SECTION 1

Introduction

This vegetation and soils (terrestrial and wetlands) report provides baseline conditions and trends at the Faro Mine Complex (FMC), to provide data to assess the potential effects of the Interim Works (IW).

This report consists of three main sections. Section 2, Methods, defines the overall study area of the baseline analysis, describes the vegetation (including re-vegetation trials) and soils data analysis methods. Sections 3 and 4 describe the results of the baseline characterizations for soil and vegetation, respectively. Baseline information on terrestrial and wetland vegetation and soils includes Project Local Study Area (LSA) and Regional Study Area (RSA) mapping, and details of rare plants and landscape-level analysis of vegetation and soil distribution (as required for the effects assessment linkages). Characterizing the terrestrial and wetlands vegetation and soils in the Project LSA includes describing the vegetation associations and species, and providing the results of a terrestrial effects study.

SECTION 2

Method

2.1 Study Areas

2.1.1 Local Study Area

The LSA is designed to represent the diversity of vegetation and soils in the immediate IW area. It comprises the area in which there is reasonable potential for effects (direct and indirect) on vegetation and soils from IW activities. Gartner Lee Limited (GLL) (2008) developed a vegetation map at a scale of 1: 20,000 using aerial photography and field data; this has been used as the local study area basis by subsequent studies such as Environmental Dynamics Incorporated (EDI) (2008) and AECOM Canada Ltd. (AECOM) (2009).

The LSA includes the area within a 1-kilometre (km)-wide buffer around FMC facilities, infrastructure, and road corridors, and covers an area of approximately 8,122.8 hectares (ha) (Figure 6I-1). The baseline FMC footprint includes the total current disturbance area of the Faro Mine Area, Vangorda/Grum Mine Area, and associated infrastructure including pits, the Rose Creek Tailings Area, quarries, ponds, and roads. The area of the baseline FMC footprint is 1,612.7 ha (Figure 6I-1).

2.1.2 Regional Study Area

The RSA was defined in order to assess effects at a broader geographical scale and to gain a better regional understanding of vegetation and soils (Figure 6I-2). The RSA includes the area where contaminants have been recorded at greater than background levels (GLL, 2006a), and is 58,803 ha in area. The Pelly River forms the western boundary of the RSA. The northern, eastern, and southern boundaries were delineated using mapped concentrations of contaminants characterizing the extent of mine impact in the area (GLL, 2006a) and geographical features, such as watershed boundaries.

2.2 Sources of Data and Information

The following data and information sources were used to evaluate vegetation and soil baseline conditions:

- Information provided in previous environmental reports and terrestrial effects studies for the LSA.
- Engineering reports for which some soil information was collected.
- Historical vegetation field monitoring results completed by various consulting firms, presented in appendices to environmental reports and in an ecological land classification delineation.
- Regional geology studies in the Anvil Mountain Range, and topography for the post-mining surface provided by 10-metre (m) contour Light Detection and Ranging data and historical orthophotographs.
- Information provided by revegetation activities on the reclaimed water reservoir (Laberge Environmental Services [Laberge], 2007), and current revegetation studies carried out as trials on the Grum Overburden Dump (EDI, 2010, 2013a) and Grum Sulphide Cell (GSC) (EDI, 2013b).
- Canadian federal (*Species at Risk Act* [SARA]) (Environment Canada, 2013) and territorial (Species at Risk) (Government of Yukon [YG], 2013a) lists of rare and endangered plant species and weed species, and national databases (NatureServe, 2013) for plant occurrence in the Yukon (YT).

This baseline study for the IW summarizes the available information gathered to date for vegetation and soil conditions at the LSA and RSA. This information provides a suitable basis for understanding conditions for the IW, from which the effects assessment may be completed.

2.3 Data Analysis and Compilation

The characterization of baseline conditions included a combination of tools and methods. Mainly, this effort consisted of a detailed data compilation and literature review. Descriptions of vegetation and soils from previous reports were reviewed and incorporated into this analysis.

Ecological land classification mapping from previous vegetation surveys (GLL, 2008) was checked against field records and other available vegetation survey results. The classifications are presented according to the GLL (2008) analysis.

Vegetation survey results for species presence/absence were compared with community association for all vegetation and rare plant surveys completed to date. Attachment 6I-1 presents the analysis table. Current SARA status (Environment Canada, 2013) and listing (YG, 2013a) was updated and is also presented in Attachment 6I-1.

Information regarding soils characterization has been collated from previous environmental and engineering studies. The information was used to provide an overview of likely soil conditions for IW activities.

SECTION 3

Soils Baseline Results

The diversity and distribution of soils in natural ecosystems play an important role in ecosystem function. Information about soils within the LSA and the RSA has been collected to determine vegetation patterns on the land and terrain types, and to consider wind and water erosion risks. The objective of the IW soil baseline is to identify the current known soil condition of the FMC and surrounding region.

3.1 Regional Studies

3.1.1 Geography

Upland soils in the study area are part of the Yukon Plateau. Lower lying, alluvial soils are found along the Ross River area. Soils in these two landscapes are described in this section.

3.1.2 Soils of the Yukon Plateau

The physical and chemical processes associated with the regional geography strongly influence soil deposition and formation across the region. The YT is part of the larger Canadian cordilleran region and is characterized by mountainous terrain and the presence of glaciers and icefields in some areas (YG, 2013b). The Faro Ross River Area is included in the Yukon Plateau ecoregion in which, according to Ecoregions of the Yukon, Part 2 (Smith et al., 2004), the majority of soils are classified as Eutric Brunisolic soils. These soils are generally characterized as having a high degree of base saturation and are usually well- to partially well-drained. They typically exhibit partial horizon development. Another major soil classification category found in the region is Turbic Cryosolic, if the soils have active layers greater than 50 centimetres (cm) and show signs of freezing and thawing. Occasional pockets of dystric brunisols occur on coarse-textured morainal and fluvioglacial materials.

The ecoregion is subject to scattered permafrost (Scudder, 1997) and soils often show evidence of mildfrost churning. On the unglaciated portion of the ecoregion, surfaces tend to be composed of long, gentle slopes at less than 10 percent grade, with uniform tussock tundra and shrub tundra vegetation cover. These soils are for the most part Orthic Turbic Cryosols with active layers less than 50 cm. The large active fans provide fresh alluvial materials to the landscapes. Older terraces have permafrost established within them, yet there has been little soil formation and weathering. These soils are Regosolic Static Cryosols.

Geochemically, YT soils are generally deficient in nitrogen and phosphorus. Levels of potassium and sulphur often depend on local geology rather than regional processes. Since 1984, more than half of the soils tested by the Yukon Agriculture Branch have been deficient in potassium (Yukon Ecoregion Working Group, 2004). The most common micro-nutrient deficiencies are boron and magnesium. Soils throughout YT are low in organic matter, and salinity has been identified as a problem in some localized areas.

Results from a Bond and Sanborn study (2006) on upland soils in unglaciated areas in west central YT showed that, from an exploration geochemistry perspective, soil development has had minimal impact on the distribution of elements in older soils because of wasting along the slopes due to gravity. Elemental distribution patterns in these upland soils were the result of (1) bedrock lithologies within the colluvium, (2) slope aspect variability, and (3) the occurrence of loess in the soil as a geochemical dilutant.

3.1.3 Soils of the Faro-Ross River Area

In general, the soils of the Faro- Ross River area are coarse-textured if fluvial in origin and medium- to coarse-textured if deposited in a morainal environment. There are approximately 60,000 ha of fluvial soils with the Magundy River and Ross River soils in the lower valleys and the Glenlyon, Lapie River, and Van Gorder soils on the upland regions (Rostad et al., 1977). There are also about 51,000 ha of morainal soils, consisting of the Fisheye Lake and Hoole River Associations. All soils are neutral to slightly alkaline below the surface (Rostad et al., 1977).

3.2 Previous Studies

The characterization of soil baseline conditions has been compiled and described based on studies completed in the FMC and the RSA. The results for the FMC have been completed on areas that were either disturbed when the study took place, or if undisturbed, were identified as potential future disturbance areas.

Table 6I-1 summarizes studies that provide information about surficial soil conditions. Figure 6I-3 shows the sampling locations from the studies focusing on soils in the LSA.

TABLE 6I-1

SRK Consulting Engineers and Scientists. 2007.	Well PW3 in Zone II Outwash Area	The PW3 well is representative of the hydrostratigraphy in the Zone II Outwash Area. The general soil profile near PW3 consists of the following: • 0-2.5 m gravelly sand with trace silt • 2.5 – 3.5 m silty sand and sandy silt with organics (lowest conductivity) • 3.5 – 6.7 m sand and gravel with cobbles (highest conductivity)
Environmental Dynamics Inc. 2008.	Faro Valley Waste Dump/Till Deposits	Faro Valley Waste Dump toe has small areas of intact (biologically active) surface soils Faro Valley Waste Dump was free-dumped till materials with coarse texture and high fragment content
	Vangorda Overburden Dump	Vangorda Overburden Dump material was heterogeneous with elevated levels of lead and zinc.
	Grum Overburden Dump	Grum Overburden Dump: glacial till with sampled textures ranging from sandy loams to loams with coarse fragment contents of approximately 15 to 75%.
	Vangorda and Grum Waste Dumps	Both WRDs were freely dumped till materials with coarse texture and high-fragment content
	Rose Creek West Pit Area	West Pit Locations ranged from coarse sands and gravels to finer-textured materials, predominantly sand or silt
	Rose Creek Haul Road	Haul Road textures were loamy sands to loams with approximately 30 to 60% coarse fragments (> 2 mm)
	Tailings Borrow Areas	Tailings Borrow ranged from sandy loams to silt loams with coarse fragment contents of approximately 5 to 55%
	Haul Road Borrow Area	Textures were sandy loams to loams with 40-60% coarse fragments

TABLE 6I-1
Soil Sampling Location and Data Summary at Faro Mine Complex
Vegetation and Soils Baseline – Faro Mine Interim Works

Source	Mine Area	Data Summary
SRK Consulting Engineers and Scientists. 2008a.	Vangorda Waste Dump	Subsurface geology is comprised of silt and clay till. The till unit generally extends to bedrock. In borehole 2001-1, the clay till unit was observed to extend to the depth of the borehole (38.1 m below grade). Clay content increased at depths ranging from 7.6 to 9.1 m, although there was no quantification of the content. Two additional borehole descriptions at the Vangorda Waste Dump in the report describe clay till extending from the surface through the full extent of the borehole. Data collection issues and design make it difficult to draw conclusions on soil property differences between treatments.

GLL (2006a) completed a terrestrial effects study that examined 168 samples (by depth and parent material) for 29 elements, to evaluate whether elevated elemental levels attributed to mine-generated airborne deposition could be due instead or in part to the influence of underlying mineralized soil materials. Out of the 29 elements evaluated, the study found patterns of elevated lead and zinc concentrations in surface organic soil similar to patterns found in in lichen (see Section 4.2.2.2), but no similar pattern of elemental concentrations existed in subsurface organic or mineral soils. Furthermore, no correlation was found to exist between underlying materials and surface-based observations.

This suggests that the spatial pattern of elevated elemental levels observed in the study area are the result of deposition from the FMC (called the Anvil Range Mine Complex in GLL [2006a]) and eliminates the possibility that these levels can be attributed to natural effects present prior to mining. Lead, zinc, and copper concentrations were elevated when compared to a reference site. Lead and zinc were weakly complexed within the soil and have the greatest potential for mobility within the soil profile. Additionally, cadmium was determined to be weakly complexed within the soil profile, therefore increasing its availability for vascular plant uptake.

Summary of Baseline Soil Conditions

In conclusion, evidence from previous studies regarding the baseline soils conditions in the FMC and in studies conducted within the LSA and RSA suggest that there are variable surficial conditions. Characterization of geochemical patterns conducted across the site by GLL (2006a) indicate that the zone of highest elemental levels is centered on the Rose Creek Tailings Area and FMC mill. This zone extends primarily northwest down the Rose

Creek Valley, and northeast up the North Fork of Rose Creek Valley in the surface organic soils. As demonstrated by the studies included in Table 6I-1, soil physical characteristics for areas within the LSA have been characterized on a case by case basis. Areas not impacted directly by mining activities are expected to conform to regional patterns of physical soil development determined predominantly by depositional environment, position on the landscape, and climate, as noted in Section 3.1.

SECTION 4

Vegetation Baseline Results

The diversity, distribution, and health of vegetation in natural ecosystems play an important role in ecosystem function. Vegetation patterns on the land are influenced by climate, terrain, substrate, water availability, and nutrient regime. Characteristic groupings of species develop in response to these conditions. Different vegetation associations provide a variety of habitats used by wildlife. Wildlife and people can influence vegetation abundance and diversity. Industrial development, in particular, has the potential to affect vegetation ecosystem health.

The objective of the IW vegetation baseline is to identify the known vegetation condition at the FMC and in the surrounding region.

4.1 Regional Studies

The FMC is located within the Yukon Plateau-North Ecoregion, in the Boreal Cordillera Ecozone of the YT (Yukon Ecoregion Group, 2004). The vegetation of the Yukon Plateau–North Ecoregion ranges from boreal to alpine. The northern boreal forest exists at elevations of up to 1,500 m. Vegetation at higher elevation in the sub-alpine zone is characterized by shrub and lichen tundra; and the alpine by low ericaceous shrubs, prostrate willows, and lichens. Talus slopes are common at high elevations, and support communities of crustose lichens. The thickness of the vegetation and humus layer are controlled by forest fire history (Smith et al., 2004).

In the boreal zone, open black spruce (*Picea mariana*) stands with a moist moss, or drier lichen understory is the dominant forest type. Black spruce dominates the moister sites and cooler north-facing slopes, while often mixed with subalpine fir (Yukon Ecoregion Group, 2004). White spruce (*Picea glauca*), occasionally with trembling aspen (*Populus tremuloides*) or lodgepole pine (*Pinus contorta*), grows on warmer, better drained soils. The mixed canopy forests are common because of frequent fires, and trembling aspen and balsam poplar (*Populus balsamifera*) are commonly found on disturbed sites (Smith et al., 2004). Feathermoss dominates the understory vegetation of nearly closed coniferous stands, but as trees become less dense, willows and ericaceous shrubs become prevalent. (Smith et al., 2004).

The 450-km-long Tintina Trench forms a defining landscape feature, traversing the ecoregion from the northwest to the southeast. The trench is an important migration corridor for large numbers of Sandhill Crane and waterfowl breeding in Alaska (Smith et al., 2004). The Pelly, Ross, Macmillan, Stewart, Hess, McQuesten, and Klondike River valleys all traverse the ecoregion. The region consists of relatively rolling highlands with an east-west orientation. Permafrost is discontinuous but widespread in this region, although less extensive near the town of Faro (Smith et al., 2004).

The ecoregion supports populations of most of the YT's typical boreal forest mammals, such as the following:

- Moose
- Woodland caribou
- Stone sheep
- Grizzly bear
- Black bear
- Wolverine
- Marten

Many forest birds reach their northern limit of breeding in the ecoregion (Smith et al., 2004).

CH2M HILL Canada Limited (CH2M HILL) completed a literature review of vegetation information specific to the Faro Mine region. Regional information about vegetation was taken from the Montreal Engineering Company Ltd in 1975 (cited in Robertson GeoConsultants Ltd. [RGC], 1996) study that included an initial inventory of vegetation in the area. In 1998, vegetation classification for Sheep Mountain, as well as a broader-scale classification of vegetation communities in the Carmacks-Ross River area, provide some general vegetation information for the

region (Oswald et al., 1983; Staniforth, 1998) that was used as the basis for Yukon Ecoregions Working Group (Smith et al., 2004).

