence of different rock types in the respective drainage areas (Gartner Lee 2003b). Total zinc concentrations generally ranged from 0.08 to <0.002 mg/L.
1998-2002 water quality.	Reference stream water quality for 1998-2002 was also slightly alkaline (pH 8.04) and of low to moderate hardness (Ca = 19 mg/L, conductivity = 156 uS and total hardness = 62 mg/L). Ammonia levels were not detectable, sulphate was low and the stream waters were clear, with total suspended solids levels of 2 mg/L. Reference site water quality data are provided in Table 25.
concentrations.	Trace metal concentrations in reference waters indicate mineralized geology, with detectable concentrations of most trace metals (Table 26). Trace metal levels in the reference streams for Al, As, Cd, Cr, Cu, Fe and Pb generally exceeded CCME (1999) guidelines for protection of aquatic life while levels for Ag, Ni and Zn generally did not. A total hardness of 60 mg/L was used for those metals where the CCME guidelines are hardness dependent.

Mine Runoff and Effluent

Mine runoff water and effluent from the Vangorda Plateau enters Vangorda Creek at three locations.

Mine runoff water and effluent from the Vangorda Plateau enter the receiving water, Vangorda Creek, at three locations:

- 1. Location V25BSP is the outlet of the Grum Interceptor Ditch, which includes periodic or seasonal release of effluent from the Grum/Vangorda water treatment plant. There is typically no flow at this location in the winter season.
- 2. Location V2 is the outlet of Grum Creek that includes runoff from the Grum rock dump.
- 3. Location V6A is the outlet of AEX Creek that includes runoff from the ore transfer pad.

Water quality at these three sites was sampled on a regular basis starting in 1996, 1988 and 1989, respectively. It is summarized from the "Anvil Range Mine Complex 2002 Baseline Environmental Information. Volume 2" Report (GLL 2002a), but additional details may be found in the annual monitoring reports that are filed with the Yukon Territory Water Board. Data for these three sites for the 1998 to 2002 timeframe is summarized on Tables 27 and 28.

Grum Interceptor Ditch

Location V25BSP was created in 1995 as part of the sediment mitigation activities that rerouted the Grum Interceptor Ditch into the Sheep Pad Pond. Prior to mine shut down in 1998, total zinc generally ranged from 0.28 to 0.01 mg/L, sulphate generally ranged from 641 to 10 mg/L and pH generally ranged from 8.40 to 6.65. Sulphate and zinc concentrations and pH fluctuated widely with periods of higher concentrations and higher pH corresponding to periods of effluent release from the Water Treatment Plant.

Water quality during the baseline period for the current environmental assessment

During the 1998 to 2002 timeframe, water quality at location V25BSP was slightly alkaline (pH 7.78) and of high hardness (Ca = 53 mg/L and total hardness = 739 mg/L, although the median value for total hardness is skewed high due to the greater frequency of analysis in 2002 as compared to 1998 to 2001). Ammonia levels were detectable but low (0.10 mg/L), sulphate was moderate (127 mg/L) and the stream waters were clear, with total suspended solids levels of 6 mg/L (Table 27). The concentration of total zinc was moderately elevated (for a mine runoff/effluent stream) at 0.11 mg/L.

2002 data is interesting as it was the only year of operation of the Grum/Vangorda Water Treatment Plant as is planned for the proposed term of the licence renewal

It is of interest to separate out the year 2002 data from the overall 1998 to 2002 timeframe because the year 2002 was the only year of operation of the Grum/Vangorda Water Treatment Plant, as is planned for the proposed term of the licence renewal. In general, water quality at location V25BSP was harder and contained higher concentrations of sulphate and zinc corresponding to the periods of effluent release from the treatment plant. For example, in 2002 water

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-45

Sulphate and zinc concentrations and pH were higher corresponding to periods of effluent release from the Water

quality at location V25BSP contained up to 810 mg/L sulphate and 0.184 mg/L total Zn and hardness was as high as 847 mg/L.

The signature of treated effluent is apparent in existing water quality, and particularly during the year 2002, as compared to water quality at the reference locations. The concentration of Ca is more than doubled and hardness is increased by an order of magnitude. Ammonia is increased slightly and sulphate is also increased by one order of magnitude. Concentrations of Mn and Zn were elevated by an order of magnitude over concentrations in the reference streams. Concentrations of Ag, As and Fe were reduced by several times, however from the reference locations. Concentrations of Cd and Ni were not changed compared to the reference locations.

Ongoing metal loadings to the receiving environment are high, but discharge concentrations from the water treatment plant were within the Water Licence limits Existing water quality conditions at location V25BSP therefore reflect ongoing metals loadings to the receiving environment. Although loadings are elevated, discharge concentrations from the Water Treatment Plant (in 2002) were within the Water Licence limits on all occasions for all licenced parameters. Of most concern is Zn because of a combination of elevated loadings and relatively high toxicity (see CCME Guidelines in Table 26). High levels of sulphate are also discharged. These serve as a good indicator of mine discharge, but are not toxic. High levels of Mn are also discharged but these are of lower toxicity.

Grum Creek

Rerouting of the Grum
Interceptor ditch
improved water qualityWater quality improved substantially at location V2 in 1995 through reduced
concentrations of total suspended solids and some metals due to the rerouting of
the Grum Interceptor Ditch away from Grum Creek and into the Sheep Pad Pond.
Over the entire period of record to mine closure in 1998, total zinc generally
ranged from 0.91 to 0.001 mg/L, sulphate generally ranged from 328 to 24 mg/L
and pH generally ranged from 7.0 to 8.6.

From 1998 to 2002, water quality at location V2 was slightly alkaline (pH 7.78) and of high hardness (Ca = 163 mg/L and total hardness = 919 mg/L). Ammonia levels were detectable but low (0.09 mg/L), sulphate was moderately high (380 mg/L) and the stream waters were clear, with Total Suspended Solids levels of 7 mg/L. The concentration of total zinc was slightly elevated (for a mine runoff stream) at 0.08 mg/L.

The effects of runoff and seepage from the Grum Rock dump on baseline period water quality The signature of runoff and seepage from the Grum Rock Dump is apparent in existing water quality at location V2 as compared to water quality at the reference locations. The concentrations of Ca and hardness are increased by one order of magnitude. Ammonia is increased slightly and sulphate is also increased by one order of magnitude. Concentrations of As, Cd, Ni, Pb and Zn were at least doubled over concentrations in the reference streams. Concentrations of Ag, Fe and Mn are reduced, however from the reference locations. Concentrations of Cr and Cu are not changed compared to the reference locations.

Grum Creek water quality reflects ongoing metals loadings to the receiving environment The existing water quality conditions in Grum Creek therefore reflect ongoing metals loadings to the receiving environment. Of most concern are As, Cd, Ni and Zn because of a combination of elevated loadings (due to the release of compliant effluent) and their relatively high toxicity (see CCME Guidelines in Table 26). High levels of sulphate are also present. These serve as a good indicator of mine discharge, but are not toxic.

AEX Creek

Zinc and sulphate concentrations At location V6A, AEX Creek, over the entire period of record to mine closure in 1998, total zinc generally ranged from 0.28 to 0.001 mg/L, sulphate generally ranged from 70 to 3 mg/L and pH generally ranged from 7.0 to 8.1.

1998-2002 water quality From 1998 to 2002, water quality at location V6A was slightly alkaline (pH 7.69) and of moderate hardness (Ca = 28 mg/L). Ammonia levels were non detectable, sulphate was low (21 mg/L) and the stream waters were clear, with Total Suspended Solids levels of 4 mg/L. The concentration of total zinc was low at 0.025 mg/L.

Mine-related metal
loadings are absent in
the baseline water
quality conditionsWater quality at location V6A in AEX Creek is very similar to that at the
reference locations. This indicates that runoff from the ore transfer pad and haul
road (in the AEX Creek drainage area) are not having an observable effect in
AEX Creek.

The existing water quality conditions in AEX Creek therefore reflect the absence of mine-related metals loadings to the receiving environment.

Receiving Water Quality

Zinc variability at V27 is attributed to the Grum/Vangorda water treatment plant discharge Location V27 is in the Main Stem of Vangorda Creek is immediately below the mine site and immediately upstream of the confluence with Shrimp Creek (reference location V4). This location is internal to the local study area but is influenced by the discharge of treated and compliant effluent and other runoff waters and by mixing with water from the Vangorda Creek Diversion Flume. From 1991 to 1998, water quality at this site was variable: sulphate ranged from 20 to 127 mg/L, pH from 7.33 to 8.24 and Zn generally from 0.02 to 0.164 mg/L (average = 0.05). The variability in zinc is attributed to the influence of a period of high volume discharge from the Grum/Vangorda Water Treatment Plant during the summer of 1997.

Location VGMAIN is at the extent of the local study area on the Main Stem of Vangorda Creek immediately upstream of the confluence with the West Fork. This includes water from the Main Stem via location V27 plus water from Shrimp Creek via reference location V4 plus natural runoff into the creek below Shrimp Creek. Routine sampling was introduced here in 1997. From 1997 to 1998, water quality at this site was variable: sulphate ranged from 23 to 233 mg/L, pH from 7.9 to 8.2 and Zn generally from 0.02 to 0.13 mg/L (average = 0.06). The variability in sulphate has been attributed to a natural seasonal cycle

Comparison of water quality in Vangorda Creek with that in the mine runoff water show dilution and assimilation of mine water in the receiving water during the baseline period

Most CCME

exceedances would have occurred during discharge periods and do not indicate acutely lethal conditions to aquatic life

Zinc and sulphate concentrations and pH. Zinc variability is attributed to initial clearing and construction work wherein higher concentrations are present in the winter season (Gartner Lee 2003b – Vangorda Annual Env. report). The variability in zinc is attributed to the influence of a period of high volume discharge from the Grum/Vangorda Water Treatment Plant during the summer of 1997.

During the 1998-2002 care and maintenance phase, the receiving waters at both locations V27 and VGMAIN (Tables 29 and 30) continued to show elevated levels of some metals as compared to the CCME guidelines and to the reference locations. Comparison of water quality in Vangorda Creek with that in the mine runoff water showed substantial dilution and assimilation of mine water in the receiving environment. Further, comparison of water quality at locations V27 and VGMAIN shows that most metals were reduced in concentration along the length of the Main Stem, with the exceptions of Mn, Ni and Pb. Nevertheless, receiving water quality was impaired when compared with CCME Guidelines for protection of aquatic life for Al, As, Cd, Cr, Cu, Pb and Zn at both locations.

Concentrations of Al, As, Fe, Mn, Ni and Pb were the same as, or less than, concentrations at the reference water quality sites at one or both of the receiving water locations V27 and VGMAIN. Concentrations of Cd, Cr, Cu, Ni, Pb and Zn were greater than the upstream reference sites at one or both of receiving water locations V27 and VGMAIN.

In summary, receiving water quality in the main stem of Vangorda Creek contained elevated concentrations of Cd, Cr, Cu, Pb, Zn and SO₄ when compared to reference water quality and CCME Guidelines. No CCME Guidelines exists for sulphate as it is of low toxicity. The CCME Guidelines represent water quality conditions that assure indefinite survival of the most sensitive life stages of sensitive aquatic species. Most exceedances would have occurred during discharge periods and were therefore short-term events. The water quality data do not indicate any conditions which are acutely lethal to aquatic life. This is supported by the acceptable toxicity testing reported in annual reports for the site (i.e. GLL, 2003b).

Location V5 is at the extent of the local study area in the West Fork of Vangorda Creek immediately upstream of the confluence with the Main Stem. This includes runoff water from AEX Creek plus a portion of the Grum Rock Dump (excluding the sulphide cell) plus natural runoff into the creek below the mine access road. Routine sampling was introduced here in 1991. From 1991 to 1998, water quality at this site was variable: sulphate ranged from 15 to 319 mg/L, pH from 7.2 to 8.8 and Zn generally from 0.001 to 0.29 mg/L (average = 0.04). The variability in sulphate has been attributed to a natural seasonal cycle wherein higher concentrations are present in the winter season (Gartner Lee 2003b). The variability in zinc is attributed to the influence of initial clearing and construction work in 1992. Sediment loading was also very high, on occasion, at location V5 (range from 2 to 1,020 mg/L total suspended solids), which is attributed primarily to initial construction and clearing work in 1992.

1998-2002 water quality During 1998-2002, the receiving waters at locations V5 (Tables 29 and 30) continued to show elevated levels of some metals as compared to the CCME guidelines and to the reference locations. Receiving water quality was impaired when compared with CCME Guidelines for protection of aquatic life for Al, As, Cd, Cr, Cu, Pb and Zn. Concentrations of Ag, Cd, Co, Cr, Fe and Mn were the same as, or less than, concentrations at the reference water quality sites.

Concentrations of Al, As, Cu, Ni, Pb and Zn were slightly greater than the reference sites. Sediment loading was also very high, on occasion, at location V5 (range up to 731 mg/L total suspended solids) which is attributed primarily to natural events downstream of the mine facilities.

A debris flow entered the creek in the summer of 2000 A significant natural sedimentation event occurred in summer of 2000 in the West Fork wherein a debris flow entered the creek from the north side upstream of location V5 and downstream of the mine access road. This event resulted in high initial sediment loads in the creek (251 mg/L total suspended sediment) and is considered to be contributing to an annual spring peak in total suspended sediments.

In summary, during the existing environment timeframe (1998 to 2002), receiving water quality in the West Fork of Vangorda Creek contained elevated concentrations of Al, As, Cu, Pb, Zn and TSS when compared to reference water quality and CCME Guidelines.

Regional Study Area Water Quality

The RSA downstream of the immediate receiving waters for the Vangorda Plateau site, is described by water quality at location V8, immediately upstream of entry into the Pelly River. This includes flow from the Main Stem via location VGMAIN plus flow from the West Fork via location V5 plus natural runoff into the creek below the confluence of the Main Stem and West Fork along the north perimeter of the Town of Faro. The Town of Faro water supply is taken from groundwater wells located at the entry of Vangorda Creek into the Pelly River.

Routine sampling was introduced at location V8 in 1989. From 1989 to 1998, water quality at this site was variable: sulphate ranged from 12 to 199 mg/L, pH from 7.0 to 8.5 and Zn generally from 0.006 to 0.36 mg/L (average = 0.05). The variability in sulphate has been attributed to a natural seasonal cycle wherein higher concentrations are present in the winter season (Gartner Lee 2003b). The variability in zinc is attributed to the influence of initial clearing and construction work in 1991. Sediment loading was also very high, on occasion, at location V8 (range from 4 to 590 mg/L total suspended solids), which is attributed primarily to initial construction and clearing work in 1991.

From the1998 to 2002, the receiving waters at location V8 (Tables 31 and 32) continued to show elevated levels of some metals as compared to the CCME guidelines and to the reference locations. Receiving water quality was impaired when compared with CCME Guidelines for protection of aquatic life for Al, As,

Cd, Cr, Cu and Pb. Concentrations of Ag, Al, As, Cr, Cu and Fe were the same as, or less than, concentrations at the reference water quality sites. Concentrations of Cd, Co, Mn, Ni, Pb and Zn were slightly greater than the reference sites. Sediment loading continued to be elevated during freshet at location V8 (range up to 184 mg/L total suspended solids), which is attributed primarily to the influence of a natural debris flow that occurred in the West Fork in 1991.

1998-2000 baseline
period water qualityIn summary, receiving water quality contained elevated concentrations of Cd, Pb
and TSS when compared to reference water quality and CCME Guidelines.

Vangorda Watershed Surface Water Quality Summary

The existing water quality for the Vangorda Plateau Mine Site was described by:

Description of the Vangorda Plateau mine site water quality

- Alkaline conditions, low solids and concentrations of some metals which exceeded CCME guidelines in reference waters isolated from mine influence;
- Entry into Vangorda Creek of mine runoff and effluent waters from the Grum Interceptor Ditch and Grum Creek which contained Ca, hardness, Zn, SO₄ and Mn at concentrations which were an order of magnitude above reference levels and of trace metals which exceeded reference levels by a factor of two;
- Water quality in the main Stem of Vangorda Creek downstream of the mine facilities, which reflected the influence of the mine facilities as elevated levels of Cd, Cr, Cu, Pb, Zn and SO₄;
- Water quality in the West Fork of Vangorda Creek downstream of the mine facilities which reflected the influence of the mine facilities as elevated levels of Al, As, Cu, Pb and Zn; TSS was also elevated between 1998-2002 and this was attributed to a natural debris flow; and
- Assimilation of all mine influences but Cd and Pb in Vangorda Creek upstream of the Pelly River.

These conditions describe the existing water quality against which the proposed project activities (Project Description, Volume I) have been assessed for the 2004 - 2008 time period (Environmental Effects Assessment, Volume III).

2.5.5 GROUNDWATER QUALITY

2.5.5.1 Overview

The baseline groundwater quality includes data from 38 locations, most containing 2 or more nested piezometers Groundwater quality for the 1987-2002 period includes data from a total of 38 regularly monitored locations, most of which contain two or more nested piezometer screens, on the Faro and Vangorda Plateau sites (Figures 22 and 23). These include locations designed to monitor subsurface seepage from the Vangorda Rock Dump, the Grum Rock Dump, the Faro Rock Dumps along the

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-53

The monitoring wells have varying periods of record due to a number of discreet installation programs

The number of sampling sites was reduced to describe the environmental baseline for the Rose Creek Tailings Facility Dumps and the Rose Creek Tailings Facility.

North Fork of Rose Creek, the Old Faro Creek channel below the Faro Rock

A management approach and considerations on possible degraded groundwater quality in these areas are described in the Adaptive Management Plan that is provided in Volume 1 of this report.

There have been a number of discreet piezometer installation programs over the mine life and, therefore, the monitoring wells discussed here have varying periods of record. The most recent programs were in 2001, focussed in the Rose Creek Tailings Facility and the Vangorda rock dump and in 1996, focussed on the Rose Creek Tailings Facility and the Faro rock dumps.

Some of the groundwater monitoring wells associated with the Rose Creek tailings facility provide information useful for detailed monitoring for the pathways of contaminants released from the tailings but do not provide information that is useful for environmental assessment (i.e. they are internal to the facility). Therefore, a smaller number of selected sites were used to describe the existing environmental conditions for the Rose Creek Tailings Facility. Additional details are provided in this volume under the topic of Mine Characterization. The most important groundwater quality requirement is to document the existing (defined as 1998 to 2002) groundwater quality. Groundwater quality data from 1998 to 2002 for the Faro and Vangorda Mine sites are provided in Appendix C.

2.5.5.2 Seepage from Faro Rock Dumps to the North Fork of Rose Creek

Groundwater seepage quality from the Faro Rock Dumps to the North Fork of Rose Creek is sampled at monitoring wells at the toe of the northeast rock dump (BH12, BH13 and BH14), at the toe of the Zone II Rock Dumps (BH1, BH2, BH4) and at the toe of the Intermediate Rock Dump (P96-6, S1, S2, S3) as illustrated on Figures 5 and 6 in Volume I. These monitoring wells vary in depth from 2.84 m to 20.85 m. Monitoring for surface water effects in the North Fork of Rose Creek is conducted at a series of surface sampling stations in the North Fork as described in Gartner Lee 2003a.

Baseline groundwater quality at wells at the toe of the NE rock dumps is impacted by seepage from the NERock Dumps Monitoring wells BH12, BH13 and BH14 at the toe of the northeast rock dumps consist of two installations each (one of the BH13 installations is currently inoperable) that vary in depth from 2.85 m to 10.0 m. These wells were installed in 1994. Groundwater quality was sampled once or twice per year from 1994 to 1998 and displayed measurable zinc concentrations (generally ranging from <0.01 to 0.12 mg/L) and variable sulphate (ranging from 93 to 883 mg/L) at neutral pH (ranging from 6.8 to 7.9). During 1998 to 2002, groundwater quality contained 0.05 mg/L zinc (median value) and 678 mg/L sulphate (median value) at continued neutral pH (7.31 median value). Therefore, existing groundwater quality in these monitoring wells is impacted by seepage from the northeast rock dumps as displayed by elevated zinc and sulphate. The possible effects of this groundwater on surface water in Rose Creek is described in Gartner Lee 2003a.

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-54

Groundwater quality slightly improved over the historical period in wells at the toe of the Zone II Rock Dumps

Baseline groundwater quality in wells BH 1,2,& 4 is impacted by historical events and possibly seepage from the Zone II Rock Dumps

Baseline groundwater quality at the toe of the Main/Intermediate Rock Dumps is impacted by seepage from the Main/Intermediate Rock Dumps and/or natural mineralization in the flow path Monitoring wells BH1, BH2 and BH4 at the toe of the Zone II Rock Dumps consist of one installation each that vary in depth from 3.20 to 5.55 m. These wells were installed in 1991. Groundwater quality was sampled nearly monthly from 1991 to 1998 except for 1992 to 1994 when only a few samples were collected. Groundwater quality from 1991 to 1998 displayed highly variable zinc concentrations (generally ranging from 0.02 to 184 mg/L), highly variable sulphate (ranging from 34 to 9050 mg/L) at variable and occasionally acidic pH (ranging from 2.6 to 8.5). During the 1998 to 2002 timeframe, groundwater quality was sampled approximately quarterly and contained 4.45 mg/L zinc (median value) and 184 mg/L sulphate (median value) at continued neutral pH (7.31 median value). Although existing groundwater quality continued to be highly variable, groundwater quality was slightly improved over the historical (1991 to 1998) period.

The poor groundwater quality in monitoring wells BH1, BH2 and BH4 has been attributed to the location of the wells within surficial soils that have been contaminated from historical events such as the initial routing of the Faro Creek Diversion over erodable gossan material to this general location and an overflow from the Zone II Pit through this location. Therefore, the high concentrations and low pH may not be directly related to ongoing seepage from the Zone II Rock Dumps. Additionally, the measured high concentrations and low pH do not have a demonstrable effect in the surface water of Rose Creek (Gartner Lee 2003a). Therefore, existing groundwater quality in these wells is impacted by historical events and, possibly, by ongoing seepage from the Zone II Rock Dumps as displayed by elevated zinc and sulphate and depressed pH.

Monitoring wells P96-6, S1, S2 ands S3 at the toe of the Main/Intermediate rock dumps consist of one or two installations each (P96-6 and S3 have only one installation) that vary in depth from 5.37 to 20.85 m. Routine monitoring results are available from 1996. Groundwater quality was sampled once or twice per year from 1996 to 1998 and displayed variable zinc concentrations (ranging from <0.01 to 3.73 mg/L) and variable sulphate (ranging from 85 to 1,372 mg/L) at neutral pH (ranging from 6.0 to 6.6). During the 1998 to 2002, groundwater quality was sampled once or twice per year and contained 0.22 mg/L zinc (median value) and 1,300 mg/L sulphate (median value) at continued neutral pH (6.3 median value). Therefore, existing groundwater quality in these monitoring wells is impacted by seepage from the Main/Intermediate Rock Dumps and/or natural mineralization in the flow path as displayed by elevated zinc and sulphate. The possible effects of this groundwater on surface water in Rose Creek is described in Gartner Lee 2003a.

2.5.5.3 Seepage from Faro Rock Dumps to the Rose Creek Tailings Facility

A large portion of groundwater flow from the Faro Rock Dumps is thought to report to the surface ponds of the tailings facility Groundwater seepage quality from the Faro Rock Dumps to the Rose Creek Tailings Facility is sampled at monitoring wells at the toe of the Main/Intermediate Rock Dumps (P96-7 and P96-8) as illustrated on Figures 5 and 6 of Volume 1. These monitoring wells vary in depth from 4.87 to 9.90 m.

Baseline groundwater

quality at wells at the

impacted by seepage

Main/Intermediate rock

Main/Intermediate

Rock Dumps are

toe of the

from the

dumps

Deloitte & Touche

A large portion of this groundwater flow is thought to report to the surface ponds of the tailings facility but some goes into the tailings.