4.2 Previous Studies

4.2.1 Plant surveys

Four vegetation surveys have been completed on and around the FMC (RGC, 1996; GLL, 2008; EDI, 2008; AECOM, 2009). An initial survey prior to later vegetation survey work was completed by Montreal Engineering in 1975 (cited in RGC, 1996). RGC (1996) described and mapped six broad vegetation zones within the FMC and surrounding region: (1) flood plain forest, (2) upland forest, (3) bog forest, (4) alpine tundra, (5) subalpine transition, and (6) alluvial plain shrub. GLL's (2008) vegetation baseline was completed on the LSA and included a slightly different region than RGC (1996); however, many of the vegetation associations from GLL (2008) may be linked to some of RGC's overall vegetation groups.

Two vegetation plot surveys were completed in 2007 (GLL, 2008; EDI, 2008), and a rare plant survey was completed in 2008 (AECOM, 2009). GLL's vegetation baseline study, completed throughout the summer of 2007, was designed to build a vegetation association map of the LSA (GLL, 2008). The EDI (2008) plant survey between July 20 and 24, 2007, described different vegetation groups that could be found within and around the LSA (EDI, 2008). The 2008 rare plant survey was completed to determine whether there were rare plants in the LSA (AECOM, 2008).

4.2.1.1 Vegetation Associations and Groups

GLL's 2007 vegetation survey included 17 ground plots and 59 visual inspections within the LSA (GLL 2008).Thirteen vegetation associations were found within the LSA (GLL, 2008) (Table 6I-2 and Figure 6I-4). The most prominent vegetation association found during GLL's (2008) vegetation baseline was the closed white spruce/willow forest, which covered 45 percent (3,657 ha) of the LSA. The second most prominent vegetation association was the mixed coniferous-deciduous forest covering 8.4 percent (682 ha) of the LSA (GLL, 2008). The white spruce/willow forest is located in both the boreal and the subalpine zones, on various upland and lowland slopes. White spruce dominates the tree canopy, with the occasional presence of subalpine fir. A well-developed shrub layer is dominated by a high cover percentage of 1-m-tall willow species, with a lower cover percentage of dwarf birch, Labrador tea, and shrubby cinquefoil. The dwarf shrubs in the ground cover layer include bog billberry, common bearberry, net-veined willow, and crowberry. Common horsetail and bluegrass species were also found frequently in this area. The following mosses and lichens are common throughout this vegetation association:

- Stair-step moss (*Hylocomium splendens*)
- Reindeer lichens (*Cladina rangifera*)
- Pelt lichens (*Peltigera* spp.)

[a] Adapted from GLL (2008)

Figure 6I-4 shows a map of the thirteen vegetation associations within the LSA.

Vegetation associations from GLL (2008) indicated that the northern boreal zone includes forested and wetland associations in the low-elevation valley bottoms and low-lying terrain. The northern boreal zone contains a number of associations, linked to morainal and glacio-fluvial terrain that are influenced by fire. The areas of the Project LSA in the subalpine zone are dominated by tall shrub vegetation. Scattered, open spruce and fir forests occur at the lower limits, and grade into lower stature shrub, herb, and lichen communities at upper elevations. Attachment 6I-2 describes all thirteen vegetation associations for the LSA from the GLL (2008) vegetation survey.

A concurrent study by EDI took place July 20 to 24, 2007. The survey included 70 plots established on and adjacent to the FMC (Figure 6I-5).

Vegetation was arranged into five groups (EDI, 2008), presented in Table 6I-3. Vegetation groups ranged from disturbed forests, where fire removed the mature spruce trees, to older, undisturbed forests.

TABLE 6I-3
Vegetation Types in the Faro Mine Complex
Vegetation and Soils Baseline – Faro Mine Interim Works

Vegetation Group	Species Present	Habitat characteristics
Pleurozium	*Pleurozium shreberi* *Abies lasiocarpa* *Peltigera sp.* *Cladina mitis*	Older undisturbed forest
Mertensia	*Mertensia panicluata* *Potentilla fruticosa* *Salix myrtillifolia* *Salix reticulata*	Rich forests in a transitional state
Ledum	*Ledum groenlandicum* *Empetrum nigrum* *Vaccinium vitis-idaea* *Vaccinium uliginosum* *Arctostaphylos rubra* *Betula glandulosa*	Link between the undisturbed forests and the lightly disturbed sites around the FMC

TABLE 6I-3
Vegetation Types in the Faro Mine Complex
Vegetation and Soils Baseline – Faro Mine Interim Works

Vegetation Group	Species Present	Habitat characteristics
Populus	*Populus balsamifera* *Salix arbusculoides* *Salix bebbiana* *Agrostis scabra* *Salix planifolia*	Characteristic species of disturbed mineral soils
Shepherdia	*Shepherdia canadensis* *Linnaea borealis* *Pinus contorta* *Geocaulon lividum* *Calamagrostis inexpansa*	Dry forest stands, often where past forest fires have removed the mature spruce. Dry forests with open grassy areas.

Notes:
Modified from EDI (2008), *Re-vegetation Study: Waste Rock Dumps and Tailings Impoundment*. Data was collected July 20 to 24, 2007.

4.2.1.2 Rare or Threatened Plant Species

Douglas et al. (1981) defined rare plants as "*one that has a small population within the area, may be restricted to a small geographical area where it may be locally common, or may occur in low numbers over a wide area. A threatened plant is one that is likely to become endangered within the forseeable future over all or a significant portion of its range, and an endangered plant is one that is in danger of extirpation throughout all or a significant portion of its range in a province, territory or state.*"

Species at Risk are plant species that are considered extirpated, endangered, threatened, or of special concern by the federal Committee on the Status of Endangered Wildlife in Canada (COSEWIC). The SARA regulates Species at Risk and legislates activities within their critical habitat. SARA does not officially protect species that are listed by COSEWIC but are classified as "no status" under SARA.

The Species at Risk in YT are listed based on their COSEWIC standing (YG, 2013a). Under the COSEWIC ranking, there are currently three plant species that are considered species at risk and one plant species that is under review in Yukon (Table 6I-4).

TABLE 6I-4
Plant Species at Risk in Yukon
Vegetation and Soils Baseline – Faro Mine Interim Works

Species	Common Name	COSEWIC[a] (date listed)	SARA [b]	NatureServe [c] Ranking Status in YT
Draba yukonensis	Yukon draba	Endangered (November 2011)	No Status	S1 [d]
Micranthes spicata	spiked saxifrage	Threatened (May 2013)	No Status	S2 [e]
Carex sabulosa	Baikal sedge	Threatened (May 2005)	Threatened	S2 [e]
Podistera yukonensis	Yukon podistera	Under review for November 2014	Not Listed	S2 [e]

[a] COSEWIC (2013)

[b] Environment Canada (2013)

[c] NatureServe (2013)

[d] S1 ranking means the species is critically imperiled, ranking ranges from S1 (critically imperiled) to S5 (secure).

[e] S2 ranking means the species is imperiled, ranking ranges from S1 to S5 (secure).

GLL did not find rare plant species during a rare plant survey conducted between August 7 and 12, 2008 (AECOM, 2008). There was one potential rare plant within the Grum survey area. Field identification indicated the presence of *Botrychium spathulatum,* which has the ranking of S1S2 (uncertainty of ranking between critically imperiled and imperiled) in YT (NatureServe, 2009); however, Bruce Bennett (former NatureServe Yukon botanist, currently with Government of YT) examined the plant species (Bruce Bennett, Personal Communication, 2008) and re-identified it as *B. minganense* (ranking S3S4; uncertainty of ranking between vulnerable and apparently secure). These species are commonly confused, and *B. minganense* is not a rare species.

The 2008 GLL rare plant survey focused on areas that are to be disturbed as part of waste rock re-sloping that will be part of the overall Faro Mine Remediation Project. GLL investigated four survey areas along the edge of the waste rock slopes, three in the Faro Mine Area, and one in the Grum area. The rare plant survey used a maximum transect distance of 200 m beyond the base of the waste rock (Figures 6I-6 and 6I-7).

CH2M HILL assessed all plant species identified in GLL (2008), EDI (2008), and AECOM (2009) vegetation surveys for status and ranking on Environment Canada (2013) and COSEWIC (2013) lists (Table 6I-1-1 in Attachment 6I-1). None of the plant species from the three vegetation surveys were listed on either of these databases (Table 6I-1-4 in Attachment 6I-1). Attachment 6I-1 (Table 6I-1-4) lists the NatureServe (2013) ranking for the surveyed plant species. Based on Nature Serve (2009) status rank for Yukon, the species of conservation concern which are ranked S1 and S2 (critically imperiled and imperiled, respectively) in the previous vegetation surveys include *Alnus crispa* ssp*. sinuate, Carex aeneta, Carex phaeocephala, Cassiope mertensiana,* and *Helictotrichon hookeri.*

All surveyed areas by GLL (AECOM, 2008) experienced some human disturbance in the form of dirt roads, old trails, scraped-up areas and piled-up earth, and large boulders at the bases of the waste rock slopes. Native shrubs, grasses, sedges, and forbs in various combination form the dominant vegetation along the sides of the roads and trails, and on the dirt piles. Young white spruce, willows, and other shrubs typically grow between the boulders at the slope bases, where the boulders have fallen into the existing vegetation.

Little-to-no soil accumulated between the boulders on the waste rock slopes themselves, and vegetation was sparse. A few willow shrubs, white spruce seedlings, and occasionally forbs (such as fireweed, and hawksbeard) grew on the slopes, but lichens and mosses were uniformly absent on and between the boulders. In a few areas, where slopes were composed of finer materials, sparse grasses also grew. Seepages and silt flows at the bases of the slopes were common, forming wet muddy patches and sometimes forming small brooks. Moisture-loving graminoids, forbs, mosses, and shrubs colonize these sites. Patches of orange-coloured deposits were seen in one of these seepage sites, mostly lacking vegetation in the exposed deposits and surrounded by dense tall Willow shrubs (AECOM, 2008).

Before GLL began its field work, Bruce Bennett provided a list of Yukon rare plants, their rare status rankings, and their expected habitats (Bruce Bennett, Personal Communication, 2007). Maps and descriptions of vegetation types in the Faro Mine Area were consulted to determine the likelihood of finding rare vascular species in the survey areas. The described vegetation types are typical of much of central YT, and do not generally host rare species. Throughout the survey, habitats and vegetation types were examined for the presence of rare species.

4.2.1.3 Introduced Plant Species

The GLL and EDI vegetation surveys identified introduced plant species in the FMC area (GLL, 2008; EDI, 2008); Attachment 6I-1 identifies these species. Further introduced plant species may be growing in mine disturbance areas and in revegetation areas.

4.2.1.4 Summary of Vegetation Surveys

CH2M HILL assembled an overall species list for the two 2007 studies (GLL, 2008; EDI, 2008) and the 2008 rare plant survey (AECOM, 2008) for comparison (Attachment 6I-1). This list excluded the following plots that were outside the LSA: VP29, VP 54, VP 55, VP 56, VP57, VP58, VP59, VP60, VP62, VP63, VP64, VP65, VP66, VP67, VP68, VP69, and VP70 from the July 20 to 24, 2007, EDI study (2008).

4.2.2 Terrestrial Contaminants

Past operations at the FMC have resulted in metals concentrations in the area that are greater than the reference/background levels. Initial studies in 2002 (C.E. Jones & Associates Ltd., 2003) indicated elemental deposition in the study area was the result of mining operations; however, no information was provided about its timing. A Terrestrial Effects Study (GLL, 2006a) took place in 2004 and 2005 to determine if deposition was ongoing. This study component was designed to determine whether measured elemental concentrations were at their maxima or would continue to increase. The report concluded that concentrations of metals that originated from the FMC are generally higher near the mine and decline with distance from the mine. Furthermore, deposition of some metals from the FMC is still occurring in the immediate area, mostly during the snow-free period. A summary of the findings from GLL (2006a) are in the following subsections.

4.2.2.1 Terrestrial Contaminants – Sampling

There is no pre-mining baseline information about contaminant levels in soils and vegetation collected from Anvil Range; therefore, information from Swim Lake, approximately 9 km southeast of the Vangorda Pit, was used for reference information for metal concentrations in soils and vegetation. Swim Lake was chosen as a reference location because it was far enough from the Anvil Range Mine Complex to be free of mine-generated airborne deposition but within the same deposit type (C.E. Jones & Associates Ltd., 2003).

To isolate the effects of airborne deposition from mineralization, GLL (2006a) determined the spatial distribution of elevated elemental concentrations, primarily by sampling lichens. GLL (2006a) selected lichens (*Cladina* spp.) as the indicator species because they are long-living, non-deciduous, and depend entirely on airborne material and precipitation for nutrients (and are therefore unaffected by the mineralization of underlying soils). Soils also accumulate metals and provide an additional record of cumulative airborne deposition; however, metal concentrations can also result from natural mineralization and larger landscape processes, such as erosion and glacial transport. GLL (2006a) sampled soil to confirm the results of lichen sampling, and detect naturally elevated elemental concentrations (that is, those unrelated to the mine).

Concurrent to the lichen study, a moss bag study was conducted (GLL, 2006a). Moss was rinsed, dried, analyzed for pre-exposure concentrations and placed into polypropylene mesh bags. An increase in elemental concentrations to above pre-exposure levels would indicate ongoing airborne deposition (GLL, 2006a).

Figure 6I-8 shows the sampling locations for 2002, 2004, and 2005.

4.2.2.2 Elemental Concentrations in Vegetation

Select plant species were collected by GLL (2006a) in the study area to determine the uptake of various elements in vegetation used by wildlife (e.g., forage species) or humans (e.g., medicinal use or ingestion). Elemental concentrations in vascular vegetation can be influenced by elemental uptake via root systems, and by airborne elemental deposition through deposits on plant surfaces or surface soils. It was necessary to distinguish between these sources and establish the difference between mining-related and natural sources. To do so, soils were collected, subsampled, and analyzed where plants important to wildlife or humans were collected.

Potential mechanisms to disperse elements in the FMC study area include windblown dusts and a historical tailings spill into Rose and Anvil Creeks, which drain portions of the FMC. Lead (Pb) is the least mobile of the heavy metals (as opposed to zinc, which can be highly mobile in both soils and plants); therefore, it likely represents the best historical record of elevated elemental levels resulting from FMC operations. GLL (2006a) used Pb in lichen tissue as the principal indicator of how elemental levels at the FMC were spatially distributed. High lichen Pb levels in the integrated 2002 / 2004 / 2005 data set are evidence of significant mine-generated accumulations. Lead in floodplain soils is probably largely the result of the 1975 tailings dam breach, while accumulations in other areas are likely the result of airborne transport.

Pb isotope tracing was used to determine the origin of lead in samples of dust, soils, and moss bags from the study area. Because it is possible for lead from naturally occurring and outside sources to affect the study area, local “background” levels had to be distinguishable from those resulting from the FMC. The lead isotope analysis for moss bag sampling (GLL, 2006a) indicated that the mine ores were the source of almost 100 percent of the lead that is currently found in the study area.

The information collected by GLL (2006a) showed that lead concentrations in lichen near the mine were up to 450 times those at Swim Lake. The concentrations of lead are generally higher near the mine, and decline with distance from the mine (Figure 6I-9).

As Figure 6I-9 shows, the zone of elevated lead concentrations in lichen extended as follows:

- Southeast to the Blind Creek Valley / Swim Lake basin (1 to 10 km from the Vangorda/Grum Area)
- Southwest to the Pelly River Valley (5 to 10 km from the FMC)
- At least 20 to 25 km from the FMC up the North Fork Rose Creek drainage
- At least 40 to 50 km from the FMC down the Rose / Anvil / Pelly drainages

The elevated concentrations of elements from the FMC down the Rose / Anvil / Pelly drainages may have been contributed from the 1975 tailings dam breach. Although the area sampled for lichens was expanded in 2004 and again in 2005, it did not necessarily determine how far the maximum spatial extent of elevated lichen-lead concentrations extended from the FMC (GLL, 2006a).