Monitoring well P96-7 (9.90 m depth) at the toe of the Main/Intermediate Rock Dumps was installed in 1996. Groundwater quality was sampled once or twice per year from 1996 to 1998 and displayed highly variable zinc concentrations (generally ranging from <0.01 to 1.55 mg/L) and variable sulphate (ranging from 362 to 662 mg/L) at neutral pH (ranging from 7.4 to 7.6). From 1998 to 2002, groundwater quality contained relatively low zinc (0.03 mg/L median value) and 1,226 mg/L sulphate (median value) at continued neutral pH (7.06 median value). Therefore, existing groundwater quality in this monitoring well is impacted by seepage from the Main/Intermediate rock dumps as displayed by elevated sulphate.

Baseline groundwater quality near the old Faro Creek Channel is impacted by seepage from the Main/Intermediate Rock Dumps Monitoring wells P96-8A and 8B (4.87 and 9.30 m depths) are located near the old Faro creek channel at the toe of the Main/Intermediate rock dumps and were installed in 1996. The old Faro creek channel is thought to be a natural conduit for seepage from the rock dumps and there is a small surface discharge at this location also. Groundwater quality was sampled once or twice per year from 1996 to 1998 and displayed highly variable zinc concentrations (generally ranging from 0.94 to 16.1 mg/L) and stable sulphate (generally ranging from 2,118 to 2,576 mg/L) at neutral pH (ranging from 6.3 to 7.7). During the 1998 to 2002 environmental assessment, groundwater quality contained relatively low zinc (16.6 mg/L median value) and elevated sulphate (3,244 mg/L median value) at continued neutral pH (6.47 median value). Therefore, existing groundwater quality in this monitoring well is impacted by seepage from the Main/Intermediate rock dumps as displayed by elevated zinc and sulphate.

2.5.5.4 Seepage from the Rose Creek Tailings Facility

Groundwater seepage quality from the Rose Creek Tailings Facility is sampled at monitoring wells located downgradient of the Cross Valley Dam. Monitoring wells X16 A/B, X17 A/B and X18 A/B were installed in 1981 and have a long period of record. Monitoring well P01-02 was installed in 2001. These wells range in depth from 5.0 to 35.5 m in depth and the locations are illustrated on Figures 5 and 6 of Volume I. There are numerous additional wells associated with the Rose Creek Tailings Facility that are described in this volume under the topic of Mine Characterization. The downgradient wells listed here provide the information appropriate for the environmental assessment.

Baseline groundwater quality near the valley centre can be characterized by low zinc and sulphate concentrations Monitoring wells X16 A/B and X17 A/B are located near the valley centre and routine monitoring data is available since 1994 although a few data points are available to 1981. Groundwater quality from 1990 to 1998 displays low but variable zinc concentrations (generally ranging from <0.01 to 0.15 mg/L) and low but variable sulphate (ranging from 9 to 143 mg/L) at neutral pH (ranging from 6.9 to 7.9). During the 1998 to 2002 environmental assessment, groundwater quality contained relatively low zinc (0.03 mg/L median value) and sulphate (30 mg/L median value) that displays a slight increasing trend over time

at continued neutral pH (7.52 median value). Therefore, existing groundwater quality in these monitoring wells can be characterized by low zinc and sulphate concentrations.

Baseline groundwater quality at the north side of the valley bottom can be characterized by low zinc and elevated sulphate concentrations Monitoring wells X18 A/B are located on the north side of the valley bottom and routine monitoring data is available since 1994 although a few data points are available to 1981. Groundwater quality from 1990 to 1998 displays low but variable zinc concentrations (generally ranging from <0.002 to 0.15 mg/L) and elevated but variable sulphate (ranging from 40 to 424 mg/L) at neutral pH (ranging from 6.7 to 7.6). During the 1998 to 2002 environmental assessment, groundwater quality contained relatively low zinc (0.02 mg/L median value) and elevated sulphate (422 mg/L median value) that displays an increasing trend over time at continued neutral pH (7.1 median value). Therefore, existing groundwater quality in these monitoring wells can be characterized as distinct from the valley centre (i.e. wells X16 and X17) with low zinc and elevated sulphate concentrations.

2.5.5.5 Seepage from Grum Rock Dump at Grum Creek

Baseline groundwater quality in the Grum Creek channel is impacted by seepage from the Grum Rock Dumps Groundwater seepage quality from the Grum rock dumps at Grum Creek is sampled at monitoring wells P96-09 A/B as illustrated on Figures 5 and 6 of Volume 1. These wells were installed in 1996 in the Grum Creek channel in a bedrock valley that is at least 20 m deep. This drainage path is thought to collect seepage from the sulphide cell area of the Grum rock dump. The deeper well (P96-09B at 18.0 m) was initially artesian during spring and fall but is currently inoperable due to downhole soil compaction or movement.

Groundwater quality was sampled once or twice per year from 1996 to 1998 and displayed relatively low and stable zinc concentrations (ranging from 0.04 to 0.07 mg/L) and variable sulphate (generally ranging from 52 to 432 mg/L) at neutral to slightly alkaline pH (ranging from 7.1 to 8.0). From 1998 to 2002, groundwater quality contained low zinc (0.03 mg/L median value) and moderately elevated sulphate (180 mg/L median value) that displays and increasing trend at continued neutral pH (7.4 median value). Therefore, existing groundwater quality in this monitoring well is impacted by seepage from the Grum rock dumps as displayed by elevated sulphate.

2.5.5.6 Seepage from Vangorda Rock Dump

Groundwater seepage quality from the Vangorda rock dump is sampled at monitoring wells GW94-01 through GW94-04 as illustrated on Figures 5 and 6 of Volume I. These wells were installed in 1994 around the perimeter of the dump. Two additional monitoring wells were installed in 2001.

Baseline groundwater quality around the perimeter of the dump is slightly impacted by seepage from the Vangorda Rock Dump

Groundwater quality was sampled once or twice per year from 1994 to 1998 and displayed relatively low and variable zinc concentrations (ranging from 0.01 to 0.13 mg/L) and variable sulphate (ranging from 12 to 342 mg/L) at neutral to slightly alkaline pH (ranging from 7.0 to 8.8). From 1998 to 2002, groundwater

quality contained low zinc (0.02 mg/L median value) and moderately elevated sulphate (144 mg/L median value) at continued neutral pH (7.4 median value). Therefore, existing groundwater quality in this monitoring well is slightly impacted by seepage from the Vangorda rock dump or natural mineralization in the area as displayed by elevated sulphate.

2.5.5.7 Summary of Groundwater Quality

The groundwater quality is characterized by:

Description of the groundwater quality baseline

- Groundwater seepage from Faro rock dumps to the North Fork of Rose Creek is characterized by elevated zinc and sulphate and, below the Zone II rock dumps, occasional acidic pH;
 - Groundwater seepage from Faro rock dumps to the Rose Creek Tailings Facility via the old Far Creek channel is characterized by very high zinc and sulphate concentrations at neutral pH;
 - Groundwater seepage immediately downgradient of the Rose Creek Tailings facility is characterized by low sulphate that displays a slight increasing trend and low zinc concentrations in the valley centre and by low zinc and elevated sulphate concentrations on the north side of the valley;
 - Groundwater seepage form the Grum rock dump in the Grum Creek valley is characterized by low zinc concentrations and elevated sulphate that displays an increasing trend; and
 - Groundwater seepage from the Vangorda rock dump is characterized by low zinc concentrations and elevated but variable sulphate concentrations.

These conditions describe the existing water quality against which the proposed project activities (Project Description, Volume I) have been assessed for the 2004 – 2008 time period (Environmental Effects Assessment, Volume III).

2.6 AQUATIC RESOURCES

2.6.1 AQUATIC STUDY AREA

The aquatic resources regional study area is identical to the water resources study area Water resources discussed here include sediment quality, benthic invertebrates (communities and metal concentrations), fish (species distribution and metal concentrations) and fish habitat. The aquatic resource regional study area is identical to the water resource study area, which is watershed based and includes both the Rose Creek and Vangorda Creek watersheds as shown in Figure 3. Data has been collected from Anvil, Rose, Vangorda, and Blind Creeks and the existing conditions upon which the environmental effects assessment is based is data available from 1998 to 2002, during care and maintenance activities. Historical information is also available and is summarized under each component section, below to provide information and perspective on changes to each component, over time, as a result of mine activities.

Benthic community structure and metals in sediment have been the subject of sampling Aquatic resource studies in Rose and Vangorda regional study areas (Figure 3) have been completed over time as both routine sampling required under the water licenses and on a less routine basis for additional purposes. Benthic community structure and metals in sediment have been the subject of sampling and analysis as required under the current water licenses.

Metals in stream sediment data and benthic invertebrate community data exists from 1973 to 2002, while fish presence and metals in fish tissue data exists from 1974 to 2002 and metals in benthic invertebrate data was collected only in 2002. Table 33 outlines the aquatic resource studies that have been completed within the regional watershed study areas. Anvil Creek sampling is included within the Rose Creek watershed for the purpose of the table.

2.6.2 CREEK SEDIMENT QUALITY

2.6.2.1 Historical Sediment Quality

Copper, lead and zinc are found in the ore deposits, can be toxic to aquatic organisms and have existing sediment quality guidelines Sediment sampling in Vangorda Creek and analyses for metals have been conducted every two years since 1993 as required by the Water Licence (plus during 1996). Samples have been collected as part of additional studies between 1973 and 2002 in Rose Creek. Sampling sites are indicated on Figure 3. A discussion of historical results for copper, lead and zinc in both watersheds is included in the 2002 baseline report and is summarized below. These three compounds are found in the ore deposits, can be toxic to aquatic organisms at high concentrations and have sediment quality guidelines available for comparison.

The 1973, 1983 and 1996 (historical data) results for Rose Creek sediments indicate that copper concentrations exceed the 35.7 ug/g Interim Sediment Quality Guideline ("ISQG") in most impact area and some reference area samples. Lead concentrations in sediment exceed the 91.3 ug/g Probable Effects

Level ("PEL") in most impact and reference area samples. Some zinc concentrations exceed the 123 ug/g ISQG while the remainder exceed the 315 ug/g PEL at impact and reference area samples. Spatial trends in the data set are not apparent and temporal trends indicate highest values for the three metals in 1983 samples from the impacted area (following a 1975 tailings spill into Rose Creek) as compared to 1973 and 1996 values.

The highest metal concentrations in sediment are found at site V27, and an increasing trend is evident The 1991, 1993, 1995 and 1997 (historical data) results for Vangorda Creek sediments indicate that the highest copper, lead and zinc concentrations are in sediments from the impacted site V27. Metal concentrations at site V5 on the West Fork are the lowest and comparable to reference site V1 results, while concentrations at the Creek mouth (V8) are between the results of the V27 and V5 site, on either creek branch. Copper levels exceeded the 35.7 ug/g ISQG for some V27 and V8 sample results. Lead levels exceeded the 91.3 ug/g PEL in all V27 and V8 results, while zinc levels exceeded the 315 ug/g PEL in all V27 and some V8 sample results. Increasing levels of all three metals at site V27 over time is an evident data trend.

2.6.2.2 Existing Sediment Quality

All Rose Creek and Rose tributary sample results exceeded the ISQG for copper Results of sediment sample analyses from 1999, 2001 and 2002 are reported for copper, lead and zinc in Table 34. This table also compares the concentrations of copper, lead and zinc to the corresponding CCME (1999) interim freshwater sediment quality guidelines (ISQG) and to the probable effects level (PEL). In general, concentrations greater than the PEL have a 50% incidence of creating adverse biological effects on aquatic life.

Results of copper in six Rose Creek samples collected from between site R2 and R4 were 44 to 87 ug/g (plus an outlier of 182 ug/g). Results of copper in three Rose tributary reference samples collected in 1999 were 42 to 81 ug/g; within the range of the Rose Creek sample results from 1999 to 2002, while copper in 2002 Anvil reference site R6 sediment was 29 ug/g. All Rose Creek and Rose tributary sample results exceeded the 35.7 ISQG for copper. This indicates that copper in sediment is higher than the ISQG in reference locations.

Nearly all Rose Creek and Rose tributary sample results exceeded the ISQG's for lead and zinc Results of lead in seven Rose Creek samples collected from between site R2 and R4 were 156 to 364 ug/g. Results of lead in three Rose tributary reference samples collected in 1999 were 54 to 202 ug/g; while lead in 2002 Anvil reference site R6 sediment was <30 ug/g. All Rose Creek and two of three Rose tributary sample results exceeded the 91.3 ug/g PEL for lead.

Results of zinc in seven Rose Creek samples collected from between site R2 and R4 were 489 to 1,603 ug/g. Results of zinc in three Rose tributary reference samples collected in 1999 were 156 to 489 ug/g; while zinc in 2002 Anvil reference site R6 sediment was 117 ug/g. All Rose Creek and one of three Rose tributary sample results exceeded the 315 ug/g PEL for zinc.

22307-vol2-tables34,35,37-39.xls

Deloitte & Touche

Copper from sediment at V27 exceeded the ISQg. Lead from sediment at V27 and V8 exceeded the PEL, and zinc from sediments at V27 and V8 exceeded the PEL and ISQG respectively Results of copper in Vangorda Creek sediment was similar in samples from V5 and V8, at between 24 and 35 ug/g, within the 19 and 39 ug/g range at reference site V1. Copper was highest in site V27 sediment at 102 and 129 ug/g; in exceedance of the 35.7 ug/g ISQG.

Lead was highest in Vangorda Creek samples from V27 and at 2,069 and 2,801 ug/g, results greatly exceeded the 91.3 ug/g PEL. Results were 30 and 32 ug/g in V5 samples; within the 45 and 18 ug/g reference site V1 results. At V8, results from 66 to 110 ug/g exceeded the ISQG or PEL.

Zinc was highest in Vangorda Creek samples from V27 and at 921 and 868 ug/g, results exceeded the 315 ug/g PEL. Results were 81 and 116 ug/g in V5 samples; even lower that the 141 and 88 ug/g reference site V1 results. At V8, results from 148 to 248 ug/g exceeded the 123 ug/g ISQG and are mid-range for the watershed.

2.6.3 BENTHIC INVERTEBRATES

2.6.3.1 Historical Benthic Community Structure

Benthic invertebrates, including insects, crustaceans, and aquatic worms can be used as a measure of ecosystem health Benthic invertebrates include insects, crustaceans, aquatic worms and mollusks that reside in stream bottoms. Benthic invertebrate community structures are often used as measure of ecosystem health. Impacts to watercourses such as substrate composition, water flows and, in particular, water and sediment quality can affect benthic organisms. Sampling has been conducted at the following stations in the Anvil and Vangorda watersheds (Figure 3):

- 1. R1 Rose Creek south fork d/s of FWSD Reservoir
- 2. R2 Rose Creek at confluence of diversion channel and tailings outlet
- 3. R3 Rose Creek between tailings and Anvil Creek
- 4. R4 Rose Creek at mouth
- 5. R5 Anvil Creek d/s of Rose Creek
- 6. R6 Anvil Creek u/s of Rose Creek, a reference site
- 7. V1 Vangorda Creek upstream of diversion a reference site
- 8. V5 Vangorda Creek west fork downstream of mine activity
- 9. V27 Vangorda Creek downstream of mine activity
- 10. V8 Vangorda Creek at mouth

Benthic invertebrate population monitoring has been conducted every second year since 1991 Sampling was initiated at some of these sites in 1973 within the Anvil/Rose watershed and in 1975 within the Vangorda watershed. From 1991 on benthic invertebrate population monitoring has been conducted at each of these sites every second year as per the requirements of the water licences. Artificial substrates were used for the majority of the sampling events, allowing consistency across much of the data set. Triplicate samples were collected at each site during each sampling event and the results pooled to report community structure.

Sampling results have been summarized in terms of abundance (total number of organisms) and richness (number of taxa), as a means of comparing the benthic invertebrate community health over time and throughout the watersheds. The 1973 to 1997 data is detailed in the 2002 baseline report (GLL, 2002a) and is outlined below.

Measures of abundance and richness have fluctuated at each sampled site over time. This fluctuation may be attributed to natural factors including climate, water flow, species life cycles, sample timing as well as differences in sampling methodology and changes in water quality. No statistical analysis has been applied to the benthic data. The following observations can be drawn for the Rose / Anvil Creek data:

1. With some fluctuation, the overall trend is an increase in abundance over time (1973 to 1997) at reference sites R1, R7 and R6;

- 2. Abundance and richness at R2 and R4 have fluctuated over time with no increasing or decreasing trend;
- 3. Abundance and richness at R3 and R5 have exhibited a slight increasing trend over the 1973 to 1997 time period; and
- 4. Abundance and richness were typically lowest at R2, immediately downstream of the tailings.

The following observations can be drawn for the Vangorda Creek data:

- 1. There is an increasing trend in abundance at V27 over time, while richness fluctuates. This does not indicate an effect from the increasing level of metals (cooper, lead and zinc) at this site from 1975 to 1997;
- 2. Community abundance and richness fluctuate over time at V5 and V8; and
- 3. Abundance is lowest in samples from V1 (reference site), where there is a slight increase in richness over time.

2.6.3.2 Existing Benthic Invertebrate Structure

The greatest abundance in the Rose watershed samples was noted at locations R1 and R5

Abundance results from Vangorda Creek were less differentiating Recent 1998 to 2002 benthic invertebrate community data is available for 1998, 2000 and 2002 for Rose Creek and 1999 and 2001 for Vangorda Creek. Abundance and richness for each site are summarized on Table 35.

Community abundance ranged from 1,200 to close to 67,000 individuals in the Rose watershed samples. The greatest abundance was found in a sample from R1 and a sample from R5. Samples from R2 and R4 in generally had the lowest abundance with R3 also relatively low, indicating the lower Rose Creek samples to contain less abundant communities than the remaining sites. The lowest taxonomic richness was between 36 and 60 communities in the samples from the Rose watershed, with samples expressing the highest richness in site R1 and sites R3 and R7 expressing the lowest. There is no impact-reference pattern in the richness data.

Observations of historical abundance and richness at Rose/ Anvil Creek and Vangorda Creek

Table 35. Benthic Invertebrate Community Abundance and Richness, 1998 to 2002

Site	Year	Total Abundance (organisms/m ²)	Taxonomic Richness
R1	1998	50,808	57
	2000	5,386	57
	2002	9,988	60
R2	1998	1,945	47
	2000	6,611	48
	2002	11,639	54
R3	1998	13,491	39
	2000	18,929	42
	2002	1,808	40
R4	1998	8,148	48
	2000	na	-
	2002	4,430	52
R5	1998	7,974	44
	2000	66,975	54
	2002	15,088	45
R6	1998	26,944	43
	2000	39,344	56
	2003	1,232	36
R7	1998	39,292	44
	2000	4,574	40
	2002	10,965	37
V1	1999	1,025	20
	2001	707	21
V27	1999	1,061	23
	2001	3,698	24
V5	1999	1,284	32
	2001	17,232	40
V8	1999	1,061	28
	2001	5,867	28

Abundance in 1999 benthic samples from Vangorda Creek were very similar from all four sites. The 2001 samples varied with the site V5 sample the highest abundance with 17,232 individuals and site V1 the lowest with 707 individuals. Taxonomic richness was between 20 and 40 communities in the samples from the Vangorda watershed, with site V5 samples expressing the highest richness. There is no impact-reference pattern in the data, and in fact, the data shows reference site V1 as the least healthy community. These results do not reflect a linkage to an effect of metals in sediment as the data collected simultaneously shows the highest copper, lead and zinc levels in V27 sediment.

2.6.3.3 Metals in Benthic Invertebrates

Analysis of metal in the tissue of benthic invertebrates was conducted to determine the pathway for bioaccumulation in larger invertebrates Benthic invertebrates were collected for the analysis of metal in tissue for the first time around the Anvil Range Mine Complex in 2002. The analysis was initiated to determine the extent to which metals are accumulating in the benthic invertebrates (benthos) and thus the pathway for bioaccumulation in aquatic vertebrates (slimy sculpin and Arctic grayling). While most metals do no biomagnify between trophic levels, small invertebrates tend to accumulate greater concentrations of metals than large invertebrates, and therefore, early-lifestage fish (which eat smaller invertebrates) may be exposed to a larger dose of metals than adults (which eat larger invertebrates; Fareg *et al* 1998). Benthos were collected at the same sites as the sediment samples at R2, R4, R6 and V8 (sampling sites noted on Figure 3).

Chironimids made up 49% and 40% of the total biomass in the invertebrate collection from sites R2 and R4, respectively. At R4, there were only three *Hydropsychidae* individuals forming the majority of the biomass, although there were approximately 150 chironomids. Table 36 outlines the results of selected metals (arsenic, cadmium, copper, mercury, lead and zinc) in benthic invertebrate tissue.

Creek	Site	Arsenic	Cadmium	Copper	Mercury	Lead	Zinc
Rose Creek	R2	0.35	0.075	12.8	0.011	6.42	50.6
Rose Creek	R4	0.25	0.055	4.7	0.006	3.14	34.2
Anvil Creek	R6	1.32	0.141	4.7	0.007	1.35	39.4
Vangorda Creek	V8	0.30	0.117	4.8	0.009	1.86	50.8

Table 36. Summary of Metal Concentrations in Benthic Invertebrate Tissue (ug/g)

Sites R2 and R6 had the highest concentrations of metals in tissue Concentrations of copper, mercury and lead are highest in benthos collected from site R2, while concentrations of arsenic and cadmium are the highest in benthos collected from the reference site R6. This correlates with the 2002 stream sediment results where sediment collected from R2 also contained the highest concentrations of copper, mercury and lead. Zinc concentrations are similar in benthos collected from R2 and V8. This does not correlate with the 2002 sediment is lower than R2 sediment.

2.6.4 FISH

2.6.4.1 Historical Fish Habitat

The Faro Mine Site is located entirely within the Rose Creek watershed and construction and operations have altered the creek to result in the following:

Description of alterations to Rose Creek

- diversion of Faro Creek around the Faro Pit to enter the north fork of Rose Creek, rather than flowing directly into the main stem of Rose Creek;
- diversion of the main stem (reach 3) around the tailings impoundment facilities;
- creation of the pumphouse pond at the junction of the north and south forks;
- two alternative routes for the lower 500 m of the North Fork one is the original channel with a series of excavated ponds, with a culvert at the upstream end preventing upstream fish migration and the other is a boulderlined channel;
- construction of the Fresh Water Supply Dam converting approximately 1500 m length of stream habitat into lake habitat;
- creation of a barrier on the south fork of Rose Creek through the installation of hanging culverts just downstream of the FWSD spillway; and
- a fish migration barrier on the North Fork at the haul road crossing; and
- fish migration barriers on the South Fork at the haul road and mine road crossings.

2.6.4.2 Existing Fish Habitat

Juvenile or spawning, Arctic grayling is the predominant species in Rose Creek The following details of fish habitat in Rose Creek are based on the reporting of P.A. Harder & Associates (1991a, 1991b, 1993) and field assessments by Gartner Lee during July and August of 2002 (GLL 2002c). Except for the construction of the haul road over the North and South Forks during the early 1990s, fish habitat observations have been consistent over this time period (studies completed between 1988 and 2002). A habitat summary of Rose and Vangorda Creeks, by stream reach (a fairly homogenous channel section), is outlined in Table 37 and subjective habitat values for juvenile and spawning Arctic grayling (the predominant species in Rose Creek) as well as habitat available in summer and winter, are shown on Figure 24.

Lower Rose Creek (reaches 1 and 2) consists of high quality habitat suitable for spawning and rearing Arctic grayling and moderate habitat for adults during both summer and winter. Flow is expected here in the winter. Rose Creek is meandering in this section and contains diverse habitat including spawning gravel as well as deep pools and side channels. Based on Harder (1988), Arctic grayling spawn in this reach. Next Creek flows from the north into reach 2 of Rose Creek. Next Creek is narrow with little flow over a relatively steep gradient (>10%) of step-pools resulting in low value for all life stages of Arctic grayling.

Watercourse	Reach	Arctio	Grayling	Habitat R	ating	Channel	Gradien	Channel	Bed	Cover	Barriers	Other
		Spawning	Rearing	Summer	Winter	Width	(%)	Туре	Materiala			
Rose Cr.	1	high	high	moderate	moderate	25	1.5	,	gravel (cobble, fine)			side channels, flows in winter

Table 37. Fish Habitat in Rose and Vangorda Watersheds

Notes:

a. fines = <2mm, gravel = 2-64mm, cobble = 64-256mm, boulder = 256-4,000mm; sub-dominant substrate in brackets See Figure 3 for reach location The diversion channel (reach 3) is considered to have little rearing habitat and moderate value spawning, winter and summer habitat. The upper two-thirds of the diversion is a wide (20 m) channel with predominantly gravel and cobble substrate. The lower one-third contains steps of boulders and pools. Velocities in the lower section may make it difficult for juvenile grayling passage. Based on Harder (1988), Arctic grayling spawn in the upper portion of this reach. Flow has been expected here in the winter due to release from the reservoir.

Reaches 1 and 2 of the south fork of Rose Creek feature moderate spawning and high value rearing and overwintering habitat

Reach 1 of the South Fork of Rose Creek includes the Pumphouse pond and a natural channel that is predominantly riffle over cobble. Due to this habitat combination and the augmented winter flows from water releases from the reservoir, the habitat value is moderate for spawning and high for rearing and over-wintering habitat. Reach 2 is a meandering section with numerous side channels created by beaver dams and a substrate dominated by fines. The deep water and augmented overwinter flows provide high value habitat for rearing, and over-wintering but the reach is low value for spawning.

Reach 3 provides high quality rearing and over-wintering habitat

Reach 3, south fork Rose Creek is the Fresh Water Supply Reservoir. At spillway capacity, the maximum depth is 16.1 m, the average depth 7.5 m. The water volume was calculated to be $4,065,500 \text{ m}^3$ and the surface area $514,960 \text{ m}^2$. Information on substrate was collected during 2002 (GLL, 2003c) and was predominantly fines with cobble, boulder, angular rock, flooded willow shrubs and spruce present. The reservoir does not provide spawning habitat but provides high quality habitat for rearing and over-wintering grayling.

There are two culverts under an access road at the lower end of the FWSD spillway, which form a drop of approximately 8 m creating an impassable barrier for fish movement from Rose Creek upstream into the Fresh Water Supply Reservoir during flow periods over the spillway (typically late spring and summer). During the remainder of the year, water is released from the reservoir via a low-level pipe.

Reach 4 of the South Fork is predominantly riffle channel over boulder and cobble with some beaver dams in the upper end. Habitat is considered to be of moderate value habitat moderate value for all grayling life stages. Reach 5 contains three fish passage barriers at the lower end: a culvert under the mine access road, the rock drain under the haul road and a steep gradient section (>20%) upstream of the haul road. Fish cannot move upstream or downstream from this section. There is moderate value rearing habitat and low habitat for all other life stages in reach 5. Reach 6 is predominantly riffle over boulders at a 5% slope, with habitat considered moderate for spawning (grayling have been observed spawning at the upper end) and low for all other life stages. Dixon Lake is a shallow basin in reach 7, which offers low quality spawning habitat but high value habitat for rearing, and moderate value over-wintering habitat.

> The lower end of reach 1 of the North Fork of Rose Creek consists of two channels. The original channel has been converted to a series of ponds that flow to the pumphouse pond and a boulder-lined diversion channel directed

Reach 4 is considered

Reaches 1 and 2 of the north fork of Rose Creek provide moderate to low value habitat. Reach 3 contains diverse habitat, while Reach 4 ponds have low habitat value

Faro Creek is considered low habitat. The Vangorda Creek contains some important rearing and over-wintering habitat as well as some spawning and rearing habitat

downstream of the pumphouse pond was created. Prior to 1996, flow was directed through the original channel during the winter season to augment flow to the Pumphouse Pond and through the diversion during the summer to prevent possible sedimentation in the pond. Since 1996, all flow is directed through the series of ponds with high flow events spilling partially into the diversion. The culvert directing flows to the series of ponds is a barrier to upstream fish passage. The series of ponds and natural channel above it, provide habitat of moderate value to all life stages of grayling. Where the haul road crosses the north fork (designated as the downstream end of reach 2), a rock drain passes the creek under the road creating an impassable barrier to fish passage in either direction. Reach 2 is a diverse stream section that provides low winter habitat and moderate spawning, rearing and summer habitat.

Deloitte & Touche

Reach 3 of the North Fork contains diverse habitat with beaver ponds and riffle sections resulting in high rearing and moderate spawning, summer and winter habitat. Grayling are known to spawn in the upper section of this reach. A series of ponds are located in reach 4. However, these have been measured as acidic with low dissolved oxygen, which would result in low habitat for all life stages (Harder 1988).

Faro Creek originally flowed in to the mainstem of Rose Creek but in order to develop the open pit the creek was diverted around the Faro Pit and now flows into reach 1 of the north fork. Faro Creek carries low flows and is a step-pool channel greater than 10% slope at the North Fork. The entire creek is considered low habitat for Arctic grayling and is not likely accessible from the north fork under most flow conditions due to low flow and steep grade.

The Vangorda Mine Site is located within the Vangorda watershed. Vangorda Creek contains two upper branches that meet to form the mainstem plus a major tributary called the West Fork. The mainstem has been diverted around the various pits and dumps and the mine haul road crosses this branch. The mine access road crosses the west fork in three locations and a culvert under the Town of Faro access road crosses the main stem. Lower Vangorda Creek (reaches 1, 2 and 3 on Figure 24) is low gradient (1.5% to 2.7%) with large gravels, cobbles and boulders that provide important rearing habitat for chinook and some overwintering habitat for the resident Arctic grayling. Some spawning habitat is available in this section (reach 1) and rearing and summer habitat is offered by the pools and in-stream cover (reaches 2 and 3).

Above reach 3, the culvert under the Town of Faro access road and waterfalls just upstream are barriers to upstream fish migration. The channel gradient becomes progressively steeper upstream (4% in the mid-section and 6% in the headwaters) with larger substrate and log debris from adjacent burn areas (Harder 1987).

2.6.4.3 Fish Presence

Several isolated fish populations exist in Rose Creek Fish species present in the upper Pelly River watershed include chinook and chum salmon, lake trout, lake, broad, humpback and round whitefish, least cisco, inconnu, Arctic grayling, northern pike, burbot, longnose sucker and slimy sculpin. Arctic grayling (*Thymallus arcticus*), burbot (*Lota lota*), slimy sculpin (*Cottus cognatus*), longnose sucker (*Catastomas catostomus*) and round whitefish (*Prosopium cylindraceum*) have been captured during sampling studies in the Rose Creek watershed (Figure 24). In addition to these species, juvenile chinook salmon (*Oncorohynchus tshawytscha*) have been captured in lower Vangorda Creek (reaches 1, 2 and 3). As noted in Table 33, reported fish studies have been conducted between 1974 and 2002 in the regional aquatic study area.

Due to barriers in the system (noted above and indicated on Figure 24), the following isolated populations exist in Rose Creek:

- North fork reaches 2, 3 and 4;
- South fork reaches 3 and 4 (downstream movement possible); and
- South fork reaches 6 and 7.

Fish within the main stem of Rose Creek, reach 1 of the north fork and reaches 1 and 2 of the South Fork can also move into Anvil Creek. Culverts on one flow option of lower reach 1 of the North Fork (series of ponds) limit upstream movement when all flows are diverted this route rather than via the diversion channel. No fish have been captured during sampling upstream of a culvert and falls barrier in Vangorda Creek.

Arctic grayling are the predominant species captured in the Rose Creek Arctic grayling watershed and have been captured in all reaches sampled (distribution noted on Figure 24). Grayling is the only species fished for sport in Rose Creek and fishing is most popular in the lower end of the south fork and within the reservoir (Harder 1991a). Once they reach maturity (age three to four in the study area), Arctic grayling spawn annually between early May and early June in the Rose Creek drainage (Weagle 1981, Harder 1988). Spawning grayling have been observed in reach 3, reaches 1, 4 and 6 of the south fork and reach 3 of the north fork. This is not likely the limit of spawning areas as spawning high value spawning habitat is located in additional reaches, as noted in the previous section. Although juveniles have only been captured in one study within the D Reservoir (reach 3 of south fork, P.A. Harder 1991a), the presence of adults and spawning throughout the drainage indicate that all life phases must be present. Grayling are also located in lower (reaches 1 to 3) of Vangorda Creek, downstream of culvert and falls barriers. Information such as fish sex, catch per unit area and comparisons of grayling weight vs. length and age was collected in early studies by P.A. Harder and Associates. Some length, weight, sex and age data is available from the 2002 sampling and is presented on Table 38.

Slimy sculpin have also been captured in reaches sampled within Rose Creek and within lower Vangorda Creek. Burbot have been captured in lower

Table 38. Summary of 2002 Fish Sampling Activities and Results

AG - arctic grayling BB - burbot

CH - chinook salmon

RW - round whitefish

SS - stimy sculpin

Vangorda Creek and reach 2 of Rose Creek, reach 1 on the north fork and Slimy sculpin, burbot reaches 2, 3 and 4 of the south fork. Round whitefish have been noted in lower and round whitefish Vangorda Creek, reach 3 of Rose Creek and reach 1 of the north fork. Longnose presence sucker have been captured in lower Vangorda Creek and reach 1 of the North Fork. Other than capture information, including location, length and in some cases, weight, little information has been collected for these species in the regional study area.

Chinook salmon fry are present in large numbers in lower Vangorda Creek (at Chinook salmon fry in the mouth) each year from the spring or early summer where they rear until lower Vangorda Creek outmigration in the fall. These fish are migrating from spawning grounds, including Blind Creek. DFO has collected information on the Blind Creek chinook stocks over a number of years. During aerial surveys and sampling, a few chinook spawners and chinook fry have been noted in Anvil Creek. As access is possible to Rose Creek, chinook may enter the lower end of the creek.

Table 38 summarizes fish sampling and catches from the 2002 field visit, which During the 2002 field was conducted primarily to collect metals in fish tissue data and confirm habitat visit, fish tissue for mapping. Therefore, not all sites sampled in the past were sampled during samples were collected this trip. No fish were captured during electrofishing at sites R1, R2 and R2b of for metals analyses reach 2 in Rose Creek. Minnow trapping at R2b captured two burbot and angling captured two grayling. Arctic grayling and sculpin were observed in reach 3 (R3, diversion channel) during electrofishing.

> Within the North Fork, slimy sculpin were captured during electrofishing in reaches 2 (site N4, 1 fish) and 3 (site N5, 26 fish), with the highest sculpin numbers (as compared to all other 2002 sites) per electrofishing effort at site N5. Electrofishing in the south fork reaches 4 (site S6) and 6 (site S8), resulted in the capture of two sculpin at S6. Minnow trapping in the reservoir captured six slimy sculpin and gill netting captured 63 Arctic grayling and one burbot.

> Electrofishing, beach seining, minnow trapping and angling efforts were undertaken at site V8 on Vangorda Creek to collect fish for metals analyses. A total of 21 sculpin, 11 grayling and 190 chinook salmon fry were captured. Blind Creek sampling (outside of the study area) was conducted to collect reference site fish for metals analyses. Grayling, sculpin, chinook and round whitefish were captured during the multiple method efforts.

2.6.4.4 Historical Metals in Fish Tissue

The analysis of metals in fish tissue has been carried out in 1975, 1976, 1977, 1989, 1992, 1997 and 2002 within the regional aquatic study area and reference site in Anvil and Blind creeks. The sampling locations, species, tissue type and metals analyses were not consistent in the historical (1975 to 1997 data) and therefore temporal and spatial trends are difficult to determine. Chinook, Arctic grayling, slimy sculpin, longnose sucker, round whitefish and burbot have all been collected for tissue analyses, which have been conducted on whole body, liver or muscle tissue.

No trends of higher metal levels were noted in fish collected from Rose Creek downstream of the tailings (site R2b) as compared to fish from the FWSD Reservoir during 1997. Likewise, there is no consistent trend in the metals data collected in fish from Vangorda Creek (site V8) during 1975, 1976 and 1997. Values that stand out in the dataset (one or two orders of magnitude higher than others) include higher values of both lead in sculpin (23 mg/kg) and whitefish from Vangorda Creek during 1992.

2.6.4.5 Existing Metals in Fish Tissue

The 2002 sampling program for metals in fish tissue revealed no trend for arsenic. Cadmium concentrations were greatest at the reference site and V8 The 2002 sampling program following a control/impact sampling layout. Five samples from each site were targeted to provide data for comparison between and within sites. Slimy sculpin and arctic grayling were targeted as they have previously been collected at each of the Rose, Vangorda and Blind sampling sites and they represent a bottom-feeding species (sculpin) that may show accumulation of any heavy metals present in sediment and benthic invertebrates as well as a species consumed by humans (grayling). Sculpins were analyzed as whole body samples while muscle and liver tissue were used from Arctic grayling (muscle to represent the tissue generally consumed by humans and liver to represent the tissue where some metals are known to concentrate). Fish collection for metals analysis was successful at:

- Rose Creek just below the tailings facility (site R2b);
- The freshwater supply reservoir (site RES);
- Upper north fork above mine activity as a reference site for the Faro Mine Site (site N5);
- Lower Vangorda Creek (site V8); and
- Lower Blind Creek as reference site for the Vangorda Mine Site (site BC).

At each site (noted on Figure 24) the capture of between five and ten fish was targeted in order to have sufficient fish tissue to make up five samples weighing 5 grams (as required by the lab for low detection) of liver and muscle tissue. In some cases the fish were too small to provide the required amount of tissue and tissue from two or more fish was composited. Due to very low catch success at some sites, five to ten samples per site were not achieved in all cases. Table 39 outlines the results of key metals (arsenic, cadmium, copper, lead, zinc and mercury) of interest in fish tissue. Details are provided in the 2002 aquatic studies technical memorandum (GLL 2002c).

There is no increasing trend in metals in fish tissue within waters draining the Faro and Vangorda Plateau mine sites No trend is evident in arsenic concentration between sites. Whole body sculpin contained greater concentrations of arsenic than Arctic grayling muscle and liver (by an order of magnitude). This difference could be attributed to the differences of tissue types in concentrating metals. Cadmium levels were noticeably highest in all Blind Creek (reference site) Arctic grayling liver samples and one V8 sample. Levels in both slimy sculpin and Arctic grayling muscle were greatest at V8.

Line and

and she have

Copper levels are generally greatest in Arctic grayling liver but the data does not indicate a spatial trend. Lead levels are greatest in sculpin and grayling liver samples from the FWSD Reservoir and sculpin from V8. Sculpin samples from the FWSD Reservoir exhibit higher levels of lead and copper than sculpin from N5, however the copper levels are similar to sculpin from the Blind Creek reference site.). Results from one of the four Arctic grayling muscle samples from Vangorda Creek (V8) are 10 times the levels of copper and lead results in grayling muscle samples from Blind Creek.

Mercury levels are similar in fish tissue types at all sites with slight elevations (much less than an order of magnitude) apparent in grayling liver as compared to sculpin and grayling muscle. Health Canada has set a consumption guideline at 0.5 mg/kg mercury per day in fish tissue. The highest mercury value in the sample set is 0.131 mg/kg wet weight, the result of two composite livers collected from Arctic grayling in the freshwater reservoir. The highest sample value is approximately 26% of the consumption guideline. Based on this data set, four or more fish from the sampling sites could be consumed by one person each day without risks associated with mercury.

Zinc levels are within the same range in all tissue types from the various sampling locations, with the level in the one V8 sculpin sample slightly elevated (much less than an order of magnitude). In summary, the results do not indicate a trend of increased levels of metals in sculpin or Arctic grayling within waters draining the Faro and Vangorda Plateau mine sites relative to the reference sites (N5 and BC) or the FWSD Reservoir.

2.7 TERRESTRIAL RESOURCES

2.7.1 TERRESTRIAL STUDY AREA

Definition of the terrestrial resources regional study Terrestrial resources include vegetation, wildlife habitat and wildlife environmental components. A wildlife study area is usually delineated by the extent of the wildlife population under study. These data are not available for all local species; there are no population distribution data available for moose, stone sheep or grizzly bears. The terrestrial resources regional study area is bounded by the Pelly River to the south, Mount Mye to the north, with Rose Mountain to the west and Sheep Mountain to the east (Figure 4), which captures the local Fannin sheep population. Vegetation and wildlife studies completed within the study area are included in Table 40.

 Wildlife and Vegetation Studies Completed

2.7.2 SOILS / TERRAIN

Significant surficial material in the study area consists of bedrock, glacial till, and glaciofluvial deposits The landforms and surficial deposits of the Vangorda Plateau have been shaped and are attributable to the last ice age which is estimated to have existed in the Yukon between 35,000 and 10,000 years ago. The southern Yukon was covered by at least four Cordilleran (i.e. mountain) ice sheets. These glaciations, from oldest to the youngest, are named the Nansen, the Kalza, the Reid and the McConnell. (Bond 2001). The landforms of the Faro area are for the most part attributed to the youngest of the Yukon glaciations, the McConnell.

Significant surficial material in the study area consists of bedrock and associated colluvium, glacial till, and glaciofluvial outwash sands and gravels (Figure 10). Glaciolacustarine, modern alluvial and organic deposits, are found sporadically but are not discussed in detail herein. The following discussion of surficial materials is derived from the *Quaternary geology and till geochemistry of the Anvil district, central Yukon Territory* (Bond 2001):

Bedrock – bedrock and/or frost shattered bedrock (felsenmeer) is frequently found at surface in the alpine areas of the Anvil Range. Elsewhere, mountain slopes are covered in thin veneer of colluvium (materials derived from slope movement processes) derived from the local bedrock. Glacial deposits are relatively absent above 1,500 m, although meltwater channels were identified as high as 1,700 m. Solifluction is common above the tree line.

Morainal Deposits (Till) – glacial till is poorly sorted deposits of clay, silt, sand, gravel and angular boulders which is deposited directly from glacial ice. A thick blanket of till is found covering the Vangorda Plateau. In some locations where pre-glacial valley existed, the till deposits can be over 100 m thick (e.g. Grum valley). Generally till deposits thin to a veneer (<1 m) along the valley walls and are generally absent above 1,500 m. Till also commonly underlies glaciofluvial deposits in areas of former meltwater drainage. The area surrounding the Grum and Vangorda Deposits is characterized by a thick till blanket overlying bedrock.

Glaciofluvial Deposits – during the retreat of the glaciers, melting water derived from the decaying ice transported and deposited sand and gravel in the valley bottoms and associated lateral meltwater channels. These deposits are typically stratified to crudely stratified deposits varying from sand with some silt to cobble gravels. These materials are found as significant valley fills as in the Rose Creek valley, as kame terraces at the mouth of alpine valleys or as glacial terraces and complexes associated with the Vangorda Creek valley and the Tintina Trench. Glaciofluvial deposits host the Rose Creek aquifer which underlies the Faro Mine tailings facility. The Faro townsite is located on a major glaciofluvial (and glaciolacustarine) terrace with a well developed stagnant ice (i.e. hummocky terrain) glacial fluvial complex to the northwest of the townsite. The valley bottom glaciofluvial deposits are frequently covered by silts, sands and gravel derived from contemporary stream.

The majority of the natural soil located in the Anvil Range Mining Complex consist of granular soils; *i.e.* locally derived tills, glacial outwash deposits and fluvial deposits. The region is within an area of discontinuous permafrost.

2.7.3 VEGETATION

2.7.3.1 Historical Vegetation Disturbance

Permanent clearing of vegetation occurred over the course of mine development Over the course of mine site development, permanent clearing of vegetation was required. Roughly 1,460 hectares of vegetation was removed for the development of the Faro and Vangorda Plateau mine sites and the haul road. Portions of the following vegetation communities were included in the clearing: subalpine transition, floodplain forest (riparian zones), and upland forest. Vegetation was also cleared for the purposes of developing access roads in the vicinity of the mine complex, including the main mine access road between the Town of Faro and the Faro Mine site, the Blind Creek access road to the Vangorda site, and the various accesses on the mine sites themselves. Most of these access roads extend through upland forest and subalpine transition

communities, according to the MEC Ltd. 1976 1:10,000 mapping (Figure 25). Vegetation removal was also required for the network of exploratory cutlines to the north and northeast of the Faro mine site through out the subalpine transition vegetation community. The development of the Fresh Water Supply dam caused eventual flooding of 51 ha plus earth fill of 5 ha of what was likely floodplain forest (riparian zones).

Indirect impacts to vegetation likely also took place during development and operation of the mine sites. For example, soil compaction due to heavy machinery can potentially impact adjacent root zones, local drainage changes can potentially impact the composition of local plant populations, contaminated seepage zones have potential to affect plant growth and health and plant species composition, and dusting from the mine site can potentially cause elevated metal concentrations in vegetation.

2.7.3.2 Existing Vegetation Communities

Six vegetation zones were identified within the study area The regional study area is located within the Yukon Plateau (North) Ecoregion, in the Boreal Cordillera Ecozone (ESWG 1995). The region lies within the zone of discontinuous, widespread permafrost. Depressional areas consist of peat bogs, fens and local palsas. Lowlands frequently contain hummocks and sedge tussocks. Upland areas commonly include scree slopes and steep south-facing slopes with vegetation dominated by grasses. Treeline occurs at 1350 to 1500 mASL.

Six vegetation zones were mapped within the study area at a scale of 1:10,000 based on the field studies and mapping undertaken by Montreal Engineering Company (MEC) Ltd. in 1976 (Figure 25). The vegetation zones include flood plain forest, upland forest, bog forest, alpine tundra, subalpine transition, and alluvial plain shrub. The structure and species composition of these vegetation zones are outlined below.

Flood Plain Forest

The flood plain forest zone represents the most developed forest stands in the study area The flood plain forest zone in the study area is restricted to the alluvial landforms along the Pelly River and the lower reaches of Blind Creek, and represents the most developed forest stands in the study area. White spruce (*Picea glauca*) forests occur where flooding is less common and subalpine fir (*Abies lasiocarpa*) stands occur in frequently flooded areas. Lodgepole pine (*Pinus contorta*), balsam poplar (*Populus balsamifera*), trembling aspen (*Populus tremloides*) and paper birch (*Betula papyrifera*) also occur in the flood plain forest zone. Dense shrub stands, consisting primarily of willow (*Salix* spa.) and balsam poplar, are common in riparian zones where active deposition is occurring. Feathermoss layers are extensive within the older stands of white spruce.

Upland Forest

The upland forest zone is dominated by either white spruce, lodgepole pine, or subalpine fir

Upland forests are found on the morainal landforms above the Pelly River and the upper Vangorda Creek area. Much of this forest was burned in a 1969 fire. Upland forest is also found on the glaciofluvial landforms along Rose Creek. The upland forest zone is dominated by stands of either white spruce, lodgepole pine, or subalpine fir. A well developed layer of tall and medium shrubs includes trembling aspen, shrub birch (Betula glandulosa), Scouler's willow (Salix scouleriana), and other willow species. The dwarf shrub strata of the upland forest consists of dwarf dogwood (Cornus canadensis), crowberry (Empetrum nigrum), Labrador tea (Ledum groenlandicum), blueberry (Vaccinium uliginosum), low-bush cranberry (Vaccinium vitis-idaea), prickly rose (Rosa acicularis), arctic willow (Salix arctica) and net-veined willow (Salix reticulata). Herb development is not extensive in the upland forest zone. Herb species in this zone include fireweed (Epilobium angustifolium), arctic lupine (Lupinus arcticus), arrow-leafed coltsfoot (Patentees sagittatus), and sedges (Carex spp.). The moss layer, particularly feathermoss, is extensive in the closed-canopy portions of the upland forest. Lichens include spotted dog lichen (Peltigera aphthosa), coral lichen (Stereocaulon paschale) and Cladonia spp.

Bog Forest

The bog forest zone is located adjacent to the Pelly River

The alpine tundra

above the treeline

vegetation zone occurs

The bog forest is limited to the organic landforms adjacent to the Pelly River. It is characterized by peat accumulation and stunted black spruce (*Picea mariana*). Black spruce is commonly the only tree species found in the bog forest. Shrub species include shrub birch, northern Labrador tea (*Ledum decumbens*) and cloudberry (*Rubus chamaemorous*). The herb layer is poorly developed in the bog forest zone. It consists mainly of sedges. A characteristic feature of the bog forest is the extensive layers of moss, usually *Sphagnum* spp. It is these moss layers that accumulate into peat. Bog forests are commonly underlain by permafrost.