4.2.2.3 Summary of Results for Elemental Levels in Lichen

The following paragraphs summarize elemental levels found compared with Swim Lake levels (reference area) (GLL 2006a; AECOM 2009).

High Elevation Relative to Reference Levels – Lead and Arsenic

Maximum lichen lead (747.7 ppm) and arsenic (23.7 ppm) concentrations in areas affected by the mine were 450 and 250 times the Swim Lake maximum, respectively (GLL, 2006a). Equivalent-to-reference levels were found southwest of the FMC, across the Rose Mountain range, and around the southeast to north perimeters of the study area. To the northeast and northwest, however, equivalent-to-reference concentrations are at least 20 to 25 km and 40 to 50 km, respectively, from the FMC. Approximately 76,900 ha of land showed lichen-lead concentrations that were at least 3 times the observed Swim Lake maximum.

Moderate Elevation Relative to Reference Levels – Zinc, Copper, Iron, Silver, and Thallium

In mine-affected areas, the maximum lichen concentrations of zinc, copper, iron, silver, and thallium were 15 to 75 times higher than Swim Lake maxima. Equivalent-to-reference concentrations were generally reached at distances of 0 to 2 km from the Vangorda/Grum Area, northeast along the exposed (mine-side) slopes of Mount Mye, and southwest along the exposed slopes of Rose Mountain. Elevated elemental levels generally extend northeast along North Fork Rose Creek, north up and past Mount Aho, and northwest down the Rose Creek Valley.

Low Elevation Relative to Reference Levels – Barium, Chromium, Mercury, Nickel, and Selenium

In mine-affected areas, maximum lichen concentrations of barium, chromium, mercury, and nickel in mine-affected areas were three to nine times the Swim Lakes maxima. Zones of elevated elemental levels are generally smaller than those for lead and other elements in the High and Moderate categories. Although selenium concentrations near the mine were 25 times the Swim Lake maximum, this element has been placed in the “low elevation” category because the area affected by elevated concentrations is very small.

Marginal Elevation Relative to Reference Levels – Antimony, Cadmium, and Cobalt

There is some evidence that elevated lichen concentrations of antimony, cadmium, and cobalt are associated with the FMC. The concentrations are, however, either within reported YT reference ranges for lichens for antimony and cobalt (Gamberg, unpublished), or are similar to other high levels in the study area that do not appear to be related to the mine (cadmium) (GLL, 2006a).

No Elevation Relative to Reference Levels – Boron, Molybdenum, Titanium, Vanadium, Aluminum, Beryllium, Calcium, Magnesium, Manganese, Phosphorus, Potassium, Silicon, Sodium, Tellurium, Tin, and Uranium

Elevated lichen concentrations of these elements either occurred in areas that were not affected by the mine or else there was no apparent pattern of elevated levels.

Consequently, elevated concentrations of these elements cannot be attributed to FMC operations.

4.2.2.4 Elemental Concentrations in Vegetation and Mineral Licks

The following paragraphs summarize the elemental level found in vegetation in the region around the FMC (GLL 2006a; AECOM 2009).

High Elevation Relative to Reference Levels – Lead

Lead concentrations for all plant species groups were greatly elevated in the area immediately adjacent to the tailings impoundment/mill complex, which indicates the mine has affected lead concentrations in vascular plants and mushrooms, as well as in lichens and soils. Lead levels near the mine ranged from 2.5 (horsetails) to 410 (tree sap) times Swim Lake reference means. Willows, grasses, forbs, horsetails, mushrooms, and bear root all had lead levels greater than Swim Lake ranges. There were no YT background levels for comparison with tree sap.

Moderate Elevation Relative to Reference Levels – Zinc

Zinc levels were significantly elevated in berries, willows, and forbs collected next to the tailings impoundment/mill complex. The magnitude of elevation ranged from three times the Swim Lake reference mean (berries) to 20 times (forbs). In most zones affected by the mine, zinc levels in forbs, willow, mushroom, and bear roots exceeded documented YT background ranges (Gamberg, unpublished).

Low Elevation Relative to Reference Levels – Copper, Nickel, Silver, Mercury, and Thallium

Copper, nickel, silver, mercury, and thallium had isolated occurrences of significantly elevated concentrations compared to Swim Lake reference levels. Concentrations ranged from approximately two (copper in willows) to nine times (silver in willows and thallium in Labrador tea) Swim Lake reference means. There is no conclusive evidence that the elevated nickel concentration in lichens can be attributed to the presence of the FMC. The maximum nickel concentrations are within published YT background ranges.

Compared with Swim Lake or YT reference levels (Gamberg, unpublished), there were elevated concentrations of the following elements in northern rough-stemmed mushrooms, bear root, and tree sap collected in mine-affected areas:

- Antimony
- Arsenic
- Barium
- Cadmium
- Chromium
- Cobalt
- Iron
- Mercury

Maximum arsenic concentrations in northern rough-stemmed mushroom and tree sap in mine-affected areas were 11 times reference levels (Swim Lake), and the maximum iron concentration in tree sap was 22 times reference levels.

Soil samples were collected from two mineral lick sites. The analysis of soils collected at Mineral Lick Site 2 indicates the potential for ungulates to consume soils that contain marginally elevated levels of mine-related elements, particularly lead; however, the effect of the mine is expected to be small. Lead levels at Mineral Lick Site 2 are no higher than Swim Lake or published maxima.

4.2.2.5 Summary

The results of the terrestrial effects study for the FMC indicated mining has resulted in elevated concentrations of several elements at the FMC and in the surrounding area (GLL, 2006a). Metal concentrations (lead, zinc, copper, nickel, silver, mercury, thallium, antimony, arsenic, barium, cadmium, chromium, cobalt, iron, and mercury) that were greater than the reference/background levels were detected in plants, small mammals, and other wildlife in the area (Gamberg, unpublished; GLL, 2006a). The presence of elevated elemental concentrations in plants

consumed by humans and animals indicates these elements are entering the environmental food chain and could also be incorporated into the human food chain (GLL, 2008).

4.2.3 Revegetation

Because some revegetation has already been undertaken at the FMC, this baseline report describes the revegetation trials and studies, and the results of those programs. Two areas have been examined for revegetation: the Vangorda/Grum Area and the Reclaimed Water Reservoir. Seven revegetation trials and activities have been undertaken in these two areas (Laberge, 2007; EDI, 2010, 2013a, 2013b):

- 2007 Vangorda Waste Rock Lysimeter Plot No. 1
- 2009 Vangorda Waste Dump revegetation
- 2008 Grum Overburden Dump Trial A and Trial B
- 2009 Grum Overburden Dump
- 2012 Grum Sulphide Cell Revegetation
- 2003 and 2004 Dewatered Freshwater Reservoir revegetation

Vangorda Waste Rock Revegetation

In 2007, a 25-m-by-25-m plot was tilled and planted with live balsam poplar and willow stakes, and seeded with alder seed (EDI, 2010). Because of shallow cover depth, live stakes were only planted to an average depth of 0.5 m, rather than the planned 1-m depth. The success of the live stake revegetation was monitored by counting the stakes and identifying them as living (signs of sprouting with no signs of drying out) or dead (signs of drying out with no signs of sprouting) in 2008 (September) and 2009 (July). In 2009, 18.5 percent of the originally planted willow stakes and 67.3 percent of the poplar stakes were still alive. The larger-diameter cuttings (>3 cm) of both species appear to be growing more successfully than smaller diameter cuttings. There was no germination from alder seed (Table 6I-5).

Species	Number Planted	% Living 2008	% Living 2009
Willow	54	28	18.5
Balsam Poplar	47	74	67.3
Alder seed	Unquantified	0	0

Source: adapted from EDI (2010)

Between September 13 and 17, 2009, potential revegetation grass mixes were applied and fertilized and alder and horizontal stakes were fertilized and planted (Table 6I-6) on a series of cover plots on the Vangorda Waste Dump (Figure 6I-10). The revegetation effort included seeding and fertilizing of the test areas. Information obtained from the test areas were used to design the Grum Overburden Dump revegetation trial.

Grum Overburden Dump Revegetation

Three revegetation studies took place at the Grum Overburden Dump between 2008 and 2009 (Figure 6I-10). In 2008, EDI completed Trial A near the bottom of the northeast side of the Grum Overburden Dump (EDI, 2010). The overburden material was loosened to a depth of 30 to 40 cm, and in autumn 2008, it was planted with willow and balsam poplar stakes (placed horizontally or vertically), and alder seed or whole cones.

In July 2009, 72 percent of the willows and 58 percent of the poplar stakes, all planted vertically, were alive (EDI, 2010a) (Table 6I-7). In August 2009, numerous alder seedlings were noted at both areas seeded with alder (i.e., alder seed and alder cones).

Species	Number Planted	% Living in 2009
Willow	36	72
Balsam Poplar	58	58
Alder seed	numerous	numerous

Source: EDI (2010)

The Trial B site was developed in 2008, and consists of nine 20-m-by-20-m test plots and one control plot on top of the Grum Overburden Dump (EDI 2010). The trial work consisted of applying four different grass seed mixes, at different rates and mixed with alder seed. One year after planting Trial B, there was sporadic grass emergence that provided little cover on any plot (Table 6I-8). Willow, fireweed, and other mature plants noted at the site were likely present because of natural introduction from the surrounding area and incomplete turning of the soil during site preparation. The soil surface is hard and is difficult to penetrate when dry; when the soil surface is wet, it becomes muddy and cements into clumps. The unfavourable growing conditions (such as higher altitude and poor soil) are likely contributors to the lack of grass cover.

TABLE 6I-8
Summary Results of Vegetation Growth Observation (July 2009) of Grum Overburden Trial B
Vegetation and Soils Baseline – Faro Mine Interim Works

Location	Plot #	Application Rates	2009 Observations
M1: Highlander slender wheatgrass (20%)	1	Low: 25 kg/ha	Grass plants 1-5 cm tall with purple leaves. Foxtail barley seed blown in. Approximately 12 fireweed and similar amounts of willow seedlings. Cover 0.5% grass, fireweed, and willow.
	2	Med: 50 kg/ha	Higher grass coverage than Plot 1. Similar amounts of willow as Plot 1, largest 60 cm tall Fireweed (5 plants). Cover 0.5 to 1 % grass, <0.5% willow, <0.25% fireweed.
M2: Awned wheatgrass (25%) Tufted hairgrass (20%) Fringed brome (15%) Alkali grass (10%) Alpine bluegrass (10%) Spike trisetum (10%)	3	Low: 25 kg/ha	Grass cover low. One horsetail present, similar amount of willow as Plots 1 and 2. Five fireweed plants. Cover 0.25% grass, <0.5% willow, <0.25% fireweed.
	4	Med: 50 kg/ha	Grass cover 0.25 to 0.5%. Willow <30 cm tall, less abundant than Plot 3. Approximately 7 fireweeds. About 0.25 m^2 of horsetail in Northwest plot corner. Several individuals of foxtail barley and other grasses.
M3 Spike trisetum (25%) Slender wheatgrass (20%) Tufted hairgrass (15%) Fringed brome (10%) Fowl bluegrass (10%) June grass (10%) Tickle grass (10%)	5	Low: 25 kg/ha	Grass emergence nearly zero. 2 willows, some clumps of foxtail barley, 2 fireweed, 1 yarrow plant (~10 cm).
	6	Med: 50 kg/ha	Grass cover minimal (<0.25%). 5 to 10 fireweed individuals, with some broad fireweed. Some purple rye outside of the Plot. 1 willow (20 cm).
M4: Violet wheatgrass (40%) Slender wheatgrass (10%) Tickle grass (5%) Sheep fescue (20%) Arctic fescue (25%)	8	Low: 20 kg/ha	Some small grass, 2 cm to 6 cm, 0.25 to 0.5% cover. 10-15 fireweed plants. Same species as seen in other Plots. 2 horsetails, several foxtail barleys. 1 tufted hairgrass and 1 slender wheatgrass plant.
	9	Med: 30 kg/ha	Slightly more grass than in Plot 8 (<0.5%). 3 tufted hairgrass plants. Fireweed (*E. angustifolium* and *E. latifolium*) plants, 2 willow, 2 horsetail plants.
	10	High: 30 kg/ha	Grass growth slightly higher than Plots 8 and 9. Several foxtail barley individuals. 3 fireweed plants. 2 horsetails. Several yarrow and 1 hairgrass plant.

M2 = Mix 2
M3 = Mix 3
M4 = Mix 4
Med = medium

In 2009, a third revegetation trial by EDI was set up at the Grum Overburden Dump (EDI, 2013a). This area was selected because it provided material representative of that planned for final cover when the FMC is reclaimed.

Three different grass mixes were seeded with and without fertilizer, on each of three surface cover treatments (rough and loose, micro-rilled, and planar). Willow cuttings, poplar cuttings (horizontally and vertically), and alder

seedlings were also planted in smaller plots throughout the trial site. Finally, a limited amount of spruce and dwarf birch seed was spread in two locations.

Revegetation monitoring results for this trial included the following observations:

- Herbaceous vegetation requires fertilizer to establish any substantial vegetation cover.
- Alder seedlings grow in fertilized and unfertilized areas, but success is limited within fertilized areas. Competition with herbaceous vegetation thriving in fertilized areas may be a potential stressor.
- Staking willow and poplar vertically and horizontally successfully established woody plants; in third-year results, horizontal staking continued to generate greater stem numbers than vertical staking. Horizontal staking may result in better erosion control than vertical staking.
- Seeding a nurse crop can provide short-term herbaceous vegetation cover; however, native grass species are important to establish longer-term cover.

During the revegetation trial, the most important contributing factors to success were the fertilizer application, appropriate seeding, and shrub planting. Site preparation methods, such as rough-and-loose surface treatment, appear to be vital to control soil erosion. Table 6I-9 provides averaged resulting vegetation cover in fertilized plots for 2010 to 2012, summarized by seed mix (Agronomic, Native, and Native with nurse crop) and surface treatment methods. The agronomic seed mix included 15 percent red fescue, 11 percent common meadow foxtail, 5 percent Kentucky bluegrass, 49 percent slender wheatgrass, and 20 percent Alsike clover. The native seed mix included 10 percent slender wheatgrass, 20 percent northern rocky mountain fescue, 37 percent glaucous bluegrass, and 33 percent tufted hairgrass. The native and nursery seed mix included 14 percent slender wheatgrass, 27 percent northern rocky mountain fescue, 58 percent glaucous bluegrass and 0.5 percent barley.

Grum Sulphide Cell Revegetation

Grum Overburden Dump revegetation trials focused on grass mixes, physical surface treatments, fertilizer effects, and inter-planting woody and herbaceous species (EDI, 2013a). Key treatments in the 2012 GSC revegetation program were guided by outcomes from the Grum Overburden Dump trials and other revegetation efforts at the FMC (Figure 6I-11). These include the following treatments and rationales:

- Nurse and native seed mix – Success between grass seed prescriptions were similar at the GSC; however, in retrospect the native and nurse crop had a low nurse seed composition. Experience from GSC hydroseeding (2011) indicated nurse crops (if applied properly) have an immediate effective response that helps address short-term revegetation goals. The native grass mix allows for better establishment over the long term.
- Fertilizer included in hydroseeding – The key driver to revegetation cover at the GSC was fertilizer. Revegetation success was dependent on the application of fertilizer.
- Surface treatment similar to rough-and-loose, ripping across the slope – Rough-and-loose was the best treatment to establish and maintain cover with little–to-no erosion at the GSC. Surface treatment implemented across the slope (perpendicular ripping) was a more cost-effective approach that should achieve similar results to the rough-and-loose treatment.
- Horizontally staked willow and poplar cuttings – Horizontal staking was successful at the GSC and can produce multiple stems per cutting, compared to the one stem a vertical stake produces. Monitoring the Grum Overburden Dump revegetation trials has shown that horizontal staking has successfully survived the unfavourable soil conditions at the FMC. Horizontal staking also has the potential to assist in the reduction of erosion because of positioning the stake across the slope, which slows runoff from moving down the slope.

Revegetation took place using the following six treatments (Figure 6I-12):

- Plugs only (P plots)
  - Woody vegetation plugs were planted without any amendments
- Stakes only (S plots)
  - Balsam poplar and willow species stakes were collected at the FMC, near the GSC, within days of planting. Stakes were collected at the following locations:
    - West and northwest of the Vangorda Waste Dump
    - South of the Vangorda Waste Dump
    - East side of the Haul Road between the gatehouse and the Grum pit
    - East of the GSC, along the access road to the Grum Overburden revegetation trials
- Plugs and stakes (PS plots)
  - Stakes were planted alternately with plugs, both across and with the slope
- Plugs with Fertilizer-pak (Chilcotin blend; Reforestation Technologies International (RTI)) teabag (Pf)
  - Chilcotin blend teabags (17-5-7) are used for disturbed planting sites with low levels of organic matter. One 10-gram teabag was placed in a separate hole, immediately upslope of the plug, about 5 cm below the soil surface. The Chilcotin blend teabag releases the following ingredients over 12 months:
    - Total nitrogen 17%
    - Urea nitrogen 9.66%
    - Ammoniacal nitrogen 8.12%
    - Available phosphate 5.00%
    - Soluble potash 7.00%
    - Magnesium 1.20%
    - Sulphur 10.40%
    - Humic acid (Leonardite-derived) 4.50%
    - Kelp extract (*Ascophyllum nodosum*) 4.00%

- Plugs with Hydration-pak (RTI) teabag (Ph)
  - Hydration-pak teabags (16-8-5) are similar to the Chilcotin-pak fertilizer, but they also contain more moisture-retaining polymer to assist seedlings establish during times of moisture stress. One 10-gram hydration-pak teabag was placed in the planting hole with the plug. The hydration-pak includes the following ingredients:
    - Total nitrogen 16.00%
    - Urea nitrogen 12.61%
    - Ammoniacal nitrogen 1.70%
    - Nitrate nitrogen 1.69%
    - Available phosphate 8.00%
    - Soluble potash 5.00%
    - Sulphur 6.60%
    - Co-polymers of acrylamide 19.00%
- Plugs with Genesis-pak (RTI) teabag (Phf)
  - One 40-gram Genesis-pak was placed in the planting hole and broken open before planting the plug. Genesis-paks release the following ingredients over 12 months:
    - Total nitrogen 8.00%
    - Urea nitrogen 4.2%
    - Ammoniacal nitrogen 3.6%
    - Nitrate nitrogen 0.2%
    - Available phosphoric acid 5.00%
    - Soluble potash 5.00%
    - Sulfur 2.00%
    - Boron 0.037%
    - Humic acid (Leonardite-derived)7.5%
    - Kelp meal (Ascophyllum nodosum) 5.0%
    - Composted vegetative matter 30%

In addition to the experimental plots, larger plots were set up in areas to add woody plant material treatments on a larger scale. The following treatments were implemented:

- S2 Plots: Poplar and willow stakes were buried at a spacing of 2.5 m between centre points of stakes.
- Pr Plots: This area was planted with plugs that remained after all experimental plots were planted. Approximately 3,354 plugs were planted on the uppermost slope in a random arrangement. Some areas were planted at very high densities to simulate a more natural setting; other areas were planted with equidistance.

Continued monitoring of the revegetation on the GSC is currently underway.

Dewatered Freshwater Reservoir

The dewatered freshwater reservoir at the FMC was revegetated in 2003 and 2004 (Arctic Alpine Seed Ltd., 2005), with annual follow-up monitoring until 2007 (Laberge, 2005, 2006, 2007). The revegetation included the following activities:

- Seeding (June and September 2003, and June, July, September and October 2004) with a mix of northern native grass species
- Transplanting stem cuttings of seven shrub and one tree species (*Salix pulchra*, *S. alaxensis*, *S. scouleriana*, *S. barclayi*, *Populus tremuloides*, *P. balsamifera*, *Shepherdia canadensis,* and *Picea glauca*; September 2003, May and October 2004)
- Staking (September 2003) at the east end of reservoir

- Staking willow stem cuttings (June 2004) on a riparian area of the Rose Creek main channel
- Staking willow stem cuttings (September and October 2004) along two main tributaries and floodplains adjacent to the reservoir dam breach.

The most recent monitoring data was collected in 2007 (Laberge, 2007). The grass seeded in June and September of 2003 has grown up to nearly 100 percent cover, except for the area immediately upstream of the dam, where cover is only 30 to 40 percent. Most of the area was dominated by sheep's fescue, except for the far-eastern portion, where there is a more even distribution of species. The newly exposed reservoir bottom (approximately 17 ha) that was seeded in June and July of 2004 has grown up to nearly 90 percent cover and is characterized by a more diverse group of grasses, as well as large amount of non-seeded native plants (Laberge, 2007).

The fourth seeded area is made up of the dam area, the disturbed area downstream of the dam, and the floodplains adjacent to the dam breach. This area was the last to be seeded in September and October of 2004. In the floodplains adjacent to the dam, the vegetation has grown up to 20 to 40 percent cover, with a few areas of up to 70 percent. In 2004 and 2005, the seeded areas of the floodplains were flooded and seed was lost. On the dam wall itself, there is little grass growth on the northwest side, 40 to 60 percent cover on the southeast side, and 5 to 20 percent cover on the sides of the dam breach. The core of the dam breach is made of highly compacted clay and is nearly barren of vegetation. Areas downstream of the dam have a grass cover of approximately 80 percent. Plant height and rooting depths for the dominant grass species (sheep's fescue and tufted hairgrass) are 55 cm high and 95 mm deep, and 90 cm high and 330 mm deep, respectively.

In general, grass seeding prescriptions have addressed short-term erosion concerns in the old freshwater reservoir. Monitoring results in a 2006 assessment of the floodplains upstream and downstream of the dam breach demonstrated 80 percent survival of staked willows (the most successful species were *S. pulchra, S. alaxensis* and *P. balsamifera*). Many staked willows died at the top but were sprouting at ground-level. Willows in the Rose Creek riparian zone and tributaries demonstrated an 80 percent survival rate, with *S. alaxensis* being most successful. A lower survival rate was found for willows in the upper reaches of the two tributaries (10 to 30 percent).

The results from Laberge (2007) monitoring of live staking treatments in 2007 showed that overall survival rates for all shrub species on the floodplains upstream and downstream of the dam breach varied between 50 and 90 percent. In the Rose Creek riparian zone and the lower reaches of the tributaries, overall survival was approximately 80 percent. Willows staked along the upper reaches of the tributaries and along the upper reaches of Rose Creek had a survival rate of only 5 to 30 percent. Among the species that were staked initially, Diamond-leaf willow and Felt-leaf willow were the most successful. Stem cuttings planted around Rose Creek and tributary riparian zones (in 2003 and 2004) had high survival rates (Laberge, 2007).

Species Lists

TABLE 6I-1-1

Committee On the Status of Endangered Wildlife In Canada[a] Status Ranking Definition

Vegetation and Soils Baseline – Faro Mine Interim Works Project Proposal

Ranking	Definition
DD	A category that applies when the available information is insufficient to resolve a wildlife species' eligibility for assessment or to permit an assessment of the wildlife species' risk of extinction.
NAR	A wildlife species that has been evaluated and found to be not at risk of extinction given the current circumstances.
SC	A wildlife species that may become threatened or endangered because of a combination of biological characteristics and identified threats.
T	A wildlife species that is likely to become endangered if nothing is done to reverse the factors leading to its extirpation or extinction.
E	A wildlife species facing imminent extirpation or extinction.
XT	A wildlife species that no longer exists in the wild in Canada, but exists elsewhere.
X	A wildlife species that no longer exists.

[a] Source: Committee on the Status of Endangered Wildlife in Canada (COSEWIC). 2012. http://www.cosewic.gc.ca/ Accessed: November 1, 2013.

Notes:

DD = Data Deficient

E = Endangered

NAR = Not at Risk

SC = Special Concern

T = Threatened

X = Extinct

XT = Extirpated

TABLE 6I-1-2

NatureServe [a] Status Rank for Yukon

Vegetation and Soils Baseline – Faro Mine Interim Works Project Proposal

Ranking	Definition
S1	Critically Imperiled – at very high risk of extirpation in the jurisdiction due to very restricted range, very few populations or occurrences, very steep declines, severe threats, or other factors.
S2	Imperiled – at high risk of extirpation in the jurisdiction due to restricted range, few populations or occurrences, steep declines, severe threats, or other factors.
S3	Vulnerable – At moderate risk of extirpation in the jurisdiction due to a fairly restricted range, relatively few populations or occurrences, recent and widespread declines, threats, or other factors.
S4	Apparently Secure – At a fairly low risk of extirpation in the jurisdiction due to an extensive range and/or many populations or occurrences, but with possible cause for some concern as a result of local recent declines, threats, or other factors.
S5	Secure – At very low or no risk of extirpation in the jurisdiction due to a very extensive range, abundant populations or occurrences, with little to no concern from declines or threats.
SNR	Unranked – national or subnational conservation status not yet assessed.
SNA	Not Applicable – a conservation status rank is not applicable because the species or ecosystem is not a suitable target for conservation activities

[a] Source: NatureServe. 2013. NatureServe Explorer: An online encyclopedia of life [web application]. Version 7.1. NatureServe, Arlington, Virginia. Available http://www.natureserve.org/explorer. Accessed: November 1, 2013.

TABLE 6I-1-3

Invasiveness Rank [a]

Vegetation and Soils Baseline – Faro Mine Interim Works Project Proposal

Ranking	Definition
1	Highly invasive – may displace or replace native ecosystems
2	Aggressive – widespread, persistent, but may not replace native species or change ecosystem function
3	Taxa present in the eh territory that area not known to be invasive here – but have been found to be invasive in other jurisdictions
4	Has been reported in the territory. Has not been shown to be problematic; may not persist
5	Species that likely do not persist
6	False reports
7	Native and introduced populations exist

Attachment 6I-2
Vegetation Association Descriptions for the Local Study Area (Gartner Lee Limited, 2008)

The following text and photos are taken directly from the Gartner Lee Limited (GLL) *Faro Mine Complex Closure Vegetation Baseline* report prepared for the Faro Project Management Team in February 2008. Please refer to that report for further information.

1) **Sedge/Willow (S/W)**

   This wetland association is common in both the boreal and subalpine zone and occurs in (moist/wet) depression or drainage areas where water collects either above or below the ground, due to bedrock or soil conditions. Wetlands are defined as being "waterlogged soils where in some cases the production of plant materials exceeds the rate of decomposition" (National Wetlands Working Group 1988). Soils are saturated for enough time that excess water and low soil oxygen levels are the main determinants of soil and vegetation development (MacKenzie and Moran 2004). Wetlands, including streams and fens, are common in low gradient valleys and catchment basins in the Faro LSA (Oswald et al. 1983). A mixture of sedge and graminoid species dominates the area, with water sedge (*Carex aquatilis*) being most common. Shrubs such as willows (*Salix spp.*), dwarf birch (*Betula glandulosa*) and some white spruce (*Picea glauca*) are also present around the edges of the wetland. Wetland mosses such as sphagnum (*Sphagnum spp.*) are also abundant.

Figure 6I-2-1: Sedge/Willow vegetation association

2) Willow/Sedge (W/S)

The willow/sedge association is linked with standing or flowing water, usually along lakes, ponds and creek drainages. It is a common riparian vegetation association found over a wide elevation range throughout the study area. Various willow species including tea-leaved willow (*Salix planifolia*) and Athabasca willow (*Salix athabascensis*) are dominant in the shrub layer though dwarf birch and shrubby cinquefoil (*Potentilla fruticosa*) may also be present. Shrub heights vary depending on water availability and exposure to wind and snow, but are generally 0.5 to 1 m tall. Sedge species (*Carex* spp.) such as water sedge are common below the shrub layer along with various wetland mosses (*Sphagnum* spp).

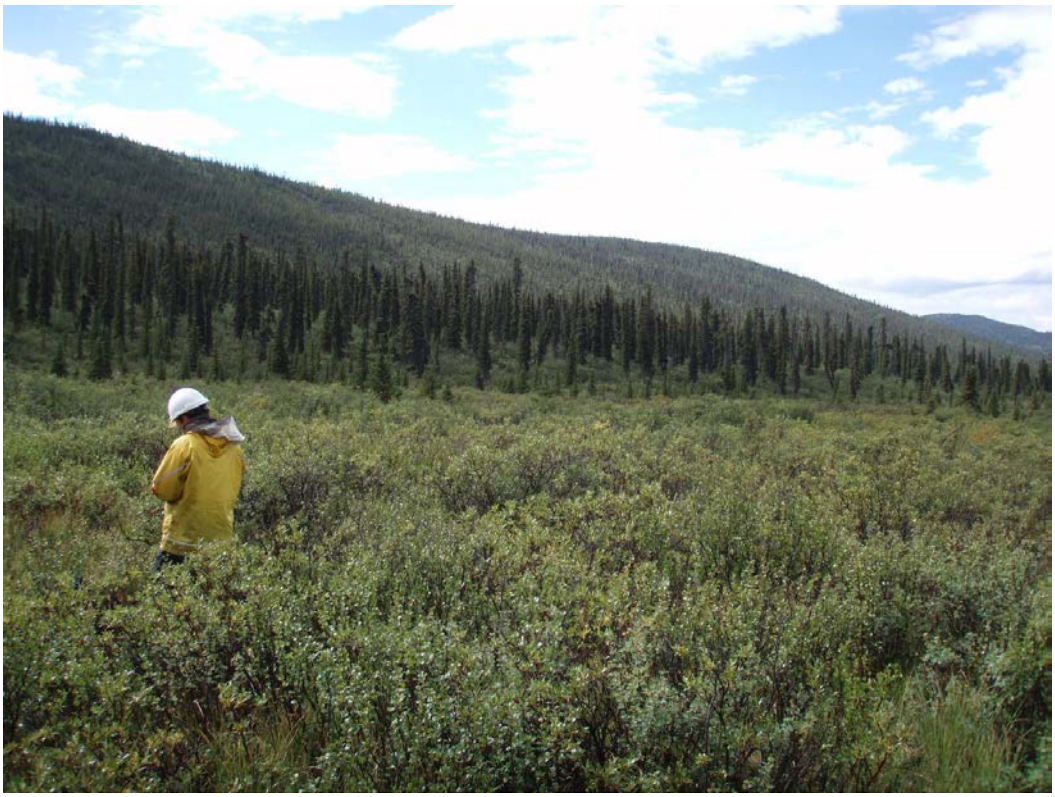

Figure 6I-2-2: Willow/Sedge vegetation association

3) Willow/White Spruce (W/Sw)

The willow/white spruce vegetation association is often found in a riparian drainage or draw, along creeks or rivers primarily in the boreal zone. An open canopy of mature white spruce is scattered among a well-developed shrub layer dominated by various willow species and dwarf birch. Ground cover is often a combination of ericaceous shrubs, sedge species, lichens and mosses. Such species include arctic bearberry (*Arctostaphylos rubra*), net-veined willow (*Salix reticulata*), common horsetail (*Equisetum arvense*) and bluegrasses (*Poa* spp.).