Alpine Tundra

The alpine tundra vegetation zone occurs above the treeline, primarily on the upper slopes of Mt. Mye and Rose Mountain. Smaller communities of alpine tundra vegetation are found in areas such as Sheep Mountain (the mountain just north of the Blind Creek Bridge). Alpine tundra consists of vegetation communities dominated by dwarf shrubs and lichens. Shrubs include dwarf birch (*Betula pumila*), mountain avens (*Dryas octopetala* and *Dryas integrifolia*), crowberry, low-bush cranberry, blueberry, arctic willow, snow-bed willow (*Salix polaris*) and other willow species. Lichens, predominantly *Cetraria spp.*, are prevalent in well-drained rocky sites. A variety of herb species occur in the alpine tundra zone, including arctic lupine, Langsdorf's lousewort (*Pedicularis langsdorffii*), alpine harebell (*Campanula lasiocarpa*), black-tipped groundsel (*Senecio lugens*), wormwood (*Artemisia sp.*) grass (*Arctagrostis latifolia*) and sedges.

transition zone occurs

in steep mountain

slopes with shallow

The subalpine

soil

Subalpine Transition

The subalpine transition, associated with colluvial landforms, occurs on the steep upper mountain slopes between the upland forest and the alpine tundra. It is also found at lower elevations where there are steep slopes and shallow soil. The mid-slopes of Mt. Mye and Rose Mountain (below the treeline), as well as the uplands adjacent to Rose Creek alluvial plain, are included in this zone. Well developed forests of white spruce and feathermoss occur at lower elevations in the subalpine transition zone. Tall and medium shrubs in these lower elevation forests include shrub birch and Scouler's willow, and the dwarf shrub layer consists of arctic willow, crowberry, Labrador tea and blueberry. The herb layer, not well developed at lower elevations, is limited to sedges and shade-tolerant species such as arctic lupine and bluebell (*Mertensia paniculata*).

At higher elevations in the subalpine transition zone, vegetation is dominated by tall and medium shrub strata containing such as species as trembling aspen, shrub birch, Scouler's willow and other willow species. Alpine fir, lodgepole pine, white spruce and black spruce are also found in the upper subalpine transition zone. Dwarf shrubs include crowberry, Labrador tea, blueberry, net-veined willow and kinnikinick (*Arctostaphylos uva-ursi*). The herb layer at higher elevations in the subalpine transition zone is much more developed. It includes fireweed, arrow-leafed coltsfoot, Labrador lousewort (*Pedicularis labradorica*), dwarf dogwood, one-sided wintergreen (*Pyrola secunda*), rayless alpine butterweed (*Senecio pauciflorus*), aster (*Aster sp.*), running clubmoss (*Lycopodium clavatum*), grass (*Arctagrostis latifolia*), and sedges. Lichens in the subalpine transition zone include spotted dog lichen and *Cladonia* spp.

Alluvial Plain Shrub

The alluvial plain shrub zone includes the upper reaches of the Vangorda Creek valley and the south fork of Rose Creek and its tributaries The upper reaches of the Vangorda Creek valley and the south fork of Rose Creek and its tributaries are included in the alluvial plain shrub vegetation zone. Shrub birch, shrubby cinquefoil (*Potentilla fruiticosa*), Scouler's willow and other willow species dominate the vegetation communities in the alluvial plain shrub zone. Scattered stands of white spruce and alpine fir also occur. Dwarf shrubs consist of crowberry, Labrador tea, low-bush cranberry, dwarf dogwood, dwarf blueberry (*Vaccinium caespitosum*) and arctic willow. Herbs species include arrow-leafed senecio (*Senecio triangularis*), tall Jacob's ladder (*Polemonium acutiflorum*), sweet coltsfoot (*Petasites hyperboreus*), alpine harebell, wormwood, arctic lupine, clubmoss, common horsetail (*Equisetum arvense*), grass (*Arctagrostis* sp.) and sedges. Feathermoss may form extensive mats in the alluvial plain shrub zone. Lichens, not well represented in this zone, include *Cladonia alpina* and other *Cladonia* species.

Additional mapping was conducted in 2002 by AEM

Additional mapping has been completed within the regional study area since the Montreal Engineering study (MEC Ltd. 1976). Staniforth (1998) described vegetation communities on Sheep Mountain to 1:20,000 scale. AEM (2002) described regional ecosystem types within the Yukon Plateau - North ecoregion at a 1:250,000 scale (Figure 26) within the regional study area.

The ecosystem mapping coverage describes the land base by ecozone (boreal, subalpine or alpine), landscape position (upland or lowland) and landscape type (depressional, riparian or terraced). Within the regional study area, the boreal zone contains forested, low elevation valley bottoms and low-lying terrain. Most waterbodies and wetlands are associated with this zone. The subalpine zone refers to the zone between the relatively closed-canopy forests in the boreal zone and the dwarf shrub, herb and non-vegetated rock areas in the alpine zone. The subalpine zone represents a broad gradient between low and high elevation conditions. The subalpine zone is dominated by tall shrub vegetation with scattered spruce and fir forests at its lower limits, grading into lower stature shrub and herb communities at upper elevations. The alpine zone is defined by treeless conditions with rock, low shrub and herb communities being characteristic features.

The available mapping can provide information on the types of habitat and foods that may be available to wildlife within the regional study area. However, it has limitations to its application as an empirical tool for wildlife habitat evaluation and assessment of impacts.

2.7.3.3 Metals in Vegetation

Study Objectives

A field program was conducted to determine if soils and plants near the mine have elevated elemental concentrations in comparison to background levels

Four components of the sampling program

In 2002, C.E. Jones and Associates Ltd. designed and implemented a field program to determine if soils and plants in the vicinity of the Anvil Range Mine Complex have elevated elemental concentrations in comparison to reference levels from the Faro area (C.E. Jones and Associates Ltd. 2003). The study was intended primarily as a preliminary investigation to determine whether any identifiable airborne contamination of soils and vegetation has occurred as a result of mine development and operation. The sampling design of this study was based on the premise that the probable primary mine-site sources for airborne contaminants were the Rose Creek Tailings Facility, with contaminant delivery to off-site areas through dusting. However, it should be emphasized that there are additional potential dust-borne contaminant sources, including the mill/crusher site, concentrate load-out facility and open pits.

This study included reconnaissance-level sampling on areas adjacent or within both the Faro and Vangorda Plateau Mine sites, as well as more intensive sampling centred on the Faro (Rose Creek) tailings impoundments, and reference sampling. This study area is shown in Figure 27. The field component of the study was conducted on August 11-17, 2002. The sampling program included four primary components:

1. Reference sampling (shown as black diamonds in Figure 27). Included nine (9) sample points to the southeast of the mine complex, from which 45 vegetation samples and 18 soil samples were collected.

Composite foliar

- 2. Rose Creek Tailings Transect sampling (shown as purple triangles in Figure 27). Included 33 sample points centred on the Rose Creek intermediate tailings impoundment, from which 140 vegetation samples and 68 soil samples were collected.
- 3. Additional Mine Area sampling (shown as black stars in Figure 27). Included 17 sample points on the Faro and Vangorda mine sites, from which 57 vegetation samples and 8 soil samples were collected.

At each sampling point, composite foliar samples were collected from scrub birch (Betula glandulosa), grey-leaved willow (Salix glauca), Altai fescue samples were collected (Festuca altaica), and green reindeer lichen (Cladina mitis). On tailings at each sampling point transects, reference, and selected mine-affected sample points the following additional samples were collected: a root sample of grey-leaved willow; a surface soil sample (0-2 cm depth from soil surface); and a sub-surface soil sample (5-10 cm depth from soil surface).

Overview Results

Study results show soil and vegetation concentrations elevated above background levels for arsenic, silver, cadmium, chromium, copper, mercury, nickel, lead and zinc. Lead and zinc had the largest magnitudes of elevation (over two orders of magnitude greater than maximum background concentrations for soil and lichen) and had elevated levels furthest from the mine site, in comparison to other analyzed elements. Examination of collected data indicates that the probable origin of these elevated concentrations is airborne dust contamination from mine site sources. The spatial distribution of elevated elemental concentrations shows that metals transport and deposition has been concentrated from northwest to north of the mine complex and Rose Creek drainage. Elemental concentrations in surface soil and lichen samples on transects to the southeast to west-southwest of the tailings impoundments are substantially lower than those across the valley, and elevated concentrations are clustered closer to contaminant sources, indicating that there has been less airborne contamination in these directions. However, even on these transects, soil and lichen lead (and frequently zinc) levels on the furthest points from the mine site (approximately 2-3 km) remain well above the study background concentrations. In synthesis, the spatial distribution data indicate that elevated elemental levels (particularly lead and zinc) resulting from airborne contamination occur in a zone that extends at minimum 2-3 km in all directions from potential mine-site contaminant dust sources, and that is concentrated and extended to the northwest to north of the tailings impoundments and mill complex. This finding of elevated soils and vegetation metals levels is not unexpected, given that mining and milling operations were conducted on a large scale at the Anvil Range site for almost 30 years, and that other studies of airborne contamination from lead-zinc mining/milling activities have documented similar off-site impacts.

It should be emphasized that while this study clearly indicates that mine development and operations at the Anvil Range mine complex have resulted in metals contamination of mine-area soils and vegetation, further work would be required to refine study conclusions, such as definition of the full areal extent of contamination. Data collected in this study do not allow determination or speculation on the specific sources of documented contamination. Therefore, results should be generally interpreted as being indicative of the occurrence of mine-site contamination of off-site (non-mine or undisturbed) areas, but not of the specific source(s) of this contamination. Likewise, the temporal nature of contamination cannot be determined, and it is unknown whether all dust contamination has been historic (due to active mining operations), or whether there are remaining contaminant sources still contributing to off-site metals additions.

Detailed Results and Discussion

Particular emphasis is placed on lead and zinc in this discussion Although metals analyses were conducted on a suite of metals, summary results here focus on lead and zinc as they are the primary metals associated with the deposits and those that were mined. In general, other analyzed metals (including silver, arsenic, cadmium copper, mercury and nickel) show similar trends.

With the exception of selenium (possibly marginally elevated), all elements in soil samples collected in the Swim reference sampling location are within published normal ranges (see Table 41). Analytical results for vegetation samples taken in the Swim Lake reference sampling site are presented in Table 41, and compared to cited levels for normal background elemental concentrations. The majority of reported results for elemental concentrations in vegetation at the Swim Lake reference area are within published normal ranges.

 Table 41. Reference Vegetation Elemental Concentrations (mg/kg)

^a Kabata-Pendias, 2001 ^b Jones *et al.*, unpublished

Data from surface soil sampling show elevated elemental concentrations on the tailings transects in comparison to background data Data from surface soil sampling show higher elemental concentrations from the Faro Mine Site transects in comparison to the Swim Lake reference data. For all analyzed elements, mean concentrations and observed maxima are higher for the Faro Mine Site transect area than for the reference sampling area. Greater concentrations of lead and zinc (as compared to the reference data) are more widespread, and extend further from the intermediate tailings impoundment than other measured elements. Elemental concentrations in sub-surface soil samples from the Faro Site transect area were generally more similar to the Swim Lake reference concentrations and, with the exceptions of lead and zinc, were within published normal ranges.

Statistical analysis of vegetation sampling results versus background data shows no significant differences between sites Results of vegetation sampling on the Faro Mine Site transects are presented in Table 42. Statistical analysis of these data versus the Swim Lake reference data for vascular plants (willow and birch) shows no significant differences between sites, with the exception of nickel in birch foliage. Comparison of transect elemental concentration means for vascular plants versus published normal levels (also means) indicates that the majority of elements in these samples were within normal ranges.

Locations where lead or zinc levels exceed published normal concentrations for willow and birch were generally confined to the transects to the north and east of the Faro Mine Site, and/or directly adjacent to the mine site, or along the downstream Rose Creek drainage transect (note that all transect data for shrub species exceed the appropriate Swim lake maxima). To demonstrate this finding, concentration ranges of zinc in willow foliage in the transect samples are shown in Figure 28.

Lichen are valuable bioindicators of contaminants

The majority of elements from lichen samples are one order of magnitude higher on the tailings transect samples than background levels

The spatial distribution of elevated metals concentrations in lichen samples on the tailings is similar to that in surface soil samples Lichen are susceptible to accumulation of airborne contaminants over time, and are valuable bioindicators of contamination (Conti and Cecchetti, 2001). Results presented in Table 42 for elemental concentrations in lichen samples on the Faro Mine Site transect area show higher concentrations for all elements, in comparison to the Swim Lake reference samples. The majority of elements are approximately one order of magnitude higher in samples from the transects than reference levels. Lead concentrations in the transects samples were approximately two orders of magnitude higher than lead in reference samples. Statistical comparison of Faro Mine Site transect elemental concentrations in lichen versus the Swim Lake reference data indicates that cadmium, chromium, nickel, lead, and zinc concentrations are significantly higher than reference levels.

As would be expected, the spatial distribution of metal concentrations in lichen samples from the Faro Mine Site transects in comparison to Swim Lake reference site concentrations is similar to that in surface soil samples. The highest concentrations were located either at sample locations adjacent to the mine site, north of the tailings impoundments (transects 4 and 5) and downstream on the Rose Creek drainage (transect 3). This is illustrated in Figure 29, which show ranges of lichen lead concentrations on the transects radiating from the Rose Creek Tailings Facility.

Bulk surface soil samples from the Vangorda Mine site indicate that elemental levels are comparable to background levels. Elevated concentrations for several elements are shown from the Faro Mine site

Results of lab analyses of vegetation samples show elevated elemental concentrations at potentially mine affected sampling points In addition to the transects, surface soils samples (0-10 cm) were collected at two sample points on the Vangorda Mine Site (sites Van 7 and 8), and three points on near the Faro Mine Site (Faro 4, 5 and 7; see Figure 27). Results from the Van 7 sample (overburden capping near the Vangorda/Grum treatment plant) and Van 8 (undisturbed ground near the Vangorda/Grum treatment plant site) indicate that elemental levels are generally comparable to Swim Lake reference levels. Results from the samples taken at the Faro Mine Site (adjacent to the older tailings impoundments [Faro 4 and 7] or the concentrate load-out facility [Faro 5]) show higher concentrations (than reference) for several elements. Arsenic, copper, mercury, lead, and zinc concentrations in these samples exceed Swim Lake reference data and published normal ranges.

Results of laboratory analyses of **foliar vegetation samples** taken from these mine site areas are presented in Table 43. These results show that silver, cadmium, chromium, copper, mercury, lead, nickel and zinc concentrations in vegetation at these points are generally greater than Swim Lake reference concentrations for at least one vegetation species, and are within the reference range for other vegetation species samples. Lead and zinc are consistently greater than reference and published normals, with maximum concentrations approximately two orders of magnitude higher than those at Swim Lake for lead and one order higher for zinc.

Table 43. Mine-Area Vegetation Elemental Concentrations (mg/kg)

^aKabata-Pendias, 2001

^b Jones *et al.*, unpublished

The highest and most consistently elevated elemental concentrations occur at points Faro 1,2,4,5,6 and at Vangorda 2 and 3 Soils and vegetation data from individual sample points within the footprint of the mine (additional mine-area sample sites) show increased concentrations of metals (Faro 1, 2, 4, 5, 6 and 7 and Van 2 and 3). In some cases, sites had no living moss or lichen layer, and there was visual evidence of phytotoxicity (chlorosis).

It is worth noting that analytical data from the vegetation samples collected on revegetated till-capped sites (Van 6 and 7) showed only marginal or no elevation in elemental concentrations in comparison to reference data and published normals. This finding is supported by soils data showing concentrations similar to reference on one of these sites.

2.7.4 WILDLIFE

2.7.4.1 Fannin Sheep

Population Status and Characteristics

The stone sheep found within the regional study area are distinctly coloured, and have been termed Fannin sheep Stone sheep (*Ovis dalli stonei*) are known to occur within the RSA. The stone sheep that occur in this area are a colour morph distinct from other stone sheep. They have been termed Fannin sheep and characteristically paler than stone sheep elsewhere within their range. Dark markings on Fannin sheep are normally confined to the saddle, tail and lower legs. Fannin sheep have not been classified as a subspecies separate from other stone sheep.

Stone sheep are valued as a food source by resident hunters and members of the Ross River Dene First Nation. Stone sheep, in particular the Fannin colour morph are highly valued by resident and non-resident hunters as trophy animals and are of significant economic value to outfitters. Stone sheep, especially Fannins, have high non-consumptive value for wildlife viewing and generate significant levels of tourism in the Yukon in general and in Faro specifically.

Historical Data (pre-1998)

Table 44 summarizes the population surveys conducted within the regional study area between 1980 and 1998. The number of sheep counted within each area varies greatly depending on a number of factors including: survey date; technique and weather conditions. Since many of the surveys summarized above were not conducted for the sole purpose of population inventory, few are consistent in technique and date of survey. Monthly variations in the number of sheep observed in any one area are influenced by the timing of migration. Sheep migrate between their summer and winter ranges between mid-September and mid-October; nursery herds migrating earlier than rams (Schweinsburg 1990a). Therefore, sheep counts during September and October on Mount Mye and Sheep Mountain are low. This would likely also be the case between May and June (since spring migration occurs between mid-May and late June).

It is believed that the sheep population on Sheep Mountain has remained relatively stable between 1980 and 1990 (Schweinsburg 1990a) at between 60 and 80 individuals (YTG 1987). Variations in the number of sheep counted is thought be more a factor of survey conditions than changes in population status (YTG 1987). Observed recruitment levels (indicated by proportion of lambs/yearling in the population) are considered to be indicative of a growing population (Schweinsburg 1990a). There are no data available for the period between 1990 and 1998.

Population surveys indicate the sheep population on Sheep Mountain has remained relatively stable between 1980 and 1990

Season/ Month	Location	Ewes	Lambs/ Yearlings	Rams	Total	Source
Spring	Mount Mye	35		15	50	Studds, 1975

Table 44.	Summary of Sheep Counts within the Regional Study Area between 1980 and 1988
	(adapted from Schweinsburg 1990a).

The following summary comments are noted from this data:

- There is no evidence to suggest a historical population decline or a significant change in the population characteristics of stone sheep within the regional study area; the population appears to have remained relatively stable prior to 1998 (Schweinsburg 1990a). The establishment of no hunting areas within much of the known range of these animals within the regional study area (Game Management Subzones (GMS) 4-46, 4-47 and 4-51, noted on Figure 4) undoubtedly contributed to the stability of this population;
- Sheep remain vulnerable to poachers within the regional study area, especially on the winter range where they are seasonally concentrated and in exposed terrain; and
- There is the potential for uptake of metals by stone sheep, however risks are unknown.

Existing (1998-2002) Data

Data from 1998-2002 suggests a stable sheep population Table 45 summarizes the population surveys conducted within the regional study area between 1998 and 2002. The observed ratio of lambs to nursery sheep in GMS 4-41 (33:100) and on Rose Mountain (38:100) indicates a stable population (J. Carey *et al.* unpub. report). The ratio of rams to nursery sheep in 4-41 (60:100) is higher than would be expected for a hunted population (J. Carey *et al.* unpub. report). Rose Mountain is known as a nursery area; the absence of rams in this survey is therefore not unexpected since rams move to Mount Mye during summer (J. Carey *et al.* unpub. report). Numbers of stone sheep observed on Rose Mountain between 1981 and 2002 (Table 45) are considered to be stable (J.

Carey *et al.* unpub. report). The observed increase in the number of nursery sheep on Rose Mountain between 1981 and 2002, is believed to be due to animal movements at the time of the survey and not only the result of increased recruitment (J. Carey *et al.* unpub. report).

 Table 45.
 Summary of Sheep Counts within the Regional Study Area between 1998 and 2002 (Carey et al. unpublished data).

Season/ Month	Location	Nursery Sheep (ewes & yearlings)	Lambs	Rams	Total Sheep	Source
July	Mount Mye	28	7	37	72	Hoeffs 1999
June	GMS 4-41	94	31	58	183	Carey <i>et al.</i> unpub. data from 2002
June	Rose Mountain	45	17	11	73	Carey et al. unpub. data from 2002

Wintering areas have been found on the Pelly River Bluff and other areas of winter range are suspected to exist It is not certain that sheep counts conducted on Sheep Mountain are indicative of the entire population of sheep that inhabit the regional study area. Although sheep that winter on Sheep Mountain can be found on either Sheep Mountain, Mt. Mye, Rose Mountain or on the mine site during summer, there appears to be a group of sheep independent of the Mount Mye/Sheep Mountain group that summer in areas around Blind and Swim Lakes and winter on windswept slopes near to their summer range. Wintering areas have also been found on the Pelly River Bluff (2.5km east of Faro) and it is suspected that areas northeast of Faro on Vangorda Creek may provide additional winter range (Schweinsburg 1990a). Given this variation in range use it is difficult to be certain that sheep counts conducted over the years on Mount Mye, Sheep Mountain or Rose Mountain are representative of one sheep population. Although surveys conducted on Sheep Mountain during the winter may act as an indicator of population status of the larger population, sheep movement to other winter ranges could affect this sampling technique. There are currently no data available on the distribution and extent of the population of stone sheep within the regional study area.

Habitat/Range Use

Three winter habitat units were identified at Sheep Mountain The southern slopes of Sheep Mountain have been identified as an area of sheep winter range (MEC Ltd. 1976; YTG 1980; McLeod 1981; YTG 1987; Schweinsburg 1990a). Schweinsburg (1990a) determined through telemetry and field observations that nursery sheep (ewes, lambs and yearlings) spent early winter on the upper slopes of Sheep Mountain while rams spent this time on the western edge of Sheep Mountain. Later these sheep are found on the lower slopes of Sheep Mountain to feed on sage (*Artemesia frigida*) and later on new herbaceous growth and aspen (*Populus tremuloides*) leaves (Schweinsburg 1990a). Additional wintering areas include: the windswept slopes near Blind and Swim Lakes (Schweinsburg 1990a), Pelly River Bluff, 2.5km east of Faro (Schweinsburg 1990a) and potentially areas north-east of Faro on Vangorda Creek (McLeod 1981; Schweinsburg 1990a).

Habitat mapping of Sheep Mountain classified three habitat units significant to sheep during winter (Staniforth 1998):

- Sage-Graminoid community occurs on the open windswept south-facing slopes and is considered to be the most important winter habitat as it would be the relatively snow-free during winter;
- Rose/Forb community is found mainly at the edges of south-facing aspen groves, in low-lying gullies and high snow accumulation areas; and
- Grass-Forb community occurs at the edge of the aspen groves but on the more northerly aspects.

Rocky outcrops occur in association with all three of the important winter range communities outlined above. Rocky outcrops increase the habitat quality of these areas by providing escape terrain. The three vegetation communities (including rocky outcrops) were therefore grouped into one habitat type: Rock/Grass/Forb. This unit covered a total of 4.9 km² or 11% of the Sheep Mountain Study Area (Staniforth 1998).

The habitat unit used during lambing is likely similar to that used during early winter Initial studies indicated that lambing areas on Sheep Mountain were found downslope of the early winter range (Studds and Hoeffs 1975). Schweinsburg (1990a) has since determined that ewes move from the lower slopes of Sheep Mountain in late winter to lamb at higher elevations. There is also some indication that ewes may lamb on Mount Mye (Schweinsburg 1989). Lambing areas were not identified during the habitat mapping study conducted on Sheep Mountain (Staniforth 1998). Through interpretation of habitat descriptions made by Schweinsburg (1990a), the habitat unit used during lambing is likely similar to that used during early winter, i.e., Rock/Grass/Forb.

Sheep generally dispersed more widely over their summer range than the winter range. Therefore a larger area has been identified as summer range and includes Mount Mye (MEC Ltd. 1976; McLeod 1981; Hoeffs 1988; Hoeffs 1989; Schweinsburg 1990a); Rose Mountain (McLeod 1981); Blind Creek and Swim Lakes area (Schweinsburg 1990a); Sheep Mountain and the Anvil Mine Complex (Schweinsburg 1989, 1990a; 1990b). Both Mount Mye and Rose Mountain are composed of upland land-types within the alpine, subalpine and boreal zones (AEM 2002). Sheep Mountain is composed of upland and lowland-riparian land types within the boreal zone (AEM 2002). The area around Blind and Swim Lakes is comprised of upland land types in the boreal zone (AEM 2002). The area around the Anvil Mine Complex is comprised of upland land types in the boreal zone (AEM 2002). The majority of Sheep Mountain, the western slopes above Blind Creek and the Vangorda – Grum deposits were burned during a fire in 1969 (Fire History Database).