Figure 6I-2-3: Willow/white spruce vegetation association

4) Willow/Dwarf Birch (W/B)

This riparian vegetation association is widespread in lower elevations, occurring on gentle to steep slopes near drainages or open water in the boreal zone. Willow species and dwarf birch are codominant in a well-developed shrub layer wherein willows can reach up to 4 m. Scattered young white spruce trees are common, along with low shrubs such as Labrador tea (*Ledum groenlandicum*), as well as sparse grasses and forbs. Moss and lichen cover varies depending on water and nutrient availability.

Figure 6I-2-4: Willow/Dwarf Birch vegetation association

5) Dwarf Birch/Willow (B/W)

The birch/willow vegetation association is characteristic of slopes at higher elevations in the subalpine zone throughout the study area. Dwarf birch is the dominant shrub, however willow species, Labrador tea, shrubby cinquefoil and bog bilberry (*Vaccinium uliginosum*) are also present. A variety of ground shrubs such as crowberry (*Empetrum nigrum*), mountain cranberry (*Vaccinium vitis-idaea*) and alpine bearberry are found in the understory; however, lichens (*Flavocetraria* spp., *Cladina* spp. and *Stereocaulom* spp.) tend to dominate the groundcover. Krummholtz subalpine fir (*Abies lasiocarpa*) and white spruce occur occasionally.

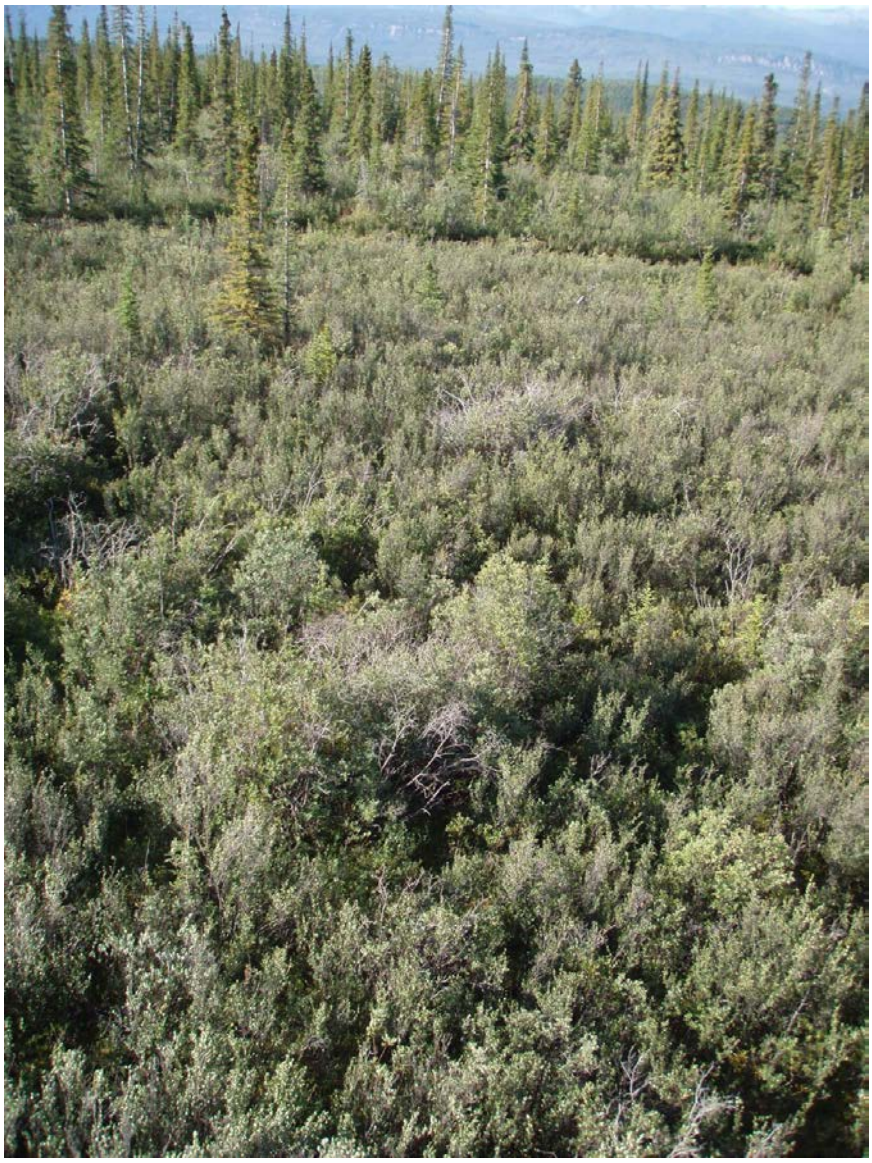

Figure 6I-2-5: Birch/willow vegetation association

6) Dwarf Birch/Lichen/Subalpine Fir (B/L/Fa)

This vegetation association is a subalpine/alpine community characterized by rocky outcrops and windswept ridges at higher elevations. Dwarf birch is the dominant cover species at a height of 0.5 m tall, followed by a high cover of lichen species (*Cladina* spp., *Stereocaulon* spp., and *Flavocetraria* spp.) intermixed with rocky outcrops. Krumholtz subalpine fir is the dominant tree species scattered throughout the vegetation association, although white spruce may also be present. Arctic bearberry, crowberry, bog bilberry and mountain avens (*Dryas* spp.) are also present.

Figure 6I-2-6: Dwarf Birch/Lichen/Subalpine Fir vegetation association

7) Dwarf Birch/Subalpine Fir (B/Fa)

The birch/fir vegetation association is a subalpine community occurring on well-drained soils and slopes at higher elevations. Dwarf birch is the dominant cover species at a height of 0.5 to 1 m tall with scattered subalpine fir as the dominant tree species at 2 – 6 m tall. Willow species, Labrador tea, mountain juniper (*Juniperus communis*) and white spruce may also be present. Low growing shrubs include bog bilberry, arctic bearberry, crowberry and mountain cranberry. Graminoid species are present in the ground cover along with various lichen species (*Cladina* spp., *Stereocolun* spp., and *Peltigera* spp.).

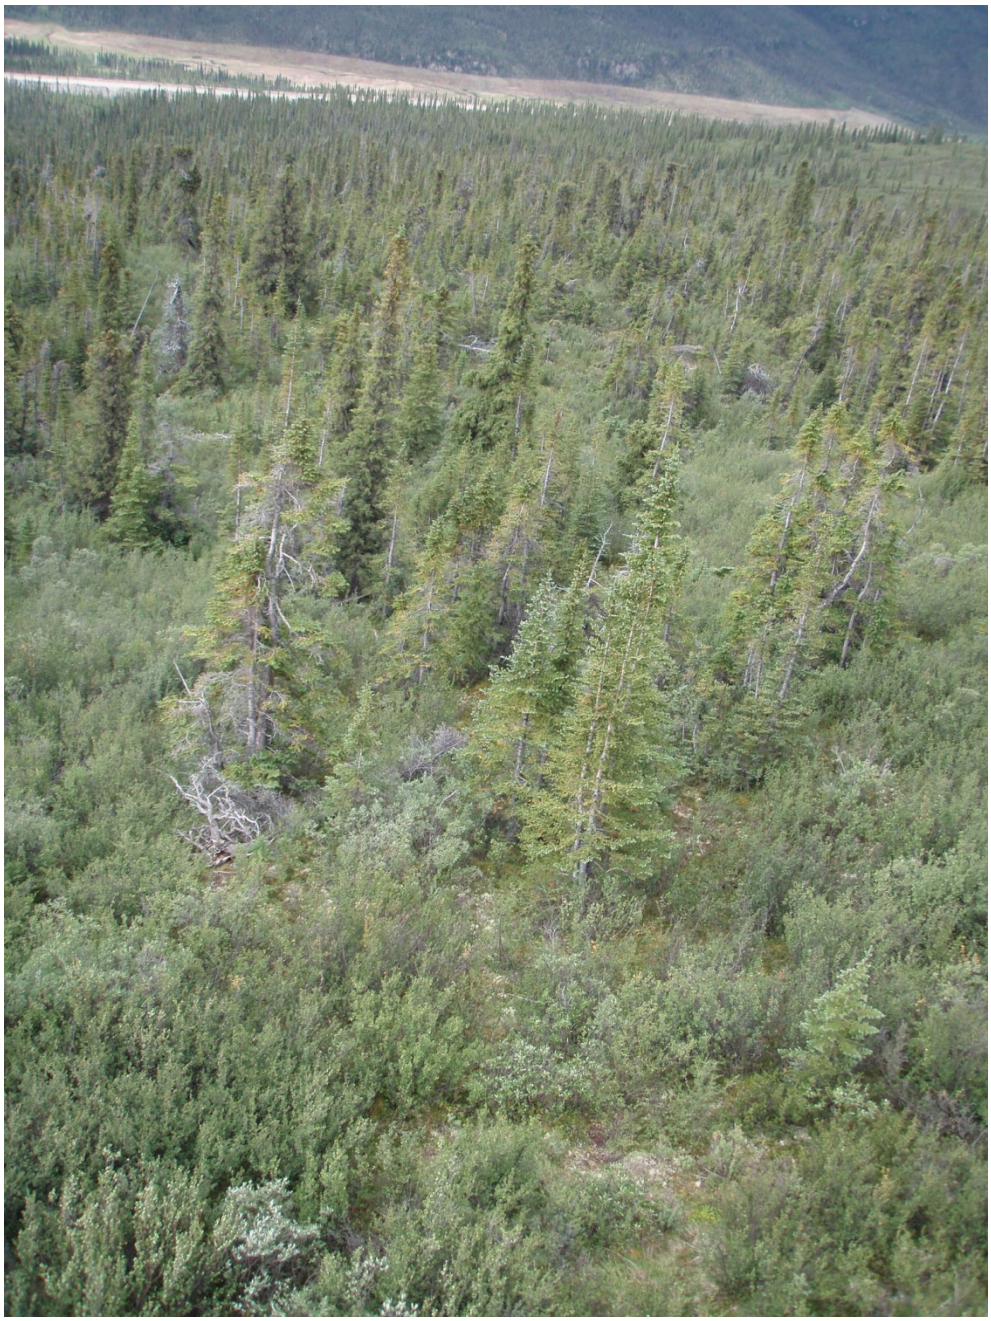

Figure 6I-2-7: Dwarf birch/subalpine fir vegetation community

8) White Spruce/Willow (Sw/W)

The white spruce/willow association is the most frequent vegetation association within the study area, occurring in both the boreal and the subalpine zones on various upland and lowland slopes. White spruce dominates the tree canopy, though subalpine fir may also be present. A well-developed shrub layer is dominated by a high cover of 1 m tall willow species, along with a lower percent of dwarf birch, Labrador tea and shrubby cinquefoil. Dwarf shrubs in the ground cover layer include bog billberry, common bearberry (*Arctostaphylos uva-ursi*), net-veined

willow and crowberry. Common horsetail and bluegrass species are also frequent. Stair step moss (*Hylocomium splendens*), reindeer lichens (*Cladina rangifera*) and pelt lichens (*Peltigera* spp.) are common throughout the vegetation association.

Figure 6I-2-8: White spruce/willow vegetation association

9) White Spruce/Feather moss (Sw/Fm)

This vegetation association occurs most frequently on well-drained alluvial flats as well as on mesic sites in lowland areas throughout the boreal zone. The tree canopy is comprised of dense white spruce trees with a sparse shrub understory. Tall shrubs consist of willow species, dwarf birch and shrubby cinquefoil whereas low growing shrubs consist of mountain cranberry, bog bilberry, alpine bearberry and crowberry. Vegetation in the herbaceous layer includes arctic lupine (*Lupinus arcticus*), alpine sweet vetch (*Hedysarum alpinum*), purple-leaved willow-herb (*Epilobium ciliatum*) and bluegrass species. A thick carpet of feathermosses such as stair step moss is also present.

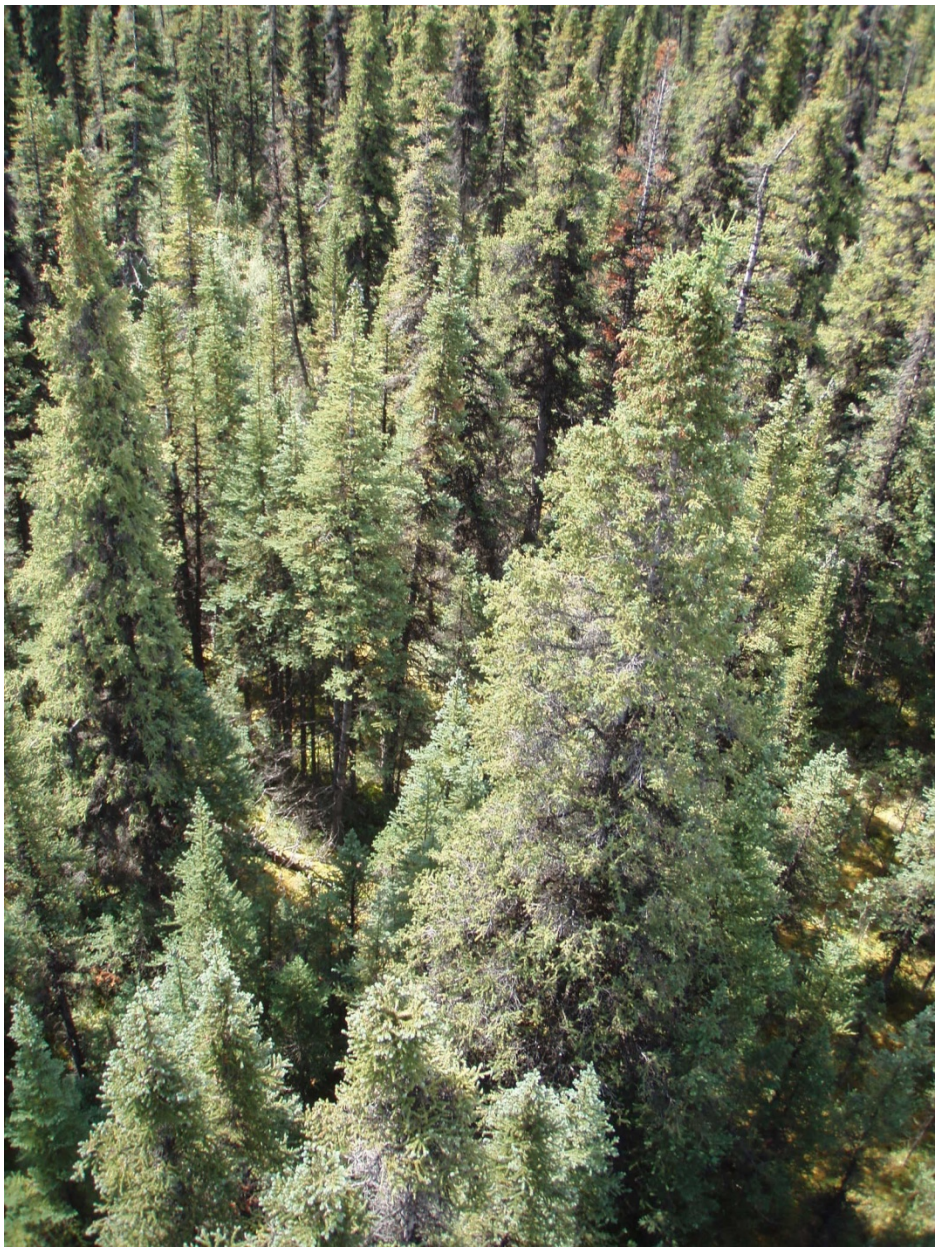

Figure 6I-2-9: White spruce/feather moss vegetation association

10) Pine (Pl)

The Pine vegetation association is as its name suggests a dominant tree canopy of lodgepole pine (*Pinus contorta*). It is found mostly on upland areas around the Grum and Vangorda pit at the SE end of the LSA in the boreal zone. The average tree canopy height is 16 m, with a few white spruce trees scattered throughout the subcanopy. A tall shrub layer of Sitka alder (*Alnus crispa* ssp. Sinuate) and Scouler's willow (*Salix scouleriana*) is common and followed by a lower shrub layer of Labrador tea, prickly rose (*Rosa acicularis*) and buffaloberry (*Shepherdia canadensis*). Ground cover consisting of bog bilberry, crowberry, bunchberry (*Cornus canadensis*), common bearberry and twinflower (*Linnaea borealis*) are noted at lower cover

values. Feathermosses are also a common ground cover. This vegetation association is a typical mid-successional forest following fire.

Figure 6I-2-10: Pine vegetation association

11) Mixed Coniferous-Deciduous (Mx)

This vegetation association establishes on well drained sites over a broad elevation range. It consists of a mixture of coniferous and deciduous trees including white spruce, trembling aspen, balsam poplar (*Populus balsamifera*), lodgepole pine. Depending on moisture and nutrients, subalpine fir and/or black spruce (*Picea mariana*) may also be present. This is often a young forest or "mid-seral community following fire" (Staniforth, 1998) whereby trees are in both the tree canopy and shrub layer. Additional shrubs include dwarf birch, willow species and Labrador tea. Bog bilberry, crowberry and mountain cranberry comprise the layer of low growing shrubs whereby stair step moss, green reindeer lichen and pelt lichens moderately cover the remainder of the ground.

Figure 6I-2-11: Mixed Coniferous-Deciduous vegetation association

12) Deciduous (Dd)

The deciduous vegetation association often establishes on sites regenerating from a disturbance, whether it be fire or human development. Sites tend to be located on well-drained slopes and are rich in diversity. Most often located in the boreal zone, trembling aspen is the dominant tree species ranging in height from 2 to 8 m tall, followed by balsam poplar on moister sites. Tall shrubs include willow species, Sitka alder, shrubby cinquefoil, Labrador tea, dwarf birch, buffaloberry and prickly rose. White spruce may also be visible in the understory. Low growing shrubs include arctic bearberry, common bearberry, mountain cranberry and blueberry willow (*Salix myrtilifolia*). The herbaceous layer consists of bunchberry, bastard toad-flax (*Geocaulon lividum*), fireweed (*Epilobium angustiflolium*), northern grass-of–parnassus (*Parnassia palustris*) and twin flower.

Figure 6I-2-12: Deciduous vegetation association

13) Graminoid (Gr)

The graminoid vegetation association is found in lowland areas on and around the project footprint in the boreal zone. It generally comprises an area re-established from seed mixtures of grasses and low growing forbs such as the freshwater reservoir located SE of the tailings pond along the access road. Grasses such as brome (*Bromus* spp.), reedgrass species (*Calamagrostis* spp.) and fescue species (*Festuca* spp.) dominate this vegetation association. Sedge species can occur as well as various forbs such as fireweed and wormwood (*Artemisia* spp.).

Figure 6I-2-13: Graminoid vegetation association

SECTION 1

Introduction

Ecological Logistics & Research Ltd. (ELR) was retained by CH2M HILL Canada Ltd. (CH2M HILL), on behalf of Government of Yukon (YG), Assessment and Abandoned Mines Branch (AAM) to prepare a wildlife baseline report to support the upcoming Project Proposal submission to the Yukon Environmental and Socio-economic Assessment Board (YESAB) as part of the Faro Mine Interim Works for the Faro Mine Complex (FMC).

The FMC is located 15 kilometres (km) north of the Town of Faro and is comprised of two former mine components, the Faro Mine Area and the Vangorda/Grum Area. These two components are separated by a 14-km haul road (Figure 6J-1). The FMC operated as an open-pit lead and zinc mine extracting concentrates that also produced silver and gold between 1969 to 1998. In 1998, the operating company went into receivership and the mine subsequently went into a care and maintenance (C&M) phase. AAM assumed management responsibilities of the FMC in 2009.

1.1 Objectives and Scope

The primary objective of this wildlife baseline report is to describe terrestrial wildlife resources at the FMC and surrounding area, to support an assessment under the Yukon Environmental and Socio-economic Assessment Act. The report forms part of a multidisciplinary program prepared to describe current conditions at the FMC.

The scope of baseline information presented in this report represents a collection of efforts dating back to the 1970s; a number of which were conducted prior to when AAM assumed responsibility for the site in 2009. More recent regional and local studies have been completed by Environment Yukon (EY) or on behalf of AAM, respectively.

Information collected from available sources was compiled, reviewed, and summarized, and is organized into three key sections: (1) Introduction, providing historical and geographical context to the information presented, (2) Methods, describing methodologies used for each baseline component, and (3) Results, presenting a synthesis of the findings from each baseline component and integrated into species-specific sections.

1.2 Environmental Setting

The FMC is located within the Yukon Plateau-North Ecoregion of the Boreal Cordillera Ecozone, a region characterized by rolling uplands, small mountain groups, and plateaus dissected by glaciated valleys (Smith et al., 2004). The FMC occurs on the Vangorda Plateau, with elevations ranging from 1,000 to 1,400 metres (m) above sea level (masl). The Anvil Range Mountains rise up immediately north of the Vangorda Plateau, with major summits exceeding 2,000 masl, including Mount Mye and Mount Aho. Drainage of the FMC is via Rose Creek and Vangorda Creek, both of which flow from the FMC to the Pelly River. The Pelly River flows northwest in the wide valley of the Tintina Trench, which is located south of the Vangorda Plateau at an approximate elevation of 600 masl. The Tintina Trench is a fault that traverses the territory from the southeast corner toward the City of Dawson in west central Yukon.

The FMC occurs primarily within mid-elevation boreal forest, dominated by white spruce and occasional lodgepole pine with willow, dwarf birch, and ericaceous shrubs in the understory. Poorly drained sites consist of black spruce, willow, birch, and mosses. Subalpine vegetation communities are dominated by scrub birch, subalpine fir, white spruce, some lodgepole pine, and lichen. Above the treeline, alpine areas are characterized by rock and bluffs, low ericaceous and willow shrubs, and an abundance of terrestrial lichen (Smith et al., 2004).

SECTION 2

Methods

2.1 Wildlife Study Areas

2.1.1 Wildlife Local Study Area

The FMC is spatially defined by the extent of the existing disturbance footprint; this area represents an immediate zone of project effects. A local study area (LSA), encompassing the area with reasonable potential for project-related effects, includes the FMC and a 1-km buffer, creating a total area of 81.2 kilometres square (km^2) (Figure 6J-2). A similar LSA was used in a 2008 wildlife baseline report, which included a description of conditions at the FMC (Gartner Lee Limited, 2008a).

2.1.2 Wildlife Regional Study Area

For some wide ranging wildlife species (e.g., moose, caribou, grizzly bears, and some raptors) the assessment requires an understanding of abundance and distribution in areas extending beyond the LSA. Accordingly, a wildlife regional study area (RSA) was used to describe wildlife populations and to assess effects at a broader geographical scale (Figure 6J-2). The RSA was defined as an area extending 15 km beyond the FMC footprint, resulting in a total area of 1,530 km^2.

2.2 Existing Wildlife Information Datasets

Several sources of existing wildlife data were reviewed to characterize baseline conditions for wildlife and wildlife habitat at the FMC. These sources include:

- YG Wildlife Key Area (WKA) datasets
- Yukon hunting regulations and EY database for harvested big game species
- Breeding bird survey data
- Species at Risk (SAR) resources including the Yukon Conservation Data Centre, the *Species at Risk Act* (SARA) Registry, and NatureServe Canada
- Previous reports and summaries prepared for the FMC

2.2.1 Wildlife Key Area Datasets

WKAs are geographic locations or areas in the Yukon that have been identified as important habitat areas used by wildlife for critical and seasonal life functions. WKA delineations are based primarily on regional surveys conducted by EY but also on local area knowledge or anecdotal information (EY, 2009). WKAs are important as they help identify the habitat requirements for key life functions (e.g., winter feeding, rutting, and calving).

The YG WKA database was spatially queried to determine the presence of WKAs within the RSA and LSA. WKAs found within the RSA are summarized within the corresponding species sections herein.

2.2.2 Hunting Regulations and Harvest Database

Hunting in the Yukon is regulated under the Yukon *Wildlife Act.* Regulations and guidelines for hunters are published annually in the Yukon Hunting Regulations Summary (EY, 2013a). Information relating to species harvest in the Faro region was compiled for each of the large mammal species sections in this report.

EY provided harvest data for moose, caribou, grizzly bear, and thinhorn sheep in the Game Management Subzones (GMSs) that overlap or occur in the vicinity of the FMC. EY compiles the data from records submitted by hunters every year. Wildlife manager typically use a 5-year period to assess and determine trends that occur in a wildlife population (Alain Fontaine, Liard Area Regional Biologist; personal communication). A 10-year period of harvest data was requested from EY for the FMC area GMS, to characterize potential trends in hunting pressures and in wildlife populations that occur in the area.

2.2.3 Breeding Bird Surveys

Breeding bird survey data for the Town of Faro was accessed, as this data can provide a valuable indication of avian species that may potentially be present in the FMC area. Two breeding bird survey databases were queried to compile a list of species that have been reported to have been observed near Faro, as follows:

- Birds of the Yukon Database - Map sheets 105K3 and 105K6 (Canadian Wildlife Service [CWS], 2007)
- North American Breeding Bird Survey Database - Faro Route (United States Geological Survey [USGS], 2013)

Species were summarized according to those most commonly observed and those being of conservation concern, and were grouped into water and land bird species in Table 6J-7 and 6J-8, respectively, for reference.

2.2.4 Species At Risk

Several resources were examined to identify potentially occurring SAR within and around the project LSA and RSA:

- Species for which WKAs were identified within the RSA were cross-referenced with federal and territorial SAR listings.
- The YESAB Geolocator was employed to spatially evaluate the RSA for the presence of important habitat for species of conservation concern. For any Conservation Data Centre (CDC) Species of Conservation Concern polygons that occurred within the RSA, an information request was submitted to the Yukon Conservation Data Centre for additional information.
- The Yukon *Wildlife Act,* the federal SARA registry, the Committee on the Status of Endangered Wildlife in Canada (COSEWIC), and NatureServe Canada were queried to determine the conservation status for species occurring or potentially occurring in the project area.

2.2.5 Previous Wildlife Reports and Studies

Three existing reports describing wildlife and wildlife habitat conditions at the FMC were reviewed for inclusion in this baseline document. The methods used to collect or compile information in these reports are summarized in the following sections.

2.2.5.1 Wildlife Habitat Local Study Area Baseline Report

A wildlife baseline study report was developed on behalf of AAM in 2008, in support of the development of a preliminary closure and remediation plan for the FMC (Gartner Lee Limited, 2008a). The objective of the document was to provide wildlife information relevant to those issues identified as important during community meetings and during consultation with First Nations (Selkirk First Nation and Ross River Dena Council), the Town of Faro, YG biologists, local residents and project scientists in the study area at that time, as well as to issues that may be associated with project effects. The geographic scope of that report was limited to the LSA; however, due to the limited wildlife and wildlife habitat information available for the mine area, regional data were used to infer conditions at the local level. Data collection methods were limited to incidental sightings during a vegetation classification survey conducted in August 2007. Information was also compiled from previous reports and available community and traditional knowledge reports. Gartner Lee Limited reviewed the data and information, and integrated it into species or functional group accounts including descriptions of species populations, movements, distribution, harvest, habitat use, and diet.

The 2008 baseline report provided a compilation of existing information. Data and observations from that report have been integrated into this baseline report document, and have been updated where possible to reflect baseline conditions at the FMC.

2.2.5.2 Faro Area Thinhorn Sheep Summary

Following the development of the Wildlife Habitat Local Study Area Baseline Report by Gartner Lee Limited in 2008, an additional report was developed by Gartner Lee Limited as a complementary component to the wildlife baseline document. Gartner Lee Limited (2008b) digitized archived sheep data that had been collected over a period of 18 years (1981 to 1999) in the FMC area by YG. The archived data included observational records logged on paper maps and in field notes taken during aerial and ground surveys. In addition, radio telemetry locations of

ewes that were collected during a sheep monitoring program that ran from November 1989 and May 1990, were also digitized. During this program, nine ewes were captured and fitted with very high frequency (VHF) radio collars (Schweinsburg, 1990). Gartner Lee Limited (2008b) also digitized sighting records logged during two additional studies: (1) an investigation conducted by McLeod (1981) of the Mount Mye sheep population, and (2) an impact assessment targeting stone sheep in the Grum and Vangorda pit areas conducted by Horejsi (1998).

Gartner Lee Limited (2008b) digitized point locations on-screen at a scale of 1:10,000 using a geographic information system (GIS) and subsequently logged location-specific attribute data into a database; only records with specific geographic reference information were digitized. The locations were spatially compiled to produce seasonal use maps and migratory movement maps. The spatial information resulting from the digitizing efforts in 2008 was summarized into the Faro Area Thinhorn Sheep - Additional Baseline Data Summary report (Gartner Lee Limited, 2008b) and is integrated into the current baseline report document to help characterize sheep distribution and use of the FMC and surrounding area.

2.2.5.3 Current Environmental Conditions Supporting Document

The Faro Mine Complex Closure and Reclamation: Current Environmental Conditions Supporting Document (AECOM Canada Ltd., 2009) reported on current environmental conditions at the FMC including climate and atmospheric environment, geology, and water resources, as well as aquatic and terrestrial resources. Wildlife baseline conditions were described as a terrestrial resource; supporting information was drawn from the Local Study Area Baseline Report (Gartner Lee Limited, 2008a), as described in Section 2.2.4.1.

2.3 Recent Regional Studies

Two regional studies have recently been conducted by EY: an early-winter moose survey and a thinhorn sheep lambing survey. EY periodically conducts such ungulate studies to monitor population trends and to inform land and harvest management decisions. Methods from these regional studies are summarized in the next section.

2.3.1 2011 Faro Region Early-Winter Moose Survey

EY conducted an early-winter moose survey of the Faro region in 2011 to estimate the abundance, distribution and composition (i.e., sex and age class) of the local moose population (Clarke et al., 2012). By comparing the 2011 survey data with data collected during previous surveys, EY also evaluated recent population trends. The survey included 10 GMS of which one (i.e., 4-40) was only partially surveyed (Figure 6J-3). Additional analytical effort was expended on GMS 4-45 to evaluate the population trends in that unit due to recently increased access and resulting heavy hunting pressure in the area. The Faro Mine Area of the FMC overlaps the southwestern portion of GMS 4-45, as well as GMS 4-44, 4-46, and 4-51 (Figure 6J-3).

The survey was conducted according to the geospatial survey methods of Kellie and Delong (2006) and included two main components: (1) an intensive stratification and (2) a population census. The survey was performed over a total survey area of 6,470 km^2 which was divided into 405 survey blocks with 4 km by 4 km dimensions (16 km^2 each). The first step in the survey was to stratify (i.e., classify) blocks using a fixed-wing aircraft. At this stage, blocks were classified according to the expected density of moose (e.g., high or low) based on observations of moose, moose tracks, and habitat characteristics, as well as local knowledge. This step helps to extrapolate field results more accurately to a population estimate. Next, 30 percent of all blocks were randomly sampled to include in the population census component. During the census, blocks were flown using helicopters and moose were enumerated and classified to sex and age class (adult or calf). Due to the difficulty in differentiating between yearling and adult cows, they were grouped as one age class. A sightability correction factor (SCF) was calculated to estimate and correct for the number of moose that were missed during the census. Clarke et al. (2012) calculated abundance ratios of adult bulls to cows, calf survival, and yearling recruitment. Statistical comparisons were made between data collected in 1997, 2004, and 2011 for the Faro study area population.