Spring migration occurs between mid-May and the end of June (McLeod 1981; Schweinsburg 1990a). Fall migration occurs between mid-September and mid-October. Nursery herds migrate earlier in mid-September and rams later in early October (Schweinsburg 1990b). A number of migration routes have been identified and are indicated on Figure 30:

> Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-92

A large area has been identified as summer range

Various sheep migration routes have been identified within the regional study area

- Migration route E (after McLeod 1981) was identified as the main migration route between Mount Mye and Sheep Mountain during spring and fall (MEC Ltd. 1976; McLeod 1981; Horejsi 1988; Schweinsburg 1990b). From Sheep Mountain, this route goes to the confluence of Shrimp Lake and Vangorda Creek, crosses the Haul Road 1 km west of Vangorda Creek and then continues to the base of Mount Mye. This route therefore passes between the Vangorda and Grum deposits.
- Migration route F (after McLeod 1981) was also identified as a significant migration route between Sheep Mountain and Mt. Mye during spring and fall (MEC Ltd. 1976; McLeod 1981; Schweinsburg 1990b). From Sheep Mountain, this route goes to the confluence of Shrimp Lake and Vangorda Creek, it then follows a small road, crosses the airstrip to the site of the proposed Vangorda Pit and then continues to Mt. Mye via the west side of Vangorda Creek.
- Migration route D (after McLeod 1981) was also identified as a significant migration route between Sheep Mountain and Mt. Mye during spring and fall (McLeod 1981; Horejsi 1988; Schweinsburg 1990b). From Mount Mye, this route goes south from Mount Mye and crosses the haul road 1 km east of the Grum Camp. The route then follows down to the confluence of Shrimp Lake and Vangorda Creek on to Sheep Mountain.
- McLeod (1981) also identified one addition migration route (route A) which follows west from Sheep Mountain along the ridge to Rose Mountain.

Rams have been observed rutting on Sheep Mountain (Schweinsburg 1990a) presumably during fall/early winter.

2.7.4.2 Moose

Population Status and Characteristics

Moose (*Alces alces*) occur throughout the regional study area. The subalpine plateau of Game Management Subzone ("GMS") 4-45 is recognized to have one of the highest seasonal densities of moose in the Yukon (Ward 1999) and is acknowledged as a significant rutting and post-rutting area of territorial significance (Ward 1997). Moose are highly valued as a food source by members of the Ross River Dene First Nation, Faro residents and non-resident hunters. Moose have economic value for outfitters and are highly valued as a food source in the food source for grizzly bears in early spring when other food sources are limited.

Historical (pre-1998) Data

A summary of the number of moose hunted within one outfitter's territory within the Faro region between 1963 and 1974 shows that the number of guided moose hunts increased by an order of four following the establishment of the Town of Faro and the Mine development (MEC Ltd. 1976). Prior to 1969, 3.8 moose were successfully hunted by non-resident hunters per year, after 1969, 15.5 moose were taken on average per year.

Deloitte

& Touche

In 1998, there was no evidence to suggest that the moose population had declined; however, the bull:cow ratio within area GMS 4-45 reached the lowest acceptable level for moose Survey results indicate that moose density within GMS 4-45 has not changed significantly between 1997 and 1998 (Table 46). However, the low bull to cow ratios observed in 1997 (30:100) and 1998 (45:100) are cause for concern (Ward 1997; Ward 1998). The bull:cow ratio has reached the lowest acceptable level for moose; where this sex ratio has been observed elsewhere in the territory, e.g., Haines Junction and south of Whitehorse, it has been followed by a population decline. Below this level there is a possibility that there are insufficient numbers of bulls to breed every female. True harvest levels (i.e., including some unreported mortalities) have reached the sustainable harvest limit for this population, i.e., 20-25 moose taken in GMS 4-45 each year (Ward 1997). The ratio of calves to cows is not high in 1997 (35:100) or 1998 (26:100) but is considered sufficient to maintain a stable population (Ward 1997; R. Ward, pers. comm.).

Deloitte

& Touche

Table 46. Summary of Moose Surveys Conducted within GMS 4-45 near Faro and Anvil Mine (1997 – 1998)

	Within GMS 4-45		
	1997	1998	
Survey Timing	Dec $8^{th} - 13^{th}$	Nov 23 rd – 28 th	
Area Surveyed (km ²)	967	1034	
Moose Density/1000km ²	586	483	
Bull: Cow	30:100	45:100	
Calf: Cow	35:100	26:100	

The following comments are of note regarding moose data during the pre-1998 period:

- There is currently no evidence to suggest that the population of moose within the regional study area has declined. However, the bull:cow ratio observed in GMS 4-45 has reached the lowest acceptable level for moose (Ward 1999). Where this sex ratio has been observed elsewhere in the territory, e.g., Haines Junction and south of Whitehorse, it has been followed by a population decline. Below this level there is a possibility that there are insufficient numbers of bulls to breed every female.
- True harvest levels (i.e., including some unreported mortalities) have already reached the sustainable harvest limit for this population, i.e., 20-25 moose taken in GMS 4-45 each year (Ward 1997) and these areas have remained open to the hunting of bulls.
- Potential for habitat displacement and extent are unknown.
- There is the potential for uptake of metals by moose. However, the risk is unknown. Available data suggest that concentrations of metals in moose tissues within the regional study area are not noticeably higher than elsewhere in Yukon (P. Roach, pers. comm., 7th October 2002). However it was recognized that sample size was low, n = 4 (P. Roach, pers. comm., 7th October 2002).

Existing (1998-2002) Data

Mature bulls likely travel from outside the study area to congregate during the rut

The density of moose observed in 1999 within GMS4-45 (Table 47) is roughly seven times higher than the Yukon average and indicates the importance of this area for post-rutting moose (Ward 1999). This seasonally high moose density indicates that mature bulls likely travel from outside of this area to congregate during the rut. There is evidence from telemetry studies conducted elsewhere (Liard River) that moose may disperse during the summer up to 80 km from their winter concentrations (J. Adamczewski, pers. comm., September 2002).

Table 47. Summary of Moose Surveys Conducted within GMS 4-45 near Faro and Anvil Mine (1999)

	Within GMS 4-45
	1999
Survey Timing	Dec $13^{th} - 19^{th}$
Area Surveyed (km ²)	218
Moose Density/1000km ²	1358
Bull: Cow	30:100
Calf: Cow	18:100

It is likely that harvest levels have been increased due to increased hunter access associated with mine developments The low bull:cow ratio observed in 1999 (30:100) is confounded by survey timing and conditions and cannot be compared to previous years. However, the low bull to cow ratios observed in 1997 (30:100) and 1998 (45:100) remain a cause for concern (R. Ward, pers. comm). There has been a voluntary harvest restriction in place in GMS 4-45 since 1999 but the effectiveness of this measure is unknown and suspected to be negligible (R. Ward, pers. comm.). It is believed that increased hunter access associated with mine developments, has increased harvest levels and has consequently impacted the moose population in the Faro area (Ward 1999).

The ratio of calves to cows is low in 1999 but may have been affected by survey technique and conditions. The proportion of calves within moose populations fluctuates naturally from year to year such that the ratio must be compared over a longer time period (R. Ward, pers. comm.).

Habitat/Range Use

The floodplain of the Pelly River is suspected to provide significant winter and summer habitat for moose (MEC Ltd. 1976). Areas within the 1969 burn and areas of alluvial plain shrub are suspected to be significant summer habitat for moose (MEC Ltd. 1976). In 1999 YTG delineated an area of high moose abundance during the rutting and post-rutting season within GMS 4-45 (Ward 1999). Within an area of 218 km² moose density was observed to be roughly seven times higher than the Yukon average. The area corresponds to the subalpine plateau of GMS 4-45 (Ward 1999). There is no data available on the current calving, summer and winter habitat use and movement patterns of moose within the regional study area.

2.7.4.3 Woodland Caribou

The Tay River herd of caribou is found within the regional study area Woodland caribou (*Rangifer tarandus caribou*) herds are defined as a group of caribou that share a common winter range that is geographically distinct from neighbouring herds (Edmonds 1988; Farnell *et al.* 1996). Caribou within the immediate vicinity of Anvil Range Mine are considered to be members of the Tay River woodland caribou herd (Kuzyk and Farnell 1997). Woodland caribou from the Redstone Herd appear to overlap at the northeastern extent of the Tay River Herd annual range, i.e., near Mac Pass (Kuzyk and Farnell 1997). This area of overlap is outside the regional study area and does not overlap with the winter range of the Tay River Herd. For the purposes of this project, data will be presented only on the Tay River Herd.

Woodland caribou are listed as a special species of concern and are found mostly along the Tay River and the South Macmillan River within the regional study area Woodland caribou within the northern mountain ecotype found in the vicinity of the Anvil Range Mine are listed as a species of special concern by the Committee on the Status of Endangered Species in Canada (COSEWIC, May 2002). This designation is reserved for a population that is particularly sensitive to human activities or natural events but is currently not endangered or threatened (COSEWIC). Woodland caribou are valued as a food source by Yukon residents, non-resident hunters and members of the Ross River Dene First Nation and have economic value for outfitters. Woodland caribou calves are a valued food source for grizzly bears in early spring when other food sources are limited.

Historical (pre-1998) Data

A population survey of the Tay River Herd was conducted between 23rd and 27th March 1991 (Table 48). A total of 3,758 caribou (± 571) were estimated to occur within the 1,266 km² survey area (Kuzyk and Farnell 1997). Caribou were found mostly along the Tay River and the South Macmillan River.

 Table 48.
 Summary of Caribou Survey Data and Population Estimate for the Tay River Herd (after Kuzyk and Farnell 1997)

Strata	Units Surveyed	Area Surveyed (km ²)	Total Caribou	Expanded Population Estimate*	Corrected Population Estimate**
Primary	31	845	3,091	3,091	
Secondary	15	421	53	185	
Total	46	1,266	3,144	3,276	3,758

* Population extrapolated from density estimates of caribou within surveyed secondary units to un-surveyed secondary units.

** Calculated using a sightability correction factor of 1.14.

The fall composition studies of the Tay River Herd indicate that the herd is stable; there were approximately 30 calves for every 100 cows and >35 bulls for every 100 cows (Kuzyk and Farnell 1997). The caribou harvest between 1990 and 1994 is considered sustainable at approximately 1% of the population of the Tay River Herd (Kuzyk and Farnell 1997). Between 35 and 43 caribou are harvested by licensed hunters during fall (residents and non-residents).

The population of woodland caribou appears relatively stable from 1991-1998

No data on the current population status of the Tay River herd is available

Range use varies according to season (i.e. calving, postcalving, or rutting) The following comments can be made based on data from this period:

- There is no evidence to suggest a historical population decline or a significant change in population characteristics of woodland caribou within the regional study area; the population appears to have remained relatively stable prior to 1998 (Kuzyk and Farnell 1997).
- Potential for habitat displacement, extent unknown.
- There is potential for uptake of metals by woodland caribou. However the risk is unknown.

Existing (1998-2002) Data

There are no data available on the current population status and characteristics of the Tay River Herd. The population estimate obtained during the study conducted by Kuzyk and Farnell (1997) can be used as a benchmark for management purposes (Kuzyk and Farnell 1997). It has been suggested that a repeat census be conducted to monitor this population and determine the current population abundance and composition of the Tay River Herd (Kuzyk and Farnell 1997; R. Farnell, pers. comm. 9th September 2002).

Habitat/Range Use

The calving and post-calving areas of the Tay River Herd have been documented south of the upper Stewart River and north of the Pelly River (Kuzyk and Farnell 1997). Calving and post-calving areas include areas in the vicinity of the Anvil Range Mine in alpine areas within GMSs 4-41 and 4-43, Figure 4 (Kuzyk and Farnell 1997). Caribou from the Tay River Herd are documented to be widely distributed during the rut especially to the north and east of the Anvil Range Mine. Rutting areas include areas in the vicinity of the Anvil Range Mine within GMSs 4-41, 4-43 and 4-45. In early winter, caribou descend from alpine areas into the lowland areas of the forested river drainages north of Faro. At this time of year, the herd is in close proximity to the Anvil Range Mine and has been observed in GMSs 4-41, 4-45, 4-46 and 4-47. In late winter, caribou are confined to the valley bottoms of the forested river drainages north of Faro. At this time of year, the herd is in closest proximity to the Anvil Range Mine and has been observed in GMSs 4-41, 4-45, 4-46 and 4-47. In 1991 caribou were observed within 10 km of the Town of Faro during late winter (Kuzyk and Farnell 1997).

2.7.4.4 Grizzly Bear

Population Status and Characteristics

Grizzly bears are listed as a special species of concern Grizzly bears occur throughout the regional study area. Grizzly bears (*Ursus arctos*) are listed as a species of special concern by the Committee on the Status of Endangered Species in Canada (COSEWIC, May 2002). This designation is reserved for a population that is particularly sensitive to human activities or natural events but is currently not endangered or threatened (COSEWIC).

Grizzly bears are vulnerable to the impacts of human activities for many reasons, including their specialist habitat requirements, large home range sizes, displacement from areas of human use; vulnerability to mortality due to food conditioning and low fecundity rates. For the reasons described above and the broad ecological amplitude grizzly bears possess as omnivorous animals, grizzly bears are considered indicators of ecosystem health. Grizzly bears are valued by resident and non-resident hunters as trophy animals and in some cases for food and have economic value for outfitters. Grizzly bears have high non-consumptive value and generate significant levels of tourism in the Yukon.

Historical (pre-1998)

There have been no telemetry studies or population estimates conducted on the grizzly bears within the regional study area and therefore no empirical data are available to assess population status and characteristics. There is indication that the grizzly bear population within the regional study area has experienced some stress (MEC Ltd. 1976; Yukon Biological Submission Forms, YTG). The level of grizzly bear harvest in the area increased markedly following the establishment of the Town of Faro and the Anvil Mine (MEC Ltd. 1976). A summary of the number of grizzly bears hunted within one outfitter's territory within the Faro region between 1963 and 1974 shows that the number of guided grizzly bear hunts increased by an order of three following the establishment of the town of Faro and the Mine development. Prior to 1969, 2.3 grizzly bears were successfully hunted by non-resident hunters per year, after 1969, 7.2 grizzly bears were taken on average per year. A total of 76 grizzly bear mortalities (47 males and 29 females) have been reported within the regional study area between 1980 and 1997 (Yukon Biological Submission Forms, YTG). This translates to an annual harvest of 4.22 grizzly bears / year or 0.95 grizzly bears / year / 1000 km². Highest mortality rates were observed in GMS 4-44 (3.38 grizzly bears / year / 1000 km²) and GMS 4-51 (4.21 grizzly bears / year / 1000 km²). GMS 4-44 is accessible from trails originating from the Anvil Range Mine and from the town of Faro. GMS 4-51 contains the town of Faro, portions of the Anvil Range Mine and many access roads and trails. The observed mortality rates are considered to be an underestimate of true mortality (K. Meister, pers. comm., September 2002). In the absence of empirical data on grizzly bear population status and characteristics and/or on home range size and the extent of home range overlap, the sustainability of the observed mortality rates cannot be empirically determined.

The following summary comments can be noted from data during this time period:

- There are no empirical data available to assess population status and characteristics of grizzly bears within the regional study area.
- There is evidence from the literature and records of mortality to suggest that grizzly bears within the regional study area may have experienced a decline. The supporting literature defines a strong correlation between the persistence of grizzly bears, the presence of roads/trails and the behaviour of humans on these roads/trails, i.e., hunting pressure. There is an extensive network of roads and trails leading from the mine complex into previously inaccessible

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-98

There is indication that the grizzly bear population has experienced some stress from increased hunting but no empirical data exists

Comments noted from

data during the

historical period

or less accessible areas within the study area and there is indication that hunting pressure within these areas has been high. There have also been an unknown number of grizzly bears killed in control actions within the study area.

- There is the potential that mine development has removed valuable feeding habitat and/or displaced grizzly bears from valuable feeding habitat. The extent and significance of this remains unknown in the absence of a comprehensive ecosystem map of the area.
- There is the potential for uptake of metals by grizzly bears. Grizzly bears are vulnerable to the bioaccumulation of contaminants in their tissues due to their position in the aquatic food chain, i.e., salmon eaters and the terrestrial food chain i.e., predators. Grizzly bears are also vulnerable to contamination due to their hyperphagic feeding habits, e.g., consuming up to 40 kg (fresh weight) of berries in a day (Welch *et al.* 1997).

2.7.4.5 Existing (1998-2002) Data

There is indication that the grizzly bear population has experienced stress historically and that hunter success has since declined There have been no telemetry studies or population estimates conducted on the grizzly bears in the area of Faro and the Anvil Range Mine and therefore there are no empirical data available to assess population status and characteristics. There is indication that the grizzly bear population within the regional study area has experienced stress historically (MEC Ltd. 1976; Yukon Biological Submission Forms, YTG) and that hunter success has since declined. A total of 12 grizzly bear mortalities (9 males and 3 females) have been reported within the regional study area between 1998 and 2002 (Yukon Biological Submission Forms, YTG). This translates to an annual harvest of 3.00 grizzly bears / year or 0.67 grizzly bears / year / 1000 km². Hunter success has most noticeably declined within those GMSs where grizzly bears experienced highest mortality rates historically; there have been no grizzly bears harvested or controlled within GMS 4-44 or 4-51 since 1998 (Yukon Biological Submission Forms, YTG). In the absence of empirical data on grizzly bear population status and characteristics and/or on home range size and the extent of home range overlap, the sustainability of the observed mortality rates cannot be empirically determined.

Habitat Use

Habitat use patterns of grizzly bears in the area were not determined in previous studies. However, seasonal food habits and habitat use patterns can be inferred from the results of studies of grizzly bears in ecologically similar areas The habitat use patterns of grizzly bears in the Anvil Range Mine area were not determined during previous studies. However, grizzly bear seasonal food habits and habitat use patterns can be inferred from the results of studies of grizzly bears in ecologically similar areas (Pearson 1976; McCann in prep). These data were interpreted to provide a summary of likely food habits and habitat use patterns for the grizzly bears within the regional study area.

During spring prior to vegetation green-up, grizzly bears in the regional study area are likely to feed on the roots of *Hedysarum spp.*, in disturbed, snow free areas at lower elevations; winter weakened ungulates, particularly moose, in lowland riparian areas such as the Pelly River floodplain and overwintered berries, such as *Artcostaphylus sp.* and *Empetrum sp.* on south facing, windswept subalpine slopes. Later in the spring when new vegetation growth has appeared, grizzly bears will feed on grasses, sedges, horsetails and forbs as well as on willow catkins and ungulate calves (particularly moose and potentially caribou). Late spring habitats will include valley bottom riparian areas and seepage slopes.

During summer grizzly bears will likely feed on the berries of *Shepherdia* canadensis and Vaccinium spp.. These berries are particularly abundant in areas burned by wildfire. The wildfire that burned a significant portion of the area around the Anvil Mine in 1969 may be on the cusp of becoming less valuable for bears. The abundance of berries in areas burned by wildfires tends to be highest 15 - 35 years post fire, depending upon growing conditions. Berry abundance will vary with habitat type and site characteristics within the burn. Berry abundance can also be high under relatively open, floodplain forests. Some grizzly bears (especially females) may continue feeding on herbaceous vegetation at higher elevations in the subalpine during summer. Some bears will also hunt for rodents, particularly ground squirrels (*Spermophilus sp.*) in subalpine meadows.

Grizzly bears will continue to feed on the berries of *Shepherdia canadensis* and *Vaccinium spp.* in burns and some in floodplain forests during fall. *Empetrum sp.* and *Artcostaphylus sp.* will also become more significant during this season and bears will find these berries on dry, south facing, subalpine upland slopes. Some bears may also feed on the roots *Hedysarum spp.* wherever this plant occurs. The distribution of *Hedysarum spp.* is fairly ubiquitous and access to roots is less limited by snow and ground conditions at this time of year. Grizzly bears that occupy home ranges that contain Blind Creek and Tay River will likely feed on spawning chinook salmon (*Oncorhynchus tshawytscha*) on the floodplains of these valley bottoms. Some bears may stay active late in the fall and feed on rut weakened ungulates, particularly moose, where these animals are found, i.e., the subalpine areas of GMS 4-45.

Grizzly bears will spend winter hibernating in dens at higher elevation in the subalpine and alpine areas. Dens may be found on steep slopes of any aspect (although there is some evidence to suggest that the excavation of dens at

northerly latitudes on north facing slopes may be impeded by ground conditions, Pearson 1975). Dens tend to be excavated in soil and may or may not be associated with the root systems of trees or shrubs. On rare occasion grizzly bears may hibernate in caves.

2.7.4.6 Black Bear

Population Status and Characteristics

Black bears occur throughout the study area and are vulnerable to harvesting Black bears (*Ursus americanus*) occur throughout the regional study area. Black bears are valued by resident and non-resident hunters as trophy animals and in some cases for food and have economic value for outfitters. Black bears have high non-consumptive value and generate significant levels of tourism in the Yukon. Black bears are vulnerable to illegal harvesting for gall bladders, as part of the international and domestic trade in bear parts.

Historical (pre-1998) Data

There is indication that the black bear population has experienced some stress from increased hunting but no empirical data exists

There have been no telemetry studies or population estimates conducted on black bears within the regional study area and therefore no empirical data available to assess population status and characteristics. There is indication that the black bear population within the regional study area has experienced some stress (MEC Ltd. 1976; Yukon Biological Submission Forms, YTG). The level of black bear harvest in the area increased markedly following the establishment of the town of Faro and the Anvil Mine (MEC Ltd. 1976). A summary of the number of black bears hunted within one outfitter's territory within the Faro region between 1963 and 1974 shows that the number of guided black bear hunts increased by an order of six following the establishment of the town of Faro and the Mine development.

Prior to 1969, 0.3 black bears were successfully hunted by non-resident hunters per year, after 1969, 1.8 black bears were taken on average per year. A total of 93 black bear mortalities (74 males and 19 females) have been reported within the regional study area between 1980 and 1997 (Yukon Biological Submission Forms, YTG). This translates to an annual harvest of 5.17 black bears / year or 1.16 black bears / year / 1000 km². Highest mortality rates were observed in GMS 4-47 (4.23 black bears / year / 1000 km²) and GMS 4-43 (3.26 black bears / year / 1000 km²). GMS 4-47 contains an extensive network of roads and trails and is in close proximity to the town of Faro and the Robert Campbell Highway. Mostly resident hunters hunt this area (Yukon Biological Submission Forms, YTG). GMS 4-43 does not contain surveyed roads or trails but is immediately accessible from the Pelly River. Mostly non-resident hunters hunt this area (Yukon Biological Submission Forms, YTG). The observed mortality rates are considered to be an underestimate of true mortality (K. Meister, pers. comm., September 2002). In the absence of empirical data on black bear population status and characteristics and/or on home range size and the extent of home range overlap, the sustainability of the observed mortality rates cannot be empirically determined.

> Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-101

Comments on the historical data The following summary comments can be made from data based on this time period:

- There is no empirical data available to assess population status and characteristics of black bears within the regional study area.
- There is the potential for overharvesting of black bears within the regional study area. Mortality associated with hunting and control actions has been high within the regional study area.
- There is the potential that mine development has removed valuable feeding habitat and/or displaced black bears from valuable feeding habitat. The extent and significance of this remains unknown in the absence of a comprehensive ecosystem map of the area.
- There is the potential for uptake of metals by black bears. Black bears are vulnerable to the bioaccumulation of contaminants in their tissues due to their position in the aquatic food chain, i.e., salmon eaters and the terrestrial food chain i.e., predators. Black bears are also vulnerable to contamination due to their hyperphagic feeding habits.