2.3.2 2011 Faro Region Lambing Sheep Survey

EY conducted lambing surveys in June and July of 2011 throughout the Anvil Range mountains (EY, 2011; unpublished data) (Figure 6J-5). EY's purpose for conducting the surveys was to collect current demographic and distribution data for the Faro area thinhorn sheep (Dall's subspecies; *Ovis dalli dalli*) population in response to

increased mineral exploration activities in the area. Furthermore, EY indicated that WKAs identified for lambing in the study area were outdated (i.e., based on lambing data from the late 1980s) and were assumed to under represent important areas that are used by ewes during the lambing season, which ranges from May to June annually (Ministry of Environment, Lands, and Parks [MELP], 2000).

The lambing surveys were conducted using a Robinson R44 helicopter to systematically search alpine habitats for cliffs in use by ewes with newborn lambs. Two surveys were conducted; the first was performed in June to count newly born lambs, and the second was performed in July to determine the survival rate of lambs approximately one month later. To minimize disturbance to nursing sheep, sheep were observed and counted from a distance using binoculars or a spotting scope. Ewes with new lambs were differentiated from nursery groups with mobile lambs by observing those that did not flee (i.e., new lambs) with those that did (i.e., mobile lambs).

2.4 Recent Field Programs

Recent onsite field programs include a 2012 winter snow tracking survey and a 2013 waterfowl study. In addition, a log of wildlife observations at the FMC has been maintained by site C&M contractors, and has been included herein to augment local species occurrence information.

2.4.1 Waterfowl Surveys and Habitat Assessment

In September of 2013 a study was conducted to collect data on the usage of pits and ponds in the FMC area by waterfowl and waterbirds, and to characterize the habitat provided by those pits and ponds as they relate to waterfowl and waterbird use. These data were collected with the intent of characterizing the potential risks to those wildlife. The study was conducted in 2013 as only anecdotal or incidental data regarding waterfowl use of the aquatic areas in the FMC previously existed. Study sites included FMC pits and ponds in the Faro Mine Area (Figure 6J-8a) and in the Vangorda/Grum Area (Figure 6J-8b). The study was limited to the fall migratory period, and was conducted by ELR biologists who employed a combination of observational and field sampling methods to better understand the contributions of the aquatic areas to waterfowl habitat, and the potential for exposure pathways.

2.4.1.1 Observational Study

ELR conducted observational surveys following protocols outlined by the British Columbia Resources Inventory Committee (RIC) protocol for presence/non-detected surveys for waterfowl (MELP, 1999a). When waterfowl were observed, behaviors such as feeding, diving, resting or drinking were also noted.

2.4.1.2 Habitat Assessment

A qualitative approach was used to describe habitat characteristics at the pits and ponds in order to characterize habitat value based on the presence of available riparian vegetation, presence and abundance of aquatic vegetation, and presence and abundance of benthic macroinvertebrates.

Benthic sediment and aquatic and riparian vegetation tissue samples were collected when present in the ponds and analyzed for total metals concentration. Laboratory results for sediment were compared to Canadian Council of Ministers on the Environment Sediment Quality Guidelines for the Protection of Aquatic Life (Canadian Council of Ministers of the Environment [CCME], 1995), including Interim Sediment Quality Guidelines (ISQG) and Probable Effects Level (PEL) guidelines to determine potential risk levels. Vegetation metals concentrations were compared to corresponding sediment metals concentrations to determine whether metals levels were elevated, and whether metals were being magnified in relation to sediment levels.

In conjunction with sediment collection for metals analysis, sediment was also assessed for the presence of benthic macroinvertebrates. Twenty litre composite samples were collected from ponds and were field sieved using a 400 micrometre sieve. Benthic invertebrates captured by the sieve were assessed visually, and were field preserved prior to being sent to an invertebrate taxonomic laboratory for identification.

2.4.1.3 Assessment of Habitat Potential

Observational and habitat data for the FMC pits and ponds were assessed to determine habitat potential for each area surveyed, which was described in terms of either stop-over or feeding habitat. The presence of stop-over

habitat potential was identified in areas where surface water was consistently present in an area large enough to be used for resting by waterfowl, and where waterfowl were previously observed. Feeding habitat potential was described as where benthic macroinvertebrates, aquatic vegetation, and riparian vegetation were observed, and where waterfowl have been observed.

2.4.2 2012 Winter Tracking Survey

ELR was retained by CH2M HILL on behalf of AAM to conduct a winter tracking survey in March 2012 to collect data on the relative abundance, diversity and habitat use of furbearers and other wildlife species at the FMC during late winter (ELR, 2012). The survey was conducted according to RIC protocols for marten and weasels, and for medium-sized territorial carnivores and selected ungulates (MELP, 1998a; 1998b; 1999b).

The tracking survey employed a ground-based track count method in the LSA, using transects based on equilateral triangles of three 1-km lengths (Figure 6J-7), distributed among 14 ecological land classification (ELC) units described by AECOM (2009; unpublished data). Biologists followed transects between 24 and 72 hours after the last snowfall, and recorded tracks as either active detections (created since the last snowfall) or incidental tracking detections (older tracks of unknown age). Sightings or other wildlife sign were also recorded as incidental observations.

Data were analyzed by overlaying Geographic Positioning System track files over the ELC polygons using GIS software, where track segments were classified according to a functional habitat type. For this analysis, the 14 ELC ecosystem units identified by AECOM (2009) were grouped into eight functional habitat groups in order to reduce the number of habitat categories and thereby minimize the effect of small sample sizes in uncommon habitats. Tracking effort (km x days) was calculated for the entire LSA and for particular habitats, while track density (tracks/km/day; TKD) was calculated for species within each of eight functional habitat types. The tracking data was also analyzed to assess effort and track density for the entire LSA. Incidental observations were also discussed.

2.4.3 FMC Incidental Wildlife Log

An incidental wildlife log has been maintained by FMC C&M staff since 2009 (AAM, 2013, unpublished data), and is currently maintained by Tlicho Engineering and Environmental Services. Log records include wildlife observations reported by C&M staff, AAM staff, onsite contractors and visitors. Each record consists of the observation date, a specific or general description of the animal (e.g., grizzly bear or bear), and most records include a reference to sighting location. The wildlife incidental reporting program has resulted in a 5-year record of nearly daily wildlife observations. The observations were made incidentally while conducting C&M activities, and were not part of a structured wildlife monitoring program. As such, the resulting dataset has some inherent limitations. Factors affecting this dataset include the variation in detectability of wildlife species, the seasonality of onsite activities (and therefore detection ability), the observers' species identification skills, and the likelihood of multiple observers reporting a single species occurrence (resulting in an overrepresentation of the number of occurrences). Although the resulting inferences from the data are limited, the records provide a list of species that have been observed onsite as well as a general indication about what seasons wildlife have been observed in the area. ELR compiled the observation records to sort and tabulate data according to species and season; species summaries are detailed in the corresponding results sections.

SECTION 3

Results

The results and information presented in the following sections have been drawn from a variety of sources; some of which pertain to more than one species or species group. As such, results for this report were synthesized into species-specific sections to provide an integrated summary of existing conditions for the FMC area. These species, listed by species group, include:

- Ungulates (Including moose, caribou, and thinhorn sheep)
- Carnivores (Including grizzly bear and furbearer species)
- Avian species (Including waterfowl and waterbirds, passerines, raptors, and upland game birds)
- Small mammals and amphibians
- Invertebrates

3.1 Ungulates

3.1.1 Moose (*Alces alces*)

Moose are distributed across the Yukon and are most concentrated in the Faro region with average population densities among the highest in the territory (Clarke et al., 2012). Moose are ranked as secure in Canada (except in Nova Scotia where they are listed as threatened) by the National General Status Working Group (Canadian Endangered Species Conservation Council, 2011). Moose are an important prey species, and maintaining healthy populations is key to ensuring biological diversity. Moose are valued as a big game species and are relied upon by First Nation and Yukon residents for subsistence.

3.1.1.1 Existing Information

Yukon hunting regulations restrict the moose harvest to one bull per year per licensed hunter (EY, 2013a). EY implements a voluntary no-hunting request each year for GMS 4-42 to 4-46, in which hunters are requested to cease moose harvest once the allowable harvest quota for these areas has been reached. Portions of GMS 4-44, 4-45, 4-46, 4-47, and 4-51 occur within the RSA; however, GMS 4-51 is closed to all big game hunting. The western portion of GMS 4-45 can be accessed through the FMC main access road and consequently this GMS sees significant hunting pressure and subsequently high harvest rates as described in Section 3.1.1.3. below.

Moose harvest data provided by EY (2013b) indicates a total of 394 moose harvested in the last decade (2003 to 2012) from the GMS surrounding the FMC, including 4-41 to 4-47 and 4-51 (Table 6J-1; Figure 6J-3). GMS 4-45 had the highest harvest rate of moose for every year in the ten-year period, providing evidence for the hunting pressures occurring in that area. The EY data includes harvests from resident, non-resident (i.e., outfitter guided) and special guided[1] hunters and does not include First Nation harvest. Resident, non-resident, and special guided hunters harvested 80 percent (n= 313), 15 percent (n = 60), and 5 percent (n = 21), respectively, of all moose reported here.

EY, 2013b, unpublished data.

Moose were the second most frequently observed species recorded in the FMC Incidental Wildlife Log, having 263 observation records of a total of 842 over the 5-year incidental wildlife reporting period (i.e., 2009 to 2013) (AAM, 2013, unpublished data). Seasonally, moose were observed in all months (except November) with the most observations occurring during the summer months. Over 70 percent of observations occurred in the Faro Mine Area, including areas in the vicinity of the parking lot and guardhouse, the Emergency Tailings Area (ETA), Cross Valley Dam (CVD) Pond, Intermediate Dam Pond (ID Pond), Rose Creek, Rose Creek Diversion (RCD), Faro Diversion area and generally in the Down Valley area. Approximately 15 percent of moose observations occurred in the Vangorda/Grum Area, including those in proximity to the Grum Pit, Vangorda Flume, Little Creek Dam and Vangorda Water Treatment Plant (WTP). The remaining 15 percent of observations of moose occurred on the Haul Road, with only a few recorded from along the Access Road. There are no moose WKAs in the FMC LSA or RSA; the nearest moose WKA lies in the Ross River valley 45 km^2 east of the Vangorda/Grum Area.

3.1.1.2 2011 Early Winter Regional Moose Survey

The early winter moose survey was conducted by EY in November 2011 and spanned across 10 GMS (Figure 6J-3). The survey covered an area of 6,470 km^2 from the Pelly River valley, northeast across the Anvil and South Fork mountain ranges to the Riddell River (Clarke et al., 2012), including the Town of Faro and the FMC. Moose were observed primarily in high elevation subalpine habitats in the Anvil and South Fork mountain ranges within the Mount Connolly and Mount Kulan areas. The intensive stratification component of the survey classified 405 survey blocks into those with a high expected moose density (n = 201) and those with a low expected moose density (n = 204). 30 percent (n = 127) of the total of 405 blocks were then randomly sampled to be included in the census component of the survey, and included 90 high strata and 37 low strata blocks (Clarke et al., 2012).

A total of 866 moose were observed during the census, including 522 cows (yearlings and adult cows combined), 210 adult bulls, 37 yearling bulls, and 97 calves. An average of 570 moose per every 1,000 km^2 were observed in high strata blocks, while an average of 80 moose per 1,000 km^2 were observed in the low strata blocks. Factoring in the SCF, Clarke et al. (2012) estimated that 12 percent and 4 percent of moose were missed from high and low strata blocks, respectively, while conducting the census survey. The total moose population within the Faro survey area was estimated to be 2,352 ±23 percent individuals and was lower than the 2004 estimate of 2,450 ±27 percent.

Clarke et al. (2012) estimate that the majority of the survey area (6,084 km^2) is considered to have high quality moose habitat, while the remaining 386 km^2 is characterized primarily by alpine habitats or large water bodies and is of limited value to moose. High moose densities in the survey area are believed to reflect the availability of high quality habitat. The average moose density was estimated at 364 moose per 1,000 km^2 of total area and 387 moose per 1,000 km^2 in suitable moose habitat (areas with shrubby browse, including subalpine and creek draws that offer willow browse)(Clarke et al., 2012). These densities exceed Yukon-wide averages of 157 and 209 moose per 1,000 km^2 in total and in suitable habitats, respectively, but were lower than the 2004 Faro area survey

densities of 379 moose per 1,000 km^2 of the total area surveyed and 403 moose per 1,000 km^2 in suitable moose habitat.

From the 2004 to 2011 surveys, the adult bull to cow ratio dropped from 53 adult bulls to every 100 cows to 42 bulls to every 100 cows in 2011. In both years; however, the ratio exceeded the Yukon average and the minimum management guideline of 30 adults bulls to every 100 adult cows. Calf survival (i.e., number of calves per 100 cows) increased from 19 in 2004 to 36 in 2011 and exceeded the Yukon average of 33, as well as the minimum management target for calf survival (i.e., 25 calves per 100 cows) to sustain a stable population. Recruitment (i.e., number of yearlings per 100 adult moose) was estimated at 10 and remained the same between the 2004 and 2011 survey events. Clarke et al. (2012) report that this recruitment value occurs within the management target of eight to 15 yearlings per 100 adult moose for ensuring a stable population increase over time.

Survey data analyzed for GMS 4-45 (which overlaps with the LSA) indicates that it has the highest average moose harvest rate of all the Yukon. Comparing the 2011 survey data with data collected in 2004 and 1997, the moose population within GMS 4-45 has declined at an annual rate of 2 percent and a total of 28 percent since 1997. The 2011 data indicate the harvest rates may be exceeding the recommended 4 percent threshold for sustaining a healthy population. Management of the area moose population has relied on the voluntary harvest restriction program; however, as quotas have been reached or exceeded in recent years, it has not been an effective management tool to limit additional moose harvest.

3.1.1.3 2012 Winter Tracking Survey

Moose were the only ungulate detected in the LSA during the 2012 winter tracking survey (ELR, 2012). Moose tracks were detected at an overall density of 0.04 TKD on active transects, and were detected incidentally (i.e., observed on transect but were older tracks of unknown age) throughout the site. The overall moose track density recorded was lower than expected for the site as suitable habitats occur within the FMC, and incidental observations were recorded across nearly all habitats types found in the LSA. The result was also lower than those of comparable studies. For example, an overall track density for moose of 0.16 TKD was recorded at the Ketza River Mine site, which is located approximately 90 km southeast of the FMC (EBA Engineering Consultants Ltd. [EBA], 2008). Several factors may have attributed to the low observed moose track density at the FMC at the time of the survey, including sub-optimal late-winter conditions such as a deep snow pack, or simply a sampling effect of the short duration of tracking surveys.

At the FMC, recent moose tracks were only detected in riparian shrub and mixed wood habitats at the time of the study, while incidental observations were more widespread (as noted above). Incidental observations from the site suggested that the majority of moose habitat use is centred around riparian areas of Rose Creek and other riparian draws.

3.1.2 Thinhorn Sheep (*Ovis dalli*)

Two subspecies of thinhorn sheep occur in the Yukon, Dall's (*Ovis dalli dalli*) and Stone's (*Ovis dalli stonei*), although southern Yukon is the northern extent for the latter. Sheep occurring in the FMC area are referred to as 'fannin', have an intermediate pelage colour between the darker Stone's sheep and the lighter Dall's sheep, and may be the result of crossbreeding (Worley et al., 2004). Fannin sheep are reported to range only in the Pelly and Ogilvie mountains. Neither Stone's nor Dall's sheep have been listed by COSEWIC.

3.1.2.1 Existing Information

Yukon hunting regulations restrict the harvest of sheep to a single full curl ram and in most of the RSA GMS harvest is managed by lottery (i.e., permit hunt authorization). EY compiles harvest information for thinhorn sheep.