Existing (1998-2002) Data

There have been no telemetry studies or population estimates conducted on the black bears in the area of Faro and the Anvil Range Mine and therefore there are no empirical data available to assess population status and characteristics. There is indication that the black bear population within the regional study area has experienced some stress historically (MEC Ltd. 1976; Yukon Biological Submission Forms, YTG). Current mortality levels within the study area remain high; a total of 23 black bear mortalities (17 males and 6 females) have been reported within the regional study area between 1998 and 2002 (Yukon Biological Submission Forms, YTG). This translates to an annual harvest of 5.75 black bears / year or 1.29 black bears / year / 1000km². Mortality rates remain highest in GMS 4-47 (4.16 black bears / year / 1000km²). Harvest rates have declined in GMS 4-43 from 3.26 to 1.47 black bears / year / 1000km². In the absence of empirical data on black bear population status and characteristics and/or on home range size and the extent of home range overlap, the sustainability of the observed mortality rates cannot be empirically determined.

Habitat Use

The habitat use patterns of black bears in the Anvil Range Mine area were not determined during previous studies. There are little data available on black bear seasonal food habits and habitat use patterns areas ecologically similar to the regional study area. Food habits and habitat use patterns were therefore inferred from general food habits and habitat use patterns of black bears based on the occurrence of potential bear foods and habitat within the regional study area.

During the spring, black bears will likely feed on grasses, sedges, horsetails, forbs, the catkins of willow (*Salix spp.*) and balsam poplar (*Populus balsamifera*)

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-102

There is no empirical data available to assess the population status and characteristics but current mortality rates within the study area remain high

Since habitat use patterns of black bears were not determined in previous studies, food habits and habitat use patterns are based on the occurrence of potential bear foods and habitats within the regional study area

in valley bottom riparian areas and on seepage slopes. During the summer, black bears will likely feed on a diversity of berry species including *Vaccinium uliginosum, Vaccinium vitis-idaea, Shepherdia canadensis* and potentially *Rosa acicularis* typically in lower elevation forested areas. Black bears will likely continue to feed on these berry species into the fall but may also feed on *Empetrum nigrum, Arctostaphylos spp.*, and *Vaccinium caespitosum* at higher elevation forested areas. Black bears may also feed on grasses and sedges at this time of the year. Black bears that occupy home ranges that contain Blind Creek and Tay River may also feed on spawning chinook salmon (*Oncorhynchus tshawytscha*) on the floodplains of these valleys. Black bears will spend winter hibernating in dens at mid to high elevations in subalpine forests. Dens tend to be excavated under the root systems of trees.

2.7.4.7 Raptors

Bald eagles are known to occur and peregrine falcons may occur within the study area. Peregrine Falcons are listed as a threatened species in the Yukon There have been no empirical studies conducted on raptors within the regional study area (D.Mossop, pers. comm., 2nd October 2002). Bald eagle (*Haliaeetus leucocephalus*) is known to occur and peregrine falcon (*Falco peregrine anatum*) may occur within the regional study area (D.Mossop, pers. comm., 2nd October 2002). Peregrine falcon are listed as threatened in Yukon (COSEWIC, May 2000). This designation is reserved for a population that is likely to become endangered if limiting factors are not reversed (COSEWIC). Short-eared owl (*Asio fammeus*) likely occur within the regional study area. This species is listed as a species of special concern by the Committee on the Status of Endangered Species in Canada (COSEWIC, April 1994). This designation is reserved for a population that is particularly sensitive to human activities or natural events but is currently not endangered or threatened (COSEWIC).

There is no empirical data available to assess population status and characteristics of bald eagles, peregrine falcons and short-eared owls within the regional study area. Contamination: bald eagles are vulnerable to the bioaccumulation of contaminants in their tissues due to their position in the aquatic food chain, i.e., fish eaters (D. Mossop, pers. comm., 2nd October 2002).

2.7.4.8 Furbearers and Small Mammals

Red fox, marten, lynx, least weasel, ermine, mink, snow shoe hare, and wolf likely occur within the regional study area. Wolverine is listed as a species of special concern There have been no empirical studies conducted on furbearers within the regional study area. Red fox (*Vulpes vulpes*), marten (*Martes americana*), lynx (*Lynx canadensiis*), ermine (*Mustela erminea*), least weasel (*Mustela nivalis*), mink (*Mustela vison*), snow-shoe hare (*Lepus americanus*), wolf (*Canis lupus*) likely occur within the regional study area. Wolverine is listed as a species of special concern by the Committee on the Status of Endangered Species in Canada (COSEWIC, April 1989). This designation is reserved for a population that is particularly sensitive to human activities or natural events but is currently not endangered or threatened (COSEWIC). Members of the Ross River Dene First Nation are known to trap marten, wolverine, lynx and wolves within the regional study area (K. Meister pers. comm., September 2002).

There are no empirical data available to assess population status or health of furbearers within the regional study area. There have been no empirical studies conducted on small mammals within the regional study area (C. Hubert, pers. comm. 13th September 2002).

2.7.4.9 Amphibians and Reptiles

No empirical data on amphibians exists for the regional study area There have been no empirical studies conducted on amphibians or reptiles within the regional study area (J. Adamczewski pers. comm., September 2002). Wood frog (*Rana sylvatica*) is likely the only amphibian to occur within the regional study area. Wood frogs can be found as far north as Old Crow YT and can inhabit forests, meadows, muskegs and alpine areas (YTG Renewable Resources & Environment Canada). Reptiles are not documented to occur within the regional study area. There are no empirical data available to assess population status and characteristics of amphibians within the regional study area.

2.8 SOCIO-ECONOMICS

2.8.1 SOCIO-ECONOMIC STUDY AREA

Potential socio-economic impacts caused by the project are assessed when they arise from a change in the environment caused by the project. This indirect consideration of socio-economic impacts does not, however, preclude the consideration of potential direct socio-economic impacts of the project.

Definition of socioeconomic study area. The RSA for socio-economic conditions is broadly defined as the Anvil Range area, with the Pelly River and Campbell Highway the southern boundaries, the Ross River the eastern boundary and the Tay River the western and northern boundaries (Figure 5). Thus, it includes anthropogenic features including the mine sites, the Faro townsite area and various roads on the north side of the Pelly River. The area includes the lands within the Rose, Anvil and Vangorda watersheds and parts of the Blind Creek watershed. A broadly defined study area was necessary as the resources upon which socio-economic conditions are based (i.e. caribou, sheep, moose) can be widely scattered across the landscape.

2.8.2 GENERAL SOCIO-ECONOMIC CONDITIONS

The RSA is a significant area of use for residents from the Town of Faro, the community of Ross River and other Yukon communities. Residents from as far away as Whitehorse travel to the region to hunt and fish. In addition, the Town of Faro is taking action in "selling" the region as a target market for Yukoners and travelers from neighboring jurisdictions (e.g. Alaska and British Columbia) as well as international travelers, such as Germany.

Summary information regarding the Town of Faro is provided in the subsequent sections. Information regarding historical and current activities by the Ross River Dena people is described in Section 2.9 of this volume.

2.8.2.1 Town of Faro

History

The Town of Faro has experienced significant population shifts from the time of its construction in 1968 when Anvil Mining Corporation established a community for employees of its lead-zinc- Faro Mine. Faro was developed as a mining town to house workers and provide services for the Faro Mine.

Town infrastructure was installed to service a population of approximately 3,000. In 1981, the population reached a peak of around 2,800 residents. In 1991, Faro's population was approximately 1,500.

Since the mine shut down, the population of Faro decreased significantly The Faro Mine shut down in 1998 and since then Faro's population has declined significantly. According to Statistics Canada, in 2001, the population of Faro was 313; these statistics also reveal 469 private dwellings. The statistics for December 2002 show the population increased to 375 (Yukon Bureau of Statistics) and is projected to grow to approximately 475 by the summer of 2004 (interview with Town Councilor, Michelle Vainio).

Infrastructure

Faro community infrastructure includes:

- the Municipal Hall;
- Municipal Works Yard;
- Del Van Gorder School;
- Faro campus of the Yukon College;
- Faro Nursing Station;
- Union Hall;
- Government of Yukon (YTG) Health and Social Services;
- Recreational Centre (with a full range of facilities);
- Indoor ice arena;
- Community library;
- Royal Canadian Mounted Police (RCMP) detachment;
- Canada Post (full-service post office);
- Retail mall;
- Two churches;
- Hotel and restaurant;
- Service station; and
- Airport (4,000 foot gravel runway with lights).

2004-2008 "Vision"

An official community plan for Faro has been drafted and encourages a more sustained sense of growth and direction

The elected Council for the Town of Faro has initiated a number of steps for the continued viability of the community. Much of the vision is based on the strength of the local businesses and attractiveness of the community as a recreational center of significance (hiking, hunting and fishing values), as well as a tourism destination.

The current draft of the Official Community Plan (OCP), 2003-2008 (anticipated to go to public hearing in April before being accepted by Town Council and forwarded to the Yukon Minister responsible), reveals an aggressive development and diversification plan relying on the continued inflow of population, and general interest in the region. The draft OCP describes the existing economy as an amalgam of the following activities:

- Small business sector (the mainstay of the Faro economy);
- Home based businesses (B&Bs, arts and crafts etc);
- Mine care and maintenance and reclamation opportunities;
- Government employment (local, territorial and federal);
- Wilderness tourism (fishing, recreational and guided hunting, canoeing, cross country skiing, hiking etc.)
- Cultural events (e.g. Farrago Music Festival and Ice Worm Squirm Winter Carnival);
- Robert Campbell Highway tourism; and
- Home base for those working away.

There is also an increasing population of retired people moving to Faro for the modest housing prices and lifestyle, and their activities provide economic stimulus to the local economy. The relationship between the Town's efforts and the Ross River Dena Council also figures prominently in the draft Plan.

Generally, the draft OCP "vision" for the economy over the next five years revolves around policies and actions in the following seven areas:

- Faro mine reclamation activities (priorities around health and safety and maximum community employment);
- Wilderness tourism (based on proximity to viewing opportunities, and natural "infrastructure");
- Retirement community (based on quality life style, low crime rate, affordable housing, excellent services);
- Artistic community (encourage more immigration to Faro of talent from other parts of Yukon and beyond);
- Government decentralization (movement of appropriate government operations to Faro given "level playing field");

- Home-based business (increase zoning flexibility to accommodate activities); and
- Mining history tourism (to capitalize on the existing knowledge base of residents).

Although the current mine site figures prominently in this draft OCP "vision" for the community and its economy, the Town is moving to a more sustained sense of direction, less dependent on the "boom-bust" cycles it has experienced during its history.

2.8.3 GENERAL LAND/RESOURCE USE

Hunting and fishing are popular activities in the area. The regional study area encompasses parts of, or all of five, hunting sub-zones in the Yukon's Zone 4 (noted on Figure 4). Although one of the five is closed completely to hunting (sub-zone 4-51 in and around the Town of Faro), the other four allow hunting of male moose and caribou, sheep (except sub-zone 4-46 just south of the Grum and Vangorda pits), spring and fall black bear, spring and fall grizzly bear, wolverine, wolf and coyote. This hunting capacity attracts both local hunters and hunters from elsewhere in the Yukon. The annual take is on average significant (e.g. in 2001 24 moose, 7 caribou and 2 sheep were taken from sub-zones 4-44, 45 and 46).

No land use plan has been established to date. Hunting is facilitated by continued access to Faro Mine lands for activities and for commuting to hunting areas (for instance, a ramp is provided over the main haul road. Although the Interim Receiver will maintain the right to close the mine site in part or in total for public health and safety reasons, there is presently no intention to restrict this current level of land access and use. Fishing is also a lifestyle choice of many of the local population, with the Rose Creek providing attractive fishing locations.

> To date, no Land Use Plan has been established for the regional study area as envisioned by Chapter 11 of the Yukon Land Claim Umbrella Final Agreement (there is no land claim in place as of the date of this EAR that provides for a Regional Land Use Plan for part or all of this regional study area).

> In addition, as per the official position of YTG, the Yukon Protected Areas Strategy is discontinued, and therefore no new protected areas will be established in the regional study area in the foreseeable future through this process. Furthermore, there are no land claims special management areas under consideration for the regional study area; at this point in time, negotiations are formally off among the Ross River Dena Council, and the governments of Canada and Yukon (Government of Yukon Land Claims Secretariat, pers. comm, 2003).

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-107

2.9 TRADITIONAL USE

2.9.1 TRADITIONAL USE STUDY AREA

Traditional use, also referred to as the subsistence economy, refers to First Nations activities such as hunting, trapping, fishing, gathering of plant resources, and travel. Social activities such as gatherings, teaching of skills and cultural values, are also part of traditional use activities.

Anthropologist M. Weinstein, who documented the historic and current traditional use of Ross River Dena in the early 1990s, defined the subsistence economy as "food production (hunting, fishing and plant gathering); fur production; the use of natural materials as tools, for structural purposes; and non-food resources; the distribution and consumption of these resources; and the set of social relations, specific to native communities, through which the production, distribution and consumption of these resources are organized" (Weinstein, 1992).

Traditional land use practices are generally considered to be more than just food collecting or harvesting of resources that can be sold for money; they are critical activities that reflect the health of the community and its members.

Traditional land use practices are more than just food collecting or harvesting The regional geographical area for traditional use is broadly defined as the Anvil Range area, with the Pelly River and Campbell Highway the southern boundaries, the Ross River the eastern boundary and the Tay River the western and northern boundaries (Figure 5). Thus, it includes anthropogenic features including the mine sites, the Faro townsite area and various roads on the north side of the Pelly River. The area includes the lands within the Rose, Anvil and Vangorda watersheds and parts of the Blind Creek and Tay Creek watersheds. A broadly defined study area was necessary as the resources upon which traditional land use is based (i.e. caribou, sheep, moose) can be widely scattered across the landscape.

2.9.2 HISTORIC AND EXISTING TRADITIONAL USE DATA

2.9.2.1 Overview

While the following summary of traditional use data for the study area includes historic as well as current (1998-2002) data, the bulk of the discussion refers to the time before the mine was developed and the period of mine operation.

The sources for information on traditional use in the study areas are:

- Data from the Council for Yukon Indians (CYI) Resource Atlas for map sheet 105K (Tay River) assembled in the 1970s for land claims purposes;
- An anthropology thesis (McDonnell, 1975) that discusses the traditional land use activities of the Ross River people;

🗖 Gartner Lee

- A retrospective study completed by anthropologist Martin Weinstein (1992) that is a detailed reconstruction of traditional land use in the mine area and changes to the traditional land use that occurred as a result of the mine;
- Aboriginal language toponyms (place names) for features on map sheet 105K (Tay River);
- A series of interviews conducted by anthropologist Sheila Greer with selected elders of the Ross River Dena community in December of 1999 to confirm if the findings of the Weinstein study were still considered valid and to record any additional information regarding land use (Greer 2000).
- A series of interviews conducted in the week of March 24th, 2003 as part of the current Water License EA by RRDC researchers Doris Dreyer and George Smith. Anthropologist Sheila Greer assisted with the first two days of these interview sessions. During these sessions, permission to release the information pertinent to the E.A. process with a wider audience was granted. Although transcripts of the interview sessions were not provided, a summary report titled "Ross River Dena Traditional Use Study for the Faro Mine Water License Application (2004 to 2008)" was prepared and provided by Ms. Dreyer and Mr. Smith. The discussion of current traditional use activities that follows herein is based on the Dreyer/Smith summary report as well as on Ms. Greer's personal notes. Further details regarding the interview process are given in Section 1.2.3 of this volume.

2.9.2.2 Historical Use Data

The oldest data set with any level of locational detail is the Council for Yukon Indians Resource Atlas material (Table 49). It includes details on two gravesite locations, and four cabin sites in the regional study area. All are situated outside the "local study area" or mine footprint area. Those within the regional study area are noted in the table and on Figure 5.

The Council for Yukon Indians data set cannot be taken as complete or necessarily locationally accurate; it was assembled to demonstrate occupancy and was not intended for land or resource management purposes. Cabin locations, for example, do not represent the geographic limit of land use activities. Rather they functioned as strategically located base camps from which land use activities would have taken place across the land.

Table 49. Coun	cil for Yukon	Indians Land	Use Data	(1970s)
----------------	---------------	--------------	----------	---------

#	Location	Description
G-1	Pelly River, at Blind Creek area, within RSA	Gravesite, there are 6 to 7 people resting here
G-2	Pelly River, below Rose Mountain, within RSA	Gravesite, there are several people resting here
C-1	Cabin, mouth of Tenas Creek, on Pelly River	Arthur John, fishing and trapping
C-2	Cabin, Pelly River, below Rose Mountain, within RSA	Sid Atkinson, old trapping cabin
C-3	Cabin, Pelly River, below Rose Mountain, within RSA	Rose cabin, built by a white man
C-4	Cabin, Pelly River, at Van Gorder Creek, within RSA	Arthur John, trapping

C-5	Cabin, Pelly River, at Blind Creek, within RSA	Hoole McLeod and Jack Sterriah
C-6	Cabin, Pelly River, at Grew Creek	Jack Ladue, located on Blind Creek
C-7	Cabin, Blind Lake	Arthur John
C-8	Cabin, Blind Lake area	4 cabins, located on the mountain creek, the people used to hunt sheep from these cabins
C-9	Cabin, Orchay Lake	"Old Jules" very old site
C-10	Cabin, lake on Orchay system	Trapping
Source: CY	I Resource Atlas, files RRDC Land Claims Office	

The Weinstein study is the most detailed source on historic traditional use activities in the study area. The McDonnell anthropology thesis (1975) helps outsiders understand organizational principles of social groups, the importance of food and resource sharing within the society and how and why family groups moved throughout the course of a year. However, it does not feature detailed spatial data on traditional land use data, showing the areas used, which families were using these areas, when they were using them and for what purposes. Nor does it consider in any detail how land use patterns changed for the Ross River people with the opening of the Faro Mine.

The 1992 Weinstein study is the most detailed available source on historic traditional use activities in the study area, as it includes both data and analysis of land use activities. In the Weinstein study, land use at different periods is mapped to build a composite picture of changes to use of the area during the second half of the 20th century. Due to a lack of other information sources, recall information was the main way by which land use data were gathered. Many members of the Ross River Dena ("RRD") community, representing a range of ages, completed extensive questionnaires on individual land use patterns during the 1980s and early 1990s. Detailed maps of land use activities and patterns for 1990 were assembled. The study also incorporated in-depth map data collected during an earlier land use and occupancy study of the Ross River Dena traditional use area (Dimitrov *et al.*, 1984).

Locational data on cabins, salmon fishing camps, and main trails, some of which fall within the RSA, that were used prior to mine development are summarized in Tables 50, 51 and 52 (Weinstein 1992).

 Table 50.
 Cabins - Pre Mine Development

Location	Description		
Mouth of Blind Creek, on the	Associated with Blind Creek salmon fishery; cabins belonging to Jack Sterriah

Table 52. Trails - Pre Mine Development

Several key sources drew the Ross River people to the area, including salmon fishing, sheep, caribou, moose, and furbearers. Several families were directly affected by the development

Mine development resulted in some disturbances to the Ross River people

Trapping at a decreased level has continued in the study area According to Weinstein (1992), prior to the development of the Faro mine, the Anvil Range and Mount Mye area was one of two focal land use areas for the Ross River people. Several key resources were drawing the Ross River people to the area. These included the salmon fishery at tributaries of the Pelly River; sheep, which were found at various places around Mount Mye; caribou, which were also found in the Anvil Range and Mount Mye area; moose, which was found across the study area; and fur-bearers, the trapping of which tended to be focused on the valley bottom areas of the Pelly River and Blind, Anvil and Rose Creeks. The families who traditionally used the area directly affected by the development were the families of Selkirk Billy, Aklack, Billy Atkinson, Long Hair John, Gumbala, Nahlier, Pat Johnnie, Sue Bill, Joe Ladue, Hoole McLeod, Jack Sterriah, Old Man Jules and Jack Ollie's wife (Weinstein 1992: 88).

Deloitte

& Touche

Weinstein noted that although the Ross River people persisted with traditional use activities in the Faro area, the intensity of use changed as harvesters encountered the impacts of mine development. These included problems of restricted access with security gates and fencing and firearms use prohibitions; declines in local animal populations which resulted from disturbance, habitat loss and degradation, and increased competition from recreational hunters and fishers; fears of health risks from consumption of wild meat exposed to toxic substances; and increased amounts of disturbance. Disturbance ranged from simple curiosity of Faro residents, for whom the activities of Ross River Dena on the land were interesting anachronisms, to the malicious destruction of trapping sets, poaching of furs, theft of gear and vandalism of cabins (Weinstein 1992).

The Weinstein study noted that the geographic focus of traditional land use by the Ross River people changed significantly with the development of the Faro mine. It was reported that most individuals whose family lands were located in the mine and town development areas shifted their primary harvest effort to other accessible western areas of the band's territory (Weinstein 1992). This geographic shift meant that other parts of the traditional territory of the Ross River people became more heavily used.

The Weinstein study indicated trapping as one traditional use activity that has continued in the study area since mine development. It was noted that fewer individuals were participating in this activity, however.

Aboriginal language place names are another key source for information on traditional land use activities. Place names, or toponyms as they are also called, document key land use activities and often encode historical data. Important resource locales are also usually named (Cruikshank, 1990; Hanks and Winters, 1983). Toponymic data for map sheet 105K have been published (Kaska Tribal Council, 1997; Moore, 1999), and are reproduced on Figure 5. This list of names is an indication of the Ross River peoples' intimate relationship with the study area, and is suggested to be most useful for providing insight into the land use patterns of the Ross River people prior to the development and operation of the Faro mine complex.

Another data set for information on traditional use activities in the study are the 1999 interview sessions conducted by Greer with Ross River Elders. This work was a post-impact assessment, overview level rather than detailed, of the Faro and Ketza mines. The sessions recorded additional information on land use patterns for the period prior to mine development, as well as during the interval of mine operation.

The information shared by the individuals interviewed in 1999 concurred with the Weinstein conclusions. These are, that the presence of the mine resulted in community members shifting their harvesting activities out of the mine site area, and that trapping was one activity that continued to take place during the period of mine operation. Reference was also made in the 1999 interviews to hunting activities in the general study area during the period since the mine was developed. These activities were mentioned in reference to concerns individuals shared about the health of the environment, as it was noted that diseased animals have been harvested here since the mine began operating.

Current Use Data

The 2003 interviews with members of the RRD community documented details on the current (1998-2002 or post mine-shut down) traditional use activities in the general study area, as well as additional information on historic land use activities. The sessions also documented traditional knowledge data on the region's environment, which is presented elsewhere in this report. The summary presented here focuses on the current land use activities and is shared with the permission of the land users who provided the information on their activities. Maps depicting the locations of current traditional land use activities, e.g., berry harvesting sites, moose harvesting locales, trap set locations, trails, etc. were not made available in the Dreyer/Smith summary report.

A considerable number of RRD community adult members are reported to be carrying out traditional use activities in either the regional or local study areas. The number of land users, even an approximate number, cannot be specified from the available information, however. Individuals from all parts of the Ross River Dena traditional territory, not just members of certain families, are reported to now be using the study area. Users include Elders as well as younger community members.

Available information does not suggest that sheep hunting, a traditional use activity that was common prior to mine development, is presently taking place in the regional study area. At least some RRD community members are aware of their right to hunt sheep and of the presence of a healthy, abundant stone sheep population, and they indicated they desired sheep meat. These same individuals reported that they do not carry out this activity because they do not want to have the larger (non-native) community think negatively of Dena people. It was noted that with the development of the Blind Creek sheep wildlife viewing area, this species has been (re)defined by the non-native community as a local tourist attraction. For the RRD community members who talked about this issue, sheep

Members from all parts of the Ross River Dena community are reported to be using the mine area for traditional use activities since the mine closed.

are a source of country food and a species with which their people have had a long and intimate relationship. They reported that they believe they are being watched as they hunt sheep in the regional study area, and that they as individuals and as a community would be viewed negatively if they took this species.

Available information suggests that sheep, caribou, gophers and marmots are not being taken in the area

It is uncertain where trapping and berry & plant collecting activities are taking place

One Ross River Dena family fishes in the mine area; most avoid it because of environmental concerns

Good moose habitat is reported in the mine site area. Moose hunting appears to be the predominant traditional use activity current taking place in the study area Available information suggests that caribou hunting, a common activity in the RSA prior to mine development, is no longer taking place here for the simple reason that there are no caribou here. This animal, represented by the large subspecies that was resident in the Mount Mye area, is reported to have moved out when mine development began.

Hunting of gophers (ground squirrels) and groundhogs (marmots) took place in the mine site area prior to mine development. These animals used to be snared in the high country in the late summer/fall, and were then dried and cached for later retrieval. Despite its importance in prior times, the information that is available suggests that the harvesting of gophers and groundhogs is not currently taking place in the study area. This is because the two species, like caribou, moved out of the area when the mine was developed and they have not returned.

A couple of RRD community members are reported to be trapping in the RSA. No harvest statistics are available (species and numbers taken), however, nor are the locations of their lines and trap-sets known.

Available information suggests that some berry and plant collecting is taking place presently in the RSA, but the location of these activities is unknown. The specific locational data that is available suggests that berry collecting may be restricted to the most southern parts of the RSA, around the town of Faro, the Campbell Highway and the Pelly River.

One Ross River Dena family is reported as fishing in the mine site area. Others noted that they do not fish in the mine area because of concerns over the quality of the water and hence the fish. Fish continue to be taken at other locales in the RSA. Drinking water is reported to be collected at various creeks in the RSA, but information on the location of the creeks where water is collected has not been made available.

Moose hunting, including spotting or searching for the species, is believed to be the predominant traditional use activity in the study area. No details (number, age, sex) are available on the moose taken, nor on the ratio of successful to unsuccessful hunting events. This activity is reported to be taking place at all times of year.

At least some of the individuals interviewed reported that the plateau area where the mine site complex is situated is good moose habit, noting as well, that moose have been appearing in increasing numbers here since the mine shut down. These same individuals reported that moose hunting is taking place along the south flank of the Anvil Range, and further west, up Rose (North Fork), Faro and Next

> Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 2-114

Creeks, as well as in the Mount Mye area, that is north, south and east, of the Grum and Vangorda Pits.

Various historic aboriginal trails once crisscrossed the RSA (Table 5.5), with a couple running right through or across the LSA. The Vangorda and Grum Pits and the undeveloped Grizzly ore body for example, are situated right where the trail that ran from the Blind Creek valley up to the hunting country of Mount Mye was located. Some current land users reported that the landscape within the LSA has changed so much that they are no longer able to recognize the old trails that they walked on as youths, or even segments of the old trails, should they even still exist. The network of old trails in the RSA has been completely destroyed and they no longer form the basis of travel through the area.

The loss of the trail system with the development of the mine, coupled with the introduction of a road and access route network is believed to have had considerable impact on the pattern of land use activities in the local study area. Road accessibility is suggested to be an important variable when community members select the mine area for hunting. Available information suggests that individuals drive as far as they can on the mine road system i.e., until a gate or road block is encountered and then proceed further either on foot, or by snow machine or ATV. Difficulty in use of the latter equipment, however, was noted by RRD community Elders and request has been made to allow Elders to drive their vehicles beyond control gates for hunting purposes.

The importance of road accessibility to hunting in this area reflects how land use patterns have changed since the mine was developed. Prior to mine development, extended multi-day hunting trips out on the land, using the traditional trails to access preferred hunting areas, were the norm in this part, as it was in all other parts, of the Ross River Dena traditional territory. Available information suggests that many of the hunting trips now taken in the mine site area are day trips, where an individual or a small group of hunters travel into the mine site area, from a home base that is located elsewhere, such as Ross River. Hunting trips of longer duration, lasting up to two weeks, are noted as occurring, but the location of these trips is not known. At least some RRD community members noted, however, that overnight hunting trips in the study area are less desirable given the extent of disturbance and the area's heavy use by non-natives.

To conclude, available information suggests that while the range of traditional use activities that are currently taking place in the study area is certainly reduced from pre-mine times, the frequency of traditional use activities appears to have increased from that which took place during the years of mine operation and even since the 1999 interviews were conducted. Details are lacking, however, on specifically where the traditional use activities of trapping, berry and plant collecting, and water collecting are taking place within the regional study area. Moose hunting, is believed to be the predominant current traditional use activity, and moose hunting appears to be taking place in the local (mine footprint) and regional study areas. Fishing within the local study area (mine footprint) appears

The loss of the aboriginal trail system coupled with the introduction of roads and access routes has changed the way in which hunting takes place in this part of Ross River Dena traditional territory

Traditional use activities are believed to have increased in the mine area since operation ceased; they are expected to further increase as environmental conditions improve

to be an activity of limited appeal within the RRD community, being carried out by only one family.

2.10 HERITAGE RESOURCES

2.10.1 HERITAGE STUDY AREAS

In considering the potential for impacts to heritage resources both a local (mine footprint) and a RSA approach are employed. The LSA, the area of project activities, includes the footprint of the mine pits, tailings piles, diversion ditches and flumes, waste dumps, landfill sites and access roads. This study area is used when considering the potential for direct impacts to heritage resources, that is, disturbance or destruction of the resource.

The RSA for traditional use is broadly defined as the Anvil Range area, with the Pelly River and Campbell Highway the southern boundaries, the Ross River the eastern boundary and the Tay River the western and northern boundaries (Figure 5). Thus, it includes anthropogenic features including the mine sites, the Faro townsite area and various roads on the north side of the Pelly River. The area includes the lands within the Rose, Anvil and Vangorda watersheds and parts of the Blind Creek watershed. A broadly defined study area was necessary as the resources upon which traditional land use is based (i.e. caribou, sheep, moose) can be widely scattered across the landscape.

The RSA is employed when considering the potential for indirect impacts to heritage resources. It incorporates the Anvil Range and all of the Vangorda and Rose Creek Watersheds, and small parts of the Blind Creek and Tay Creek watersheds. The RSA thus includes the following anthropogenic features: the mine sites, the Faro townsite area and the various roads on the north side of the Pelly River.

Indirect impacts refer to the pilfering of moveable heritage resources (artifacts) from heritage sites through illegal collecting, or the unintentional destruction or vandalism of sites in the region, through increased human presence in the general project area. Another example of an indirect impact might be destruction of grave fences at gravesites located off the project property.

The potential for direct impacts to heritage resources is considered to be higher than the potential for indirect impacts, and therefore the potential for the former are examined more closely in an environmental assessment. Consideration of direct impacts to Heritage Resources is limited to the local study area, whereas for consideration of indirect impacts the regional study area is being used. This differential treatment is justified because the scale of proposed project activities is limited in nature i.e., care and maintenance, rather than extensive new development. Indirect impacts such as artifact pilfering and structure vandalism are more typical with a larger development projects in pristine or undisturbed

contexts. Similarly, the extent of human presence in the local and regional study areas in the period between when the mine was first developed to when it closed in 1998 is much larger by many orders of magnitude that which is expected to take place during the period of project operation. A larger population using the area would mean a greater chance of indirect impacts, and the anticipated small population means significantly less chance of indirect impacts.

2.10.2 CHARACTERIZATION/DEFINITION OF HERITAGE RESOURCES

The term heritage resource is used most often to refer to material remains that relate to human history. Of present concern are locale-specific resources, or heritage sites, where heritage structures or moveable heritage resources (artifacts) or structures are found. Natural landscape features, such as legend places and named places that are of historic or cultural significance can also be considered heritage resources or sites, even though they do not have material remains. This might be the case if such locales have heritage value to a group, such as the First Nations, who have traditionally lived in the area.

Archaeological sites are the most commonly recognized type of locale-specific heritage resource in Yukon. They are an important part of the Territory's record of human history since they are the material remains that represent the precontact (or prehistoric) way of life of the ancestors of the Territory's First Nations. Some prehistoric sites include above ground structures such as caches and hunting blinds.

Historic sites, featuring buildings or above-ground structures, as well as buried archaeological deposits, are another type of commonly recognized heritage site in the Territory. The upper cut-off or most recent date for historic sites varies; the Yukon Heritage Branch currently uses a date of ca. 1950.

In the Yukon, while paleontological finds are also considered Heritage Resources, impacts to paleontological sites are not considered as part of project development impact assessment studies. Nonetheless, it is worth noting that while there are no known paleontological sites in the RSA, a significant paleontological find area is located just outside of Ross River.

While the Ross River Dena Council are not signatory to the Yukon Umbrella Land Claim Agreement, this Constitutional document formally recognizes First Nations' interests in the Territory's heritage resources. First Nations own all heritage resources on Settlement Lands and all ethnographic moveable heritage resources that are found in their respective Traditional Territories that are directly related to the culture and history of Yukon First Nations people.

2.10.3 HISTORIC AND EXISTING DATA ON HERITAGE RESOURCES

For heritage resources, historic and current data are one and the same.

Information on heritage resources prior to, during and following the facility operation within the regional study area has been collected from the following sources:

- The Canadian Heritage Inventory Network database, which is the register for archaeological sites maintained by the Canadian Museum of Civilization (available at the Yukon Heritage Branch);
- The Yukon Historic Sites Inventory database, which is maintained by the Yukon Heritage Branch; and
- Existing sources on the history and traditional land use patterns of the Ross River people, including interviews with selected elders of the Ross River Dena community in Ross River conducted by S. Greer in December of 1999, and the more recent interviews conducted in 2003.

Review of the data in the Canadian Heritage Inventory Network shows that there are no registered archaeological sites within the RSA. Archaeological sites have been identified only a short distance outside the RSA boundary as well as around the Ross River settlement and elsewhere along the Campbell Highway.

There are no historic sites registered in the Yukon Historic Sites Inventory database. Review of the site files shows six historic sites, listed in Table 53, identified just outside the RSA boundary (also noted on Figure 5).

YHSI #	Name/Label	Location	Description/Comment*
105K/03/001	Pelly River Cabin Remains	Pelly River at Blind Creek	Believed to be associated with nearby Sawmill
105K/03/002	Pelly River Sawmill Remains	Pelly River at Blind Creek	Heavy timber frames
105K/03/003	Blind Creek Cabin & Dog Houses	Pelly River at Blind Creek	Abandoned; may have belonged to either Joe Ladue or Jack Sterriah
105K/03/004	Sawmill Buildings	Pelly River at Blind Creek	Equipment shed, 2 residence buildings
105K/03/005	Pelly River Foundation	Pelly River at Blind Creek	Related to lumbering, milling activities
105K/03/006	Blind Creek Grave Site	Pelly River at Blind Creek	5 standing grave fences, and "as many as 25 grave mounds"

Table 53. Registered Historic Sites Located Just Outside Study Area

Source: Yukon Heritage Branch, Historic Sites Office. * Note: little or no oral history research regarding these sites has been completed.

A significant collection of aboriginal language toponyms has been assembled by the Kaska Tribal Council (1997). The named landscape features within the regional study area are shown on Figure 5. There is no information in the available sources to indicate if any natural landscape features in the study area might be considered heritage resources by the Ross River people.

Deloitte & Touche

More detailed examination of the existing heritage resource data sources and related documentation shows, however, that:

- No archaeological or historic site inventory work has ever been completed in either the local (mine footprint) or regional study areas. That is, no information was collected on heritage resources in the mine area prior to development.
- Traditional Use data, recorded in interviews with selected Ross River Elders in 1999, as well as that which appears in earlier sources, and in the Dreyer/Smith summary report on the 2003 interviews, suggests that the RSA should have heritage site potential, since prior to the mine development it was a key land use area of the Ross River people. This means it was likely used in earlier times as well, and archaeological evidence of such prior use can be expected.
- A collection of Kaska language toponyms (place names) exists for the RSA, which suggests that there may be natural landscape features or specific locales in the RSA that might be considered heritage resources by the Ross River people.
- Two Ross River Dena gravesites are located in the regional study area. One of these gravesites (the Blind Creek graves) has been registered as a historic or heritage site (105K/03/006), but the second gravesite, located at Rose Creek along the Pelly River (see Table 5.1 in Traditional Use section) is not registered in any government heritage site database (either historic sites or archaeological sites database). Both gravesites are located outside the local study area.

In summary, it is reasonable to conclude that the lack of registered heritage sites in the LSA and RSA can be attributed to the lack of field research and inventory work, rather than the non-existence of heritage resources of interest. The presence of known archaeological and historic sites just outside the RSA is further support for the potential existence of heritage sites within the RSA or within the LSA. There could well be heritage sites within the Local Study area that have not yet been documented.

2.11 VALUED ECOSYSTEM AND CULTURAL COMPONENTS

2.11.1 RATIONALE

Definition of VECC

The detection of environmental effects from a project is complicated by the number of environmental components, vegetation and wildlife species, as well s the natural changes within locations of component study areas. CEAA recognizes that it is not possible, nor particularly useful, to measure effects on all possible receptors (at the component or species level); rather, it is advantageous to focus a limited number of locally significant and measurable receptors that will serve as surrogates for the environmental components as a whole. The same can be said for the social context.

Gartner Lee

This process involved the selection of a few Valued Ecosystem and Cultural Components (VECCs) for each environmental and social component (such as aquatic resources and traditional use). VECCs can be defined as features of the regional environmental and social setting selected to be a focus of an environmental assessment because of their ecological, social and economic value and their potential vulnerability to effects of the project. VECCs can then be used as a focus of the environmental assessment, as is done in Volume III – Effects Assessment.

In addition, for each VECC, indicators have been identified that can be used to measure changes in that VECC. Detailed descriptions of the selected VECCs and indicators are provided below.

2.11.2 Integration of Traditional Knowledge

Traditional knowledge is acquired by indigenous people over time through direct experience with the environment, and is considered equal to scientific knowledge in EA As defined under CEAA, Traditional Knowledge is the knowledge base acquired over hundreds of years by indigenous peoples through direct experience and contact with the environment. It takes several forms:

- An intimate and detailed knowledge of the environment including plants, animals and natural phenomena;
- The development and use of appropriate technologies and methods for hunting, fishing agriculture and forestry; and
- A holistic world view that parallels the scientific discipline of ecology.

Traditional knowledge carries the same weight in environmental assessment as scientific knowledge.

For this project, the descriptions of information for traditional land use and heritage resources (areas where traditional knowledge is essential) both identified information gaps that limited the ability to fully describe the conditions. Nonetheless, the information that is available on these topic areas is sufficient to allow for the assessment of the proposed project activities because of the limited scope of the activities (i.e. care and maintenance only).

The gathering and integration of traditional knowledge specific to this project is described in Section 1.2.3 of this volume. The consultation that took place during the environmental assessment process and the integration of the results of the consultation into the Project Description are described in Section 3 of Volume III.

2.11.3 VECCS AND INDICATORS

The selected VECCs and indicators are identified in Table 54. The indicators were selected based on the following selection criteria:

- presence in the regional study area;
- ecological importance;
- existing monitoring where a baseline is available;
- degree of exposure to stressors produced by the project;
- sensitivity to stressors produced by the project;
- socio-economic importance;
- traditional use importance; and
- heritage importance.

VECC indicators were selected as a means of measuring change in the VECC. These were selected based on the existence of data at established locations and the ability to detect measurable changes.

In total, 14 VECCs and 26 indicators were developed (as noted on Table 54). These are used in Volume III, Environmental Effects to determine where project activities will interact with the environmental and social components and to determine what effect, if any, these interactions will result in on the indicator and VECC.

Table 54. Valued Ecosystem and Cultural Components Defined for the Environmental Assessment

Component	VECC	Indicator							
Air Quality	air quality in the airshed	maintain air quality within territorial objectives (CCME CWS objective for							
		particulate)							
Water Resources	stream flow in the receiving environment	maintain pit elevations within desired range							
	stream flow in the receiving environment	maintain site water flow patterns							
	stream flow in the receiving environment	maintain water flow patterns off site							
	surface water quality in the receiving environment	zinc, sulphate and pH in Rose Creek at R2/X14							
	surface water quality in the receiving environment	zinc, sulphate and pH in Vangorda Creek at V8							
	groundwater flow in the receiving environment	maintain pit and pond surface water elevations within desired range							
	groundwater flow in the receiving environment	construction of new facilities or alterations to existing facilities that would result in							
		changes to groundwater recharge or discharge areas							
	groundwater quality in the receiving environment	subsurface zinc, sulphate and pH measured at site X16							
	groundwater quality in the receiving environment	subsurface zinc, sulphate and pH measured along the North Fork of Rose Creek							
	groundwater quality in the receiving environment	subsurface zinc, sulphate and pH measured below the Vangorda rock dump							
	groundwater quality in the receiving environment	subsurface zinc, sulphate and pH measured below the Grum rock dump							
Aquatic Resources	fish habitat	metals in sediment in Rose Creek (R2 to R5) compared to reference levels and CCME							
	fish habitat	metals in sediment in Vangorda Creek (V5, V27, V8) compared to reference levels and CCME							
	fish habitat	benthic invertebrate community structure (abundance and richness) in Rose Creek (R2 to R5) compared to reference communities							
	fish habitat	benthic invertebrate community structure (abundance and richness) in Vangorda Creek (V5, V27, V8) compared to reference communities							
	fish population health	metals in fish tissue (Arctic grayling liver and muscle, slimy sculpin whole body)							
	fish population health	fish presence and abundance							
Terrestrial Resources	wildlife habitat integrity	metals in vegetation							
	wildlife habitat integrity	vegetation community (structure, diversity)							
	wildlife population health	wildlife presence and abundance							
Socio-economics	commercial, subsistence and recreational use	Continued use opportunities							
Traditional Use	Aboriginal fishery	Continued fish harvesting opportunities							
	wildlife harvesting	Continued wildlife harvesting opportunities							
	plant harvesting	Continued plant harvesting opportunities							
Heritage Resources	heritage sites	No disturbance of heritage sites							

3 SITE CHARACTERIZATION

3.1 OVERVIEW OF SITE CHARACTERIZATION

A characterization of the environmental effects of the previous mining activities is not a direct input into the assessment of effects related to the proposed care and maintenance activities. However, such a characterization of historical effects does provide context for understanding the general conditions at the mine sites.

A comprehensive site characterization that describes the historical trends in environmental data and the impacts that the mine has had in the environment was compiled and submitted as Volume 2 of the May 2002 Project Description. Some information from that report is brought forward here for ease of reference, but readers are referred to that report for a more comprehensive description of the historical environmental impacts related to previous (i.e. pre-1998) mining activities.

Additionally, a summary of information that was gathered in 2002 regarding the rock piles around the mine site is summarized herein, with readers referred to the original report (SRK 2003) for more comprehensive descriptions.

3.2 SOIL QUALITY

3.2.1 PHASE 1 ESA METHODOLOGY

Soil samples were collected and analyzed to assess potential contaminants of concern at the site A Phase 1 Environmental Site Assessment was conducted in the fall of 1999 (GLL 2001) that included the collection and analysis of 58 surficial soil samples from various locations on the Faro and Vangorda Plateau Mine sites (noted on Figures 31 and 32). On the basis of known industrial activities that have occurred at the site, the potential chemicals of concern and their sources were identified as follows:

- 1. *Petroleum Hydrocarbons* from diesel fuel, gasoline, hydraulic and lubricating oils from the storage, use and disposal of fuels and oils;
- 2. Mill and Laboratory Chemicals from cyanide, xanthates, glycols and others;
- 3. *Heavy Metals* from mining, milling and processing of mineralized rock as well as naturally occurring concentrations due to natural geochemistry; and
- 4. *Transformer and Capacitor Fluids* potentially contributed from the former presence of PCB-containing electrical equipment.

Soil samples were collected as surface grab samples. The majority of the soil samples were analyzed to determine concentrations of extractable petroleum hydrocarbons (EPHs) and heavy metals (lead and zinc) with selected soil samples analyzed to determine concentrations of non-halogenated volatiles (BTEX compounds and VPH) polycyclic aromatic hydrocarbons (PAHs), metals and PCBs. One soil sample, collected beneath an area of treated timber storage, was analyzed to determine the concentration of chlorinated phenols and PAHs.

Samples were submitted for chemical analysis to provide confirmation for contaminant observations during the site inspection.

3.2.2 PHASE 1 ESA RESULTS

3.2.2.1 Petroleum Hydrocarbons

Details of elevated petroleum As indicated on Tables 55 and 56, elevated concentrations of petroleum hydrocarbons were noted in soil samples collected at the following locations:

- hydrocarbon concentration locations
- 1. *Faro mill site*: volatile petroleum hydrocarbon (VPH) and xylene from one sample of the berm, which are indicative of gasoline contamination;
- 2. The Emergency Diesel Generator and Fuel Supply: LEPH from one surface soil sample collected downslope of a historical fuel spill and two surface soil samples collected near the pumphouse and fuelling nozzle for the primary fuel tank, also evidence of small scale spills;
- 3. *Faro Lube Building*: LEPH concentrations in all of four samples and HEPH in one sample, with the source likely being diesel and heavy oils;
- 4. *Diesel Storage Tanks for Lube Shack Fuel Pump*: Samples LEPH in samples collected from the west side of the gravel berm and at the NE corner of the bermed area;
- 5. *Historic Fuel Storage Near the Core Shacks and at Scrap Area to NW of Faro Pit*: LEPH in samples collected directly adjacent to the tank pads and dispensing area;
- 6. *Waste Oil Handling Area*: LEPH and HEPH in the sample collected at the shipping container;
- 7. Partially Buried Waste Oil Tank and Washbay Diesel Tank: LEPH in the sample taken at the front of the washbay;
- 8. *Reagent Mix Building*: HEPH in one sample taken in front of the loading doors for the building;
- 9. *Grum Ore Haul Maintenance Shop*: LEPH in samples from the weigh scale and the east exit of the area; and
- 10. *Grum Lube Shop and Diesel Storage Tanks*: LEPH in two of the soil samples collected in the near a former aboveground fuel tank location at the lube shop and downslope of the lube shop area in the direction of surface runoff.

3.2.2.2 Lead and Zinc

The highest concentrations of lead and zinc were found near the concentrate load-out on the Faro Mine site Lead and zinc concentrations were also determined in selected soil samples collected from various areas. Metal concentrations in soil samples were determined from the old tailings spill area downstream of the Rose Creek tailing facility. Generally, the concentrations of lead and zinc detected in the soil samples are indicative of metal contamination from historical mining and milling activities.

As noted on Table 57 soil samples collected at the Faro Mine site contain higher concentrations of lead and zinc than samples collected at the Grum mine site due, likely to the presence of milling operations and the longer operating history. The highest concentrations of lead and particularly zinc were found in soil samples collected near the concentrate load-out on the Faro Mine site. The major source of metal contamination in surface soils within the Faro mill area was attributed to the presence of concentrate storage areas and vehicle tracking within the mine and mill site areas.

3.2.2.3 Summary

The following summary regarding surficial soil quality are repeated from GLL 2001:

In terms of surficial soil quality, several localized areas of concern were identified

- 1. Petroleum hydrocarbon contamination appears to be localized within the source areas for storage and dispensing of fuel and oil products;
- 2. Concentrations of LEPH were greatest at several fuel and oil storage and dispensing areas at the Faro and Vangorda Plateau Mine sites. PAHs and BTEX compounds were not present at elevated concentrations;
- 3. Levels of petroleum hydrocarbon contamination in soils are higher at the Faro Mine site than at the Vangorda Plateau, likely due to the longer history of mine operations; and
- 4. High concentrations of residual oils in surface soils were noted at the Faro Pit Lube Shop and Grum Lube Shop, which may be migrating from the source area via surface runoff.

The concentrate load-out area represents an area of concern with respect to the presence of residual concentrate and the associated elevated metal concentrations in surficial soils.

3.3 CONTAMINANT LOADING

3.3.1 METHODOLOGY

Contaminant loadings were calculated using 'predicted' and 'observed' loadings A preliminary contaminant loading study was completed in 2002 for sulphate and total zinc in Rose Creek (GLL 2002b). The results of water balances for the North Fork of Rose Creek, Rose Creek at X14 and Vangorda Creek were combined with measured and extrapolated concentrations of sulphate and zinc to provide calculated loadings for each of the time steps defined in the water balances. Total zinc was used for this study (rather than dissolved zinc) because the record of analysis for total zinc is much more extensive.

Loadings for the three areas were calculated in two ways:

• A "predicted" loading was calculated as the sum of the individual source terms; and

• An "observed" loading was calculated from sulphate and zinc concentrations and extrapolated flows at the downstream monitoring location for each area: location X2 for the North Fork of Rose Creek, location X14 for Rose Creek and location V8 for Vangorda Creek.

The predicted and observed loadings were compared as a means of assessing the ability of the model to adequately predict the actual loadings.

3.3.2 ROSE CREEK METAL CONCENTRATIONS

The following notes apply to the concentrations used for the North Fork of Rose Creek:

- 1. Concentrations for location R7 were applied to runoff areas unaffected by mine developments such as runoff from the south side of the North Fork valley;
- 2. Concentrations from database station FAROCR were applied to flow from the Faro Creek Diversion;
- 3. Concentrations for groundwater wells BH12, BH13 and BH14 were applied to flow from the Northeast Rock Dump. The shallow groundwater flow was used because this has been regularly collected (twice per year) whereas some intermittent freshet surface flows have been sampled in recent years but this data are sparse and irregular;
- 4. Concentrations for groundwater wells BH1, BH2 and BH4 were applied to seepage from the Zone II Pit;
- 5. Concentrations for groundwater wells P96-6, S1, S2 and S3 were applied to runoff from the Intermediate Rock Dump; and
- 6. Concentrations for database station X2 were applied to the combined flow at location X2.

For the time steps incorporated into this study, three sulphate concentrations and two zinc concentrations were extrapolated from neighbouring data to "patch" the record in places where no data was available.

The following notes apply to the concentrations used for Rose Creek:

- 1. Flow from the North Fork of Rose Creek was treated as a single source using the measured concentrations at location X2 (i.e. corresponding to the "observed" loadings per section 4.2);
- 2. Concentrations for location R7 were applied to runoff areas unaffected by mine contaminants such as runoff from the South Fork of Rose Creek, the North Wall Interceptor Ditch and runoff from the south side of the Rose Creek Diversion Canal;
- Concentrations for location X5 were applied to surface release from the Cross Valley Pond;
- 4. Concentrations for location X13 were applied to seepage at the toe of the Cross Valley Dam;

- 5. Groundwater concentrations in the aquifer as presented in the 2001 Tailings Investigation Study (GLL, 2002) were applied to groundwater discharge to surface between the Cross Valley Dam and location X14;
- 6. Surface runoff between the Cross Valley Dam and location X14 was provided as a separate line item to provide flexibility for future sensitivity analyses with respect to the 1975 tailing spill; concentrations for location R7 were applied to this flow in this study;
- 7. Concentrations for database station X14 were applied to the combined flow at location X14; and
- 8. One sulphate concentration for location X14 was increased slightly because the data set excluded samples during a period of release of higher sulphate water from the Cross Valley Pond.

3.3.3 ROSE CREEK LOADINGS

The loading calculations for the North Fork of Rose Creek provide the following observations:

- 1. The model predicts 111% of the observed sulphate loading at location X2, which is considered to be a good correlation for this stage of study;
- 2. The model predicts 77% of the observed zinc loading at location X2; however, the model predicts 90% of the observed loading when one poorly correlated time step (time step no. 10) is excluded, which is considered to be a good correlation for this stage of study;
- 3. The largest source sulphate loading (over the entire period of study) was natural runoff upstream of location R7 (43% of total) followed by the Faro Creek Diversion and the Intermediate Rock Dump (23% and 22%); and
- 4. Given item no. 2 above, the largest source of zinc loading (over the entire period of study) was natural runoff upstream of location R7 (52% of total) followed by the Faro Creek Diversion (31%).

The loading calculations for Rose Creek at location X14 provide the following observations:

- 1. The model predicts 61% of the observed sulphate loading and 68% of the observed zinc loading at location X14, which suggests an imprecise or unknown source term that requires further investigation;
- 2. The trends in loadings indicate summer peaks corresponding to periods of surface release from the Cross Valley Pond (X5);
- 3. The largest source of predicted sulphate loading (over the entire period of study) was surface release from the Cross Valley Pond (47%) followed by seepage from the Cross Valley Dam (29%); and
- 4. The largest source of predicted zinc loading (over the entire period of study) was the North Fork of Rose Creek (50%) followed by surface release from the Cross Valley Pond (32%).

The models for the North Fork of Rose Creek and Rose Creek predicted the largest sources of sulphate and zinc loadings

3.3.4 VANGORDA CREEK METAL CONCENTRATIONS

The following notes apply to the concentrations used for Vangorda Creek:

- Concentrations for location V1 were applied to runoff areas unaffected by mine contaminants such as the Vangorda Creek Diversion Flume and runoff from into Vangorda Creek below Shrimp Creek;
- Concentrations for location V25BSP were applied to flow from the Grum Interceptor Ditch;
- Concentrations for location V2 were applied to runoff from the majority of the Grum Rock Dump (approximating Grum Creek drainage area);
- Line items for seepage from the Vangorda Rock Dump and Little Creek Dam were incorporated into the study to allow flexibility in future sensitivity analyses and assumed concentrations were applied for this study;
- Concentrations for database location V4 were applied to flows from Shrimp Creek; and
- Concentrations for database stations V5 and V8 were applied to flow from the West Fork of Vangorda Creek and Lower Vangorda Creek, respectively.

One sulphate concentration for location V4 (Shrimp Creek) was extrapolated from other data for a time step where no data were available.

3.3.5 VANGORDA CREEK LOADINGS

The model for Vangorda Creek showed the largest source for sulphate and zinc loadings was the west fork of the Vangorda Creek The loading calculations for Vangorda Creek at location V8 provide the following observations:

- 1. The model predicts 73% of the observed sulphate loading at location V8, which is considered adequate for this stage of study but should be followed with further investigation;
- 2. The model predicts 74% of the observed zinc loading at location V8, which is considered adequate for this stage of study but should be followed with further investigation;
- 3. The largest source of sulphate loading (over the entire period of study) was the West Fork of Vangorda Creek (56%) followed by the Grum Rock Dump via Grum Creek (18%); and
- 4. The largest sources of zinc loading (over the entire period of study) were the West Fork of Vangorda Creek (25%) and the Grum Rock Dump via Grum Creek (23%) followed by the Vangorda Creek Diversion Channel (19%) and the Grum Interceptor Ditch (17%).

3.4 ROSE CREEK TAILINGS FACILITY

3.4.1 SUMMARY OF ACID GENERATING POTENTIAL

The Rose Creek Tailings Facility contains tailings demonstrating strong acid generating potential The Rose Creek Tailings Facility contains tailings with demonstrated strong acid generating potential (i.e. surface tailings with pH less than 1.5). Oxidation of the exposed tailings over the life of the mine has produced a store of soluble oxidation products, including sulphates, soluble metal salts and acidity. A large portion of the oxidation products appear to be stored in the tailings, due to the buffering of underlying unoxidized tailings.

A comprehensive hydrogeological and geochemical investigation of the tailings facility was conducted in 2001 (GLL 2002c) that included the collection of insitu samples of tailings and subsequent analysis by static and kinetic test procedures. The study included a comparison of the 2001 information to similar geochemical information that had been collected 11 to 15 years earlier (1986 to 1990) through several studies. A summary of the conclusions of the 2001 geochemical interpretation as repeated from GLL 2002c is as follows:

- A summary of the conclusions of the 2001 geochemical interpretations
- 1. Oxidation of tailings in the unsaturated zone has increased since the 1988-1990 studies as displayed primarily by lower paste pH to greater depths;
- 2. The water level within the tailings controls the extent of oxidation. This is an important consideration for reclamation since lowering the water elevation in the Intermediate Pond will lower the water level in the tailings upgradient of the pond;
- 3. Oxidation products (represented by sulphate and zinc) have reached the tailings/native soil interface at most locations. The sulphate "front" has migrated deeper than the zinc "front". This is interpreted to be due to attenuation of zinc enabled by neutral pH within the saturated zone of tailings;
- 4. Tailings in the southeast end of the Second Impoundment and unsaturated tailings in the northern area of the Original Impoundment are highly oxidized relative to other areas. This is considered to be due to the predominantly coarse particle size and well-drained, unsaturated conditions that have existed at times over the life of the operation; and
- 5. The southeast end of the Second Impoundment and the northern area of the Original Impoundment are calculated to be the source of approximately 75% of the sulphate load in the aquifer. These two areas occupy only approximately 20% of the total surface area of the tailings impoundments. This suggests that surface remediation of these areas may represent an efficient means of substantially reducing contaminant loading to the aquifer.

3.4.2 SUMMARY OF WATER QUALITY

3.4.2.1 Overview of Available Groundwater Quality Information

Eleven wells were installed within each of the impoundments as part of a hydrogeological and geochemical investigation of the tailings facility A series of groundwater wells were installed in 2001 as part of a comprehensive hydrogeological and geochemical investigation of the tailings facility: P01-01 to P01-11. These wells are located within each of the impoundments, at the toe of the Intermediate Dam and downgradient of the Cross Valley Dam. These monitoring wells complement the information collected from older wells that were installed in 1981 and 1996.

Three data sets are available for the complete set of 2001 and older monitoring wells: fall (September) 2001 (at the completion of the 2001 drilling activities), spring (June) 2002 and fall (September) 2002. The fall 2001, spring 2002 and fall 2002 data are tabularized and provided in Appendix D. A summary comparison of select parameters for the three recent data sets is also presented in Appendix D.

3.4.2.2 Summary of Observations

Summary observations of the 2001 and 2002 groundwater quality information The 2001 and 2002 groundwater quality information provides these summary observations:

1. Contaminants leached from the tailings are present at depth in the native aquifer beneath the tailings impoundments and, in some locations, contaminant concentrations increase with depth;

This is a somewhat unexpected observation and the precise mechanism for dispersion of contaminants to depth has not been identified given the verification by the hydrogeological model that contaminants would be generally expected to travel in the upper zone of the aquifer.

2. Tailings porewater migration within the aquifer does not transport zinc to downgradient areas in substantial concentrations that would allow zinc to be utilized as an indicator of the extent of porewater migration;

This is not unusual for groundwater migration from sulphidic materials due to chemical and physical mechanisms within the tailings and aquifer that can attenuate the mobility of zinc.

3. Based on observed concentrations of SO₄, porewater migration extends downgradient of the tailings deposit to the toe of the Cross Valley Dam and may have reached the furthest downgradient monitoring wells in the valley centre (locations X17 and X16); and

Additional investigation and sampling may be beneficial to more precisely determine the "background" level. The current conclusion is based on comparison to sampling upstream of the tailings impoundments.

4. A concentration gradient appears to exist across the width of the valley with greater concentrations of SO₄ observed along the north side. This gradient has been evident since around 1987 at location X18 (as compared to locations X16 and X17). Although the root cause is not clearly understood, the lateral gradient may extend upstream into the Intermediate

Impoundment where greater concentrations of SO_4 in tailings and in the shallow aquifer are observed on the north side of the valley (locations P01-06 and X21) than in the valley centre (location P01-05)

3.4.3 HYDROGEOLOGICAL MODEL

3.4.3.1 Approach

Tasks related to groundwater modelling A hydrogeological model for the Rose Creek Tailings facility was completed as part of the 2001 comprehensive hydrogeological investigation. The following four tasks related to groundwater modeling were completed:

- 1. Review of hydrogeologic data to be used in model development;
- 2. Development and calibration of the groundwater flow model;
- 3. Model analyses to demonstrate flow paths, travel times and contaminant loadings; and
- 4. Presentation.

3.4.3.2 Review of Hydrogeologic Data

Key factors determining flow paths, travel time and contaminant loadings Several key factors determine flow paths, travel times and contaminant loadings. These include local stratigraphy, the hydraulic properties of the water-bearing units on-site (i.e. the various types of tailings, native soils, and upper bedrock), rates of recharge, and rates of groundwater discharge to the lower reaches of Rose Creek. A great deal of data was available from historical investigations and from the 2001 field investigation and was compiled into a Microsoft Access and ViewLog geologic database system. The data was analyzed to refine the understanding of the stratigraphy within the Rose Creek valley and estimates of aquifer properties that were needed for development of the groundwater flow model were derived.

3.4.3.3 Development and Calibration

A conceptual model was formulated including an evaluation of the key factors affecting groundwater flow

MODFLOW was used to transform the conceptual model into a detailed numerical model A conceptual model was formulated as an interpretation of the hydrogeological setting of the study area that included an evaluation of the key factors affecting groundwater flow. Model geometry, boundaries, and initial values for aquifer properties were determined based on the review of existing data and analysis of new information.

The conceptual model was transformed into a detailed numerical model for the Rose Creek valley utilizing the U.S. Geological Survey MODFLOW code ("MODFLOW"). MODFLOW is a three-dimensional, finite-difference code capable of simulating transient and steady-state flow in multi-layered, confined and unconfined, aquifer systems. The computer code is recognized worldwide and has been extensively tested and verified. The code is ideally suited to simulate the highly variable tailings and overburden materials in the study area.

An MS-Access database contains information from wells and test holes

Information from wells and test holes related to stratigraphy, formation properties, and observed water levels and water quality data are contained in an MS-Access database base linked to ViewLog for graphical display and analysis. Model development is made easier through special geostatistical analysis functions used to interpolate hydrogeologic data to the model grids.

A finite-difference grid was designed to represent the study area. Model layers A finite difference grid were used to represent the various hydrogeologic units (i.e. tailings, sand and was designed to gravel, basal till, upper bedrock). Estimates for soil and tailing properties and represent the study recharge and discharge rates were used in the initial model runs. Model calibration was conducted by adjusting the initial estimates of aquifer properties and recharge rates until a close match with observed water levels and flow directions was achieved. Sensitivity analyses were conducted to verify the accuracy of the calibration. The particle tracking model, MODPATH, was used to illustrate flow paths and the location of recharge and discharge zones.

3.4.3.4 Analyses

area

The model was run for various test cases and scenarios with the intent of characterizing the existing subsurface flow regime in the Rose Creek valley. Various scenarios of source terms for particle tracking were analyzed and several selected for presentation that were considered to most clearly characterize the system

3.4.3.5 Presentation

Modelling input data and results are presented in Gartner Lee 2003d.

The raw stratigraphic information used to develop the conceptual model, the parameters used to develop and calibrate the model and the results of model runs that characterize the existing subsurface flow regime are presented in Gartner Lee 2003d. Model input data is presented in tabular format, contour maps or cross sections, as appropriate. Model results, including modeled potentials, drawdowns, and groundwater flow paths under existing hydrogeologic conditions are presented along with an analysis of model results. Stratigraphic sections and borehole logs were provided from the database and presented with geophysical and groundwater quality data as an aid in interpretation of those data.

ROCK DUMPS 3.5

3.5.1 1996 STUDIES – FARO SITE

The geochemistry and ARD potential of the Faro Rock Dumps (see Volume I for a discussion of the dumps and detailed locations) was evaluated as part of the development of the 1996 closure plan (RGC 1996). The evaluation consisted of both a static and kinetic testing program. A summary of the geochemical information, as repeated from RGC 1996, is provided below.

The 5 main rock units identified in the Faro Main pits

Conclusions of the

static and kinetic well testing program The five main rock units identified in the Faro Main Pits and, thereby, in the rock dumps were as follows:

Deloitte

& Touche

- 1. Non-Calcareous Schists (Unit 1): includes schist and altered schist from Faro, phyllite from Vangorda Plateau, and carbonaceous phyllite and schist;
- 2. Sulphides (Unit 2): includes massive and disseminated sulphides and also ribbon banded graphic quartzite from Faro;
- 3. Calc-Silicate (Unit 3): includes calc-silicate found primarily at Faro but elsewhere in the district and calcareous phyllite from Vangorda Plateau but also elsewhere in the district;
- 4. Intrusives (Unit 4): includes both intrusives from Faro and meta-intrusives which can be massive or foliated; and
- 5. Overburden (Unit 5).

Based upon the results of the static and kinetic cell testing programs the following was concluded:

- 1. The Unit 1 rock type (i.e., non-calcareous schists) could be initially classified as a potentially weak acid generator. However, based on the results of the static and kinetic testing programs it is unclear if this rock type will become significantly acidic in the future. Further kinetic cell testing is required to determine the long-term pH drainage characteristics of this rock type. The testing also indicated that long-term metal leaching, primarily zinc, would occur from this material;
- 2. The Unit 2 rock type (i.e., sulphide and pyritic quartzite) could be characterized as a relatively strong acid generator with significant levels of associated metal production. Production of acid and various metals from this rock type was considered likely to be rapid due to the high levels of contained sulphur and the lack of any significant levels of neutralizing capacity;
- 3. The Unit 3 rock type (i.e., calc-silicate) could be classified as a relatively strong acid consumer with the potential for the long-term release of low levels of soluble zinc; and
- 4. The Unit 4 rock type (i.e., intrusives) could be classified as generally inert. No significant levels of acid producing or acid consuming minerals were present in the intrusives. In addition, no significant levels of leachable metals were present in this rock type.

Strong acid generation is only anticipated from approximately 10% of the total waste rock in the Faro Rock dumps In summary, strong acid generation is only anticipated from approximately 10% to the total waste rock in the Faro Rock Dumps (i.e., sulphides). The potential for weak acid generation from the schists is a possibility and could potentially increase the acid drainage problem at the site if it were to occur. Metal leaching, primarily zinc, is anticipated to occur at various rates from greater than 90% of the waste rock in the Faro Area.

From an ARD point of view the intrusives appear to be the best material available for construction at the site due to their minimal acid generating and metal leaching characteristics.

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 3-16

3.5.2 1989 AND 1996 STUDIES - VANGORDA PLATEAU SITE

Two acid rock drainage assessment programs were conducted that characterized rock groups mined in the Grum and Vangorda Pits. The 1989 Initial Environmental Evaluation (IEE) report (Curragh 1989) that was prepared as part of the water licensing process included a geochemical characterization of sulphides and phyllites. The 1996 ICAP study (RGC 1996) included geochemical testing that was intended to complement the earlier work and fill in data gaps. The ICAP study included a summary presentation of the earlier test results that was used for this overview. Both studies included both static and kinetic testing.

The following are the primary observations provided in RGC 1996 regarding the available geochemical information:

Primary observations provided by RGC 1996 on available geochemical information.

- 1. Sulphides from both the Grum and Vangorda Rock Dumps are potentially acid generating and capable of releasing metals over a wide pH range including neutral pH;
- 2. Vangorda phyllites are slightly acid generating and capable of releasing metals over a wide pH range;
- 3. Test results for Vangorda Pit phyllites are not directly applicable to the Grum Rock Dump but a correction factor of 12.5% may be appropriate; and
- 4. Application of the suggested correction factor to Vangorda phyllite test results suggests that Grum phyllites might not be acid generating and might not release metals in significant quantities.

The Vangorda rock dump oxidized fines contain a relatively high acid production potential. The oxidized fines (Vangorda rock dump, see Volume I for discussion and location) is completely depleted of neutralization potential and contains a relatively high acid production potential, in a range similar to sulphides. The oxidized fines contain a ready store of soluble oxidation products and extraction testing confirmed that metals are readily leached from this material in high concentrations. Several metals were extracted from the oxidized fines in concentrations at least one order of magnitude higher than extracted from a sample of fresh (unoxidized) massive sulphide.

3.5.3 2002 STUDIES

A geochemical study of the Faro and Vangorda Plateau rock dumps was undertaken in 2002 to update the existing body of information and to assess how contaminant loadings from the dumps might change over time (SRK 2002). The 2002 work included:

- 1. data review;
- 2. two detailed surface seep sampling surveys (spring and fall);
- 3. surface mapping and test pitting on rock dumps;
- 4. drilling and sampling of boreholes with installation of downhole oxygen and temperature probes; and

Anvil Range Mine Complex (Interim Receiver) 2004 to 2008 Water Licence Renewal Environmental Assessment Report Volume II of III: Existing Environment Page 3-17

Gartner Lee

5. initiation of laboratory testing for acid rock drainage characterization (intended to be ongoing).

The following is the Executive Summary of the 2002 project report provided by SRK Consulting (pers. comm., S. Day):

"The Anvil Range Mining Complex, located in Faro, Yukon, ceased operations in January 1998 when Anvil Range Mining Corporation filed for creditor protection under the Companies' Creditor Arrangement Act. Deloitte & Touche Inc. was appointed Interim Receiver of Anvil Range Mining Corporation ("Interim Receiver") on April 21, 1998. The Interim Receiver has overseen the management of the property The Interim Receiver has overseen the management of the property under the terms of two water licenses since that time. SRK Consulting is evaluating various aspects of the site as part of closure planning for the complex. This report describes progress on the investigation of the geochemical stability of waste rock.

Mining in both areas of the complex (Faro Site and Vangorda Plateau) was dominantly by open pit. Both areas involved significant pre-stripping of overburden and rock, and ongoing waste rock stripping as mining proceeded. At both sites, several hundred million tonnes of waste rock were produced and placed in nearly 40 dumps, fill areas and stockpiles.

Waste rock in both areas comprises rock types with geochemical characteristics that range from already acid generating to potentially acid generating and acid consuming. Monitoring data indicates generally that seepage is non-acidic, with some exceptions, but often contains elevated concentrations of zinc and cadmium. The long-term trend in seepage chemistry is an important consideration for remedial planning. The objectives of this project are therefore to evaluate the current sources of contaminant loadings from the site and evaluate how these sources might change in the long term.

This report reviews the existing information (Phase 1) and the programs implemented in 2002 to collect additional information and samples for testing (Phase 2). The testing program (Phase 3) is currently underway.

A bibliography of more than 250 reports was compiled based on existing document lists at SRK Consulting, Deloitte & Touche Inc., Access Consulting Group (ACG) in Whitehorse, the Yukon Water Board and Indian and Northern Affairs Canada. These reports were ranked according to title and four individuals at SRK and ACG reviewed the 140 top-ranked documents. Review comments were compiled using a standard template. The documents were reviewed to evaluate the adequacy of the existing geochemical database, operational procedures for managing waste rock, the inventory of rock in the waste rock dump and the loading of acidity from various sources. The main conclusions of the review were: (1) the extensive water quality database is not easily accessed due to the version of software used to manage the data; (2) the rock geochemical database is useful but more testing will be needed to link the data to field

conditions; (3) no documents describing operational procedures are in the public domain; and (4) a detailed inventory of rock types for the Faro waste rock dumps has been completed, but the degree to which different rock types were mixed is not well known.

Field work completed in 2002 included two seepage surveys (June and September), surface waste rock mapping of several waste rock dumps in both mining areas, excavation of 100 test pits and trenches (including five along the Vangorda Plateau Haul Road), drilling and instrumentation of seven holes in waste rock and collection of bulk water samples from the pit lakes.

The seepage surveys showed that a wide range of water chemistry exists in the Faro area with water chemistry broadly correlated to surface waste rock type. Seepage chemistry at the Grum and Vangorda waste rock dumps showed that zinc and sulphate concentrations are probably increasing.

Surface mapping identified sulphide-rich waste rock placed outside areas designated for this type of rock. Field leach tests showed that any rock mixture can be acidic. Sulphide pockets in the Faro waste rock may be present at scales up to 10 of metres. During mapping, three warm air vents were found in the Faro site waste rock.

Test pits and trenches documented the degree of local mixing of waste rock and evaluated the current weathering condition in near-surface materials. Only a few test pits in the Faro area encountered pockets of sulphide rock that were not apparent on surface. In the Grum area, sulphide rock was found in several test pits outside the designated sulphide area and in the uppermost lift of the waste rock dump and few samples had low pH. At Vangorda Pit, test pits indicated that several materials had low pH. A few test pits along the Vangorda Plateau Haul Road identified sulphide rock mixed in with the non-acid generating rock fill. This indicated that rock used for road construction may be a source of acidity and metal leaching.

Sulphide waste rock was confirmed at the location of sulphide rock cells in the Intermediate Dump (Faro) and Grum Dump by drilling. In addition, sulphide waste rock was also encountered in the Intermediate Dump outside the area designed for sulphide waste rock.

The laboratory testing program is based on the information gaps identified by the review and the needs for eventual revision of the site wide water quality predictions and assessment of remedial measures. It is likely that the static testing will be completed by early to mid-January. Kinetic testing, which will follow the static testing, will continue well into 2003."