Thinhorn sheep harvest data provided by EY (2013b) for five GMS surrounding the FMC (including 4-41 to 4-45) indicates a total of 56 individual sheep have been harvested in the last decade (2003 to 2012) (Table 6J-2). There were no sheep harvested from GMS 4-46, 4-47, and 4-51 during this period. GMS 4-45 had the highest number of sheep harvested overall (i.e., pooled years) followed by 4-44 and 4-41. The sheep harvest data represents

harvests by licensed resident and non-resident hunters; the harvest data does not include First Nation sheep harvest. Resident and non-resident hunters harvested 37.5 percent (n = 21) and 62.5 percent (n = 35), respectively, of all sheep reported here.

EY, 2013b, unpublished data.

Fannin sheep have been observed in the FMC in all months from May to November (AAM, 2013, unpublished data). Observation data pooled across the 5-year period from 2009 to 2013 includes observations in May (n = 495), June (n = 522), and September (n = 518) in all five years. Sheep were less frequently observed in July (n = 18), August (n = 37), October (n = 106), and November (n = 1) and were not consistently observed in all of these months in all five years. The majority of these sightings were concentrated in the Vangorda/Grum Area. Several sheep were incidentally observed during the waterfowl surveys conducted by ELR in September 2013. A large group of rams, ewes, yearlings, and lambs were observed resting at the base of the remediated slopes below the Grum Sulphide Cell. In addition, several sheep were observed along the north wall of the Grum Pit; they were variably observed to be resting or licking the exposed minerals along the north wall.

Thirty-one thinhorn sheep WKAs occur within the RSA, indicating that there are important habitats for the thinhorn sheep population in the area. The WKAs include mineral licks, seasonal ranges, and migration corridors (Figure 6J-4). Of these, four occur within the immediate FMC LSA, including portions of three migration corridors that traverse the FMC site between Mount Mye and Rose Mountain. Additionally, a portion of one winter range extends down from a southern slope of Mount Mye into the LSA.

3.1.2.2 2008 Thinhorn Sheep Summary

A total of 1,427 individual sheep locations were digitized from archived data observations that had been compiled from three sources that documented sheep occurrences over an 18-year period (1981 to 1999; Gartner Lee 2008b). Of these, rams (n = 327), ewes (n = 765), yearlings (n = 26), lambs (n = 199), and unclassified individuals (n = 110) were observed. Most observations were recorded during the summer months with few recorded during the fall and winter. The majority of individuals were observed on Mount Mye, Sheep Mountain, and Rose Mountain, with some individuals observed on Mount Kulan and the Yukon Plateau; mountain locations are indicated in Figure 6J-5. The sheep were observed to be concentrated primarily on Sheep Mountain during spring months, and were dispersed across on Mount Mye and Rose Mountain during the summer. During the fall months, sheep were observed moving along migration routes from Mount Mye to Sheep Mountain. Although few observations were recorded during the winter months, sheep were again observed to be dispersed on Mount Mye and Rose and Sheep Mountains, as well as lower elevations in these areas.

Gartner Lee Limited (2008b) reported that during the YG telemetry program, a total of nine ewes were collared and monitored during a 7-month period from November 1989 to May 1999. A total of 118 telemetry locations were collected among the nine animals during this time and only five ewes were collared and monitored for the full 7-month period. One ewe was collared and monitored only during the winter months and the remaining four ewes were collared and monitored only in the spring months. Telemetry locations for all individuals during the winter and spring months were clumped on the southern slopes of Sheep Mountain. During spring months, locations for two ewes were recorded on the western slopes on Sheep Mountain, followed by movement to higher elevations during the lambing season.

Gartner Lee Limited (2008b) synthesized data from all archived data sources to summarize seasonal range use by thinhorn sheep in the Faro area. Data indicate that while ewes, yearlings, and lambs spent winter months in groups on the south slopes of Sheep Mountain, rams were observed on the western slopes indicating these areas are important winter range. From their wintering and early spring areas on the lower slopes of Sheep Mountain, ewes were observed to move to higher elevations to lamb. During summer months, all age classes were observed to disperse to more general habitats including areas of Mount Mye, Rose Mountain, Blind Creek and Swim Lakes, Sheep Mountain, and the FMC. Observations recorded during rutting season were very limited and rams were only observed during this period on Sheep Mountain.

One additional sheep winter range occurs on the southern slopes of Mount Mye within 1 km of Grum Pit. Additional wintering areas were also identified but do not fall within the LSA; these include Blind and Swim Lakes, Pelly River Bluff, Rose Mountain, and areas along Vangorda Creek.

3.1.2.3 2011 Anvil Range Lambing Survey

During the lambing survey in June, a total of 192 sheep were observed in five mountain blocks in GMS 4-41, 4-45 and 4-46 (EY, 2011, unpublished data) (Figure 6J-5); the latter two of which overlap the northern boundary of the LSA. Of the total number of sheep observed, 12 percent were lambs (n = 23), 10 percent were ewes (n = 20), 12 percent were rams (n = 23) and 66 percent were unclassified (i.e., unknown sex) adults (n = 126). As a result of the large proportion of unclassified individuals during the June survey, EY was not able to calculate sex ratios (2011, unpublished data). Furthermore, due to survey conditions that likely resulted in missed observations, it was not possible to compare lamb data between the two surveys to determine lamb survival during their first month of life.

During the post-lambing survey conducted in July of 2011, EY surveyed eight GMS (4-17, 4-41, 4-43 to 4-46, 4-48, and 4-51) (Figure 6J-5). Combined productivity was estimated to be 27 lambs per 100 nursery sheep for all surveyed GMS, which suggests a stable population (EY, 2011, unpublished data). The combined ram to ewe ratio was estimated at 61 rams per 100 nursery sheep. EY (2011, unpublished data) cautions that while the observed proportion of rams is higher than average for a hunted population, that hunting pressures have increased in the area, particularly in GMS 4-45, because of an increase in access. EY (2011, unpublished data) reports that the primary management concern for the surveyed population at this time is an increase in mineral exploration activities in the area.

Although there were no observations of sheep in the FMC during the 2011 survey, there was a report of a nursery group observed along the Grum Pit edge in early June. It was suggested that these sheep may have been en route from their winter to summer range along a migration corridor between Sheep Mountain and Mount Mye (EY, 2011, unpublished data).

3.1.3 Caribou (*Rangifer tarandus caribou*)

The annual ranges of four woodland caribou (Northern Mountain population; *Rangifer tarandus caribou*) herds, occur in the Faro region and include the Tay River, Finlayson, Moose Lake, and Pelly herds (EY, 2012). Only the annual range of the Tay River caribou herd overlaps the project RSA. The Tay River herd annual range extends from the Pelly River in the south to the upper Stewart River in the north, east to the Ross River and west to Moose Lake. The Tay River herd overlaps with the Moose Lake caribou herd in the west, shares a boundary with the Pelly herd in the south and roughly meets the western extent of the Finlayson herd in the Ross River valley. Caribou observed within the FMC LSA therefore most likely belong to the Tay River herd, with limited potential for

observing individuals from the Pelly herds (Alain Fontaine, Liard Area Regional Biologist, personal communication). There are no caribou WKAs within the project LSA or RSA.

All woodland caribou of the Northern Mountain population are ranked by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) and are listed under Schedule 1 of SARA as a species of special concern. Caribou are traditionally hunted for food and have a high local value for both First Nations and Yukon residents. EY hunting regulations limit licensed hunters to one bull caribou per year in the Faro region; however, GMS 4-51 is closed to all big game hunting (EY, 2013a). A Department of Renewable Resources report stated that the annual harvest from the Tay River herd was estimated to be approximately 1 percent of the population in 1996 and was considered to be a sustainable amount at that time (Gartner Lee Limited, 2008a).

3.1.3.1 Existing Information

Caribou have infrequently been observed in the FMC according to the FMC Incidental Wildlife Log records (AAM, 2013, unpublished data). Over the five years of wildlife reporting, there have been 13 recorded caribou observations onsite. Observations have occurred in the months of May, June, or July only, in 2010 (n = 1), 2011 (n = 4), 2012 (n = 6) and 2013 (n = 2). Caribou were observed in several locations including on the haul road, near Rose Creek, in the area of the Faro diversion, near the Grum Dump meteorological station, and near the ETA.

EY (2013b) provided caribou harvest data for GMS in the FMC RSA for the 10-year period from 2003 to 2012 (Table 6J-3). During this period, 119 caribou were harvested from GMS 4-41 to 47; however, no caribou were harvested from GMS 4-51. When considering 2003 to 2012 data, caribou harvest was highest in GMS 4-45 (n = 83), and next highest in GMS 4-46 (n = 19). The majority (72 percent) of all caribou were harvested between 2005 and 2009, with notably lower harvest number in recent years. The EY data includes harvests from resident, non-resident (i.e., outfitter guided), and special guided hunters and does not include First Nation harvest. Resident, non-resident, and special guided hunters harvested 75 percent (n = 89), 19 percent (n = 23), and 6 percent (n = 7), respectively, of all caribou reported here.

EY, 2013b, unpublished data.

3.2 Carnivores

Several carnivore species occur in the FMC area and are discussed according to species group or family below. Although both grizzly and black bears are known to occur in the area, only grizzly bears are discussed here to due to their conservation status and the ecological and socio-economic value of the species. Furbearer information is summarized according to mustelid, canid, and felid family groups. Although considered a furbearer, red squirrels are discussed with small mammals in Section 3.4.

3.2.1 Grizzly Bear (*Ursus arctos*)

Grizzly bear (*Ursus arctos*) are often considered to be a keystone species and referred to as ecological indicators, as they are critical components to ensuring ecosystem diversity and integrity. Grizzly bears range across the entire territory, with the exception of the southwestern limit of the Yukon (which is characterized by the largely uninhabitable Icefield Ranges of the St. Elias Mountain Range). The western population of grizzly bears is listed by COSEWIC as a species of special concern but currently has no protection status under SARA.

Resource development activities are a limiting factor for grizzly bears and can result in habitat loss or fragmentation and an increased potential for mortalities due to human-bear encounters. In addition to this, the species has a naturally low, reproductive rate reproducing once every six to seven years. EY is making efforts to reduce female grizzly bear harvest numbers to reduce the impact of removing reproductive females from the population. Hunting regulations restrict bag limits to one bear every three license years (EY, 2013a). There are spring and fall hunts in the Faro area GMS, but GMS 4-51 (i.e., spans the Pelly River valley immediately to the southwest of the Town of Faro) is currently closed to all big game hunting (Figure 6J-6).

3.2.1.1 Existing Information

EY (2013) provided Grizzly bear harvest data for GMS in the FMC area for the ten-year period from 2003 to 2012 (Table 6J-4). During this time, a total of 13 grizzly bears were harvested across GMSs 4-41 to 4-47 and 4-51 inclusive, ranging from 0 to 2 bears in any one year within individual GMSs. No Grizzly bear harvests were recorded for GMS 4-43 or 4-46, and no Grizzly bear harvests were recorded for any GMS in 2007, 2008, and 2010. When considering all 10 years, GMS 4-45 had the highest number of grizzly bear harvests (n = 4) among the data provided.

TABLE 6J-4

EY, 2013b, unpublished data.

The FMC Incidental Wildlife Log indicates a total of 60 grizzly bear sightings occurred from May 2009 to July 2013 (AAM, 2013; unpublished data). This is likely an underestimate, as bear sightings were classified in the records as either grizzly bear (n = 60), black bear (n = 58) or bear (n = 37). Thus, the 'bear' category would likely include bears of either species. Pooled for all years, grizzly bear sightings occurred during the period of April to October, with the most observations recorded each May (n = 21), followed by June (n = 17). Furthermore, grizzly bears were consistently observed during the month of May in all five years of observation records while the timing of sightings was not consistent across observation years. Of the 60 grizzly bear records, four observations were of sows with either one, two or three cubs, accounting for a total of 12 of the individual observation records. Approximately half of the grizzly bear observations occurred in the Faro Mine Area, including areas in proximity to the CVD and CVD Pond, RCD, ID Pond, Rose Creek Tailings Area and the Faro Pit and Diversion. A third of the

grizzly bear observations occurred in the Vangorda/Grum Area, including areas in the vicinity of the Grum Pit, Grum Sulphide Cell, Vangorda Flume and Sheep Pad Ponds (SPP). The remaining 20 percent of observations occurred along or near the Haul Road.

For comparison, black bear sightings were also the most abundant (n = 22) during the month of May, which was the only month during which sightings occurred during all five years of record. June (n = 11) and July (n = 12) were the next most common for black bear observations. While there was only one observation of a black bear sow with two cubs, there were another six sightings of a bear sow 'with two cubs' (n = 6) and 'with cubs' (n=9). Black bear and bear sightings occurred equally frequently, with approximately one third of observations occurring in each of the Faro Mine Area, Vangorda/Grum Area, and the area in between these (including the Haul Road, mine Access Road, and the Freshwater Dam area). Faro Mine Area sighting locations included the parking lot and guardhouse area, as well as areas in the vicinity of Rose Creek and the RCD, ID Pond, Rose Creek Tailings Area, ETA, S-Wells and Sludge Cells, as well as generally in the Down Valley area. In the Vangorda/Grum Area, observations were made near the SPP, Little Creek Dam, Grum Pit, Grum Sulphide Cell, Grum Haul Road, Vangorda Pit, and Vangorda WTP Sludge Pond.

The immediate project footprint has limited habitat that is suitable for grizzly bear life requisites due to the disturbed nature of most areas; however, reclaimed areas that support grass species growth, surrounding woodlands and shrubby subalpine hillsides likely provide vegetation species for foraging (e.g., berry-producing shrubs such as *Hedysarum* sp.) as well as potential prey items (e.g., ungulates and arctic ground squirrels).

3.2.2 Furbearers

Many furbearing species are common to the Yukon and include American marten (*Martes americana*), ermine (short-tailed weasel; *Mustela erminea*), mink (*Mustela vison*), fisher (*Pekania pennanti*), wolverine (*Gulo gulo*), otter (*Lontra canadensis*), beaver (*Castor canadensis*), muskrat (*Ondatra zibethicus*), Canada lynx (*Lynx canadensis*), red squirrel (*Tamiasciurus hudsonicus*), as well as grey wolf (*Canis lupus*), coyote (*Canis latrans*), red fox (*Vulpes vulpes*), and arctic fox (*Vulpes lagopus*) (EY, 2013c). Among these species, COSEWIC has indicated that the Canada lynx is not at risk. The wolverine is listed as special concern by COSEWIC although is not currently listed under SARA; the wolverine is believed to be stable within the Yukon (Yukon Conservation Data Centre, 2011). The remaining species listed here have not been assessed by COSEWIC.

Trapper harvest of furbearers is an important economic activity in much of the Yukon. The FMC falls within a large group trapping concession that is approximately 35,400 km^2 in size.

The 2012 winter tracking survey provided local data set describing the presence and abundance of furbearers within the LSA (ELR, 2012). During this study, a total distance of 35.28 km was surveyed along tracking transects (Figure 6J-6), resulting in a total survey effort of 77.3 km days. Winter track study results for furbearers is presented below according to species and FMC Wildlife Incidental Log data is included where furbearing species data exists.

3.2.2.1 Mustelids

Five mustelid species were detected during the 2012 winter tracking survey (Table 6J-5). American marten and ermine were the most commonly detected mustelids, while one set of fisher tracks were observed. Mustelid species were detected in all functional habitat types occurring on the FMC but were highest in habitats having a conifer species component (i.e., mixed, pine, or conifer). The fewest mustelid detections were recorded in non-riparian shrub, deciduous and footprint habitat types (Table 6J-6).

TABLE 6J-5

American Marten

A total of 60 marten observations were made during the 2012 winter tracking survey, with an overall track density of 0.77 TKD within the LSA (ELR, 2012). Marten were detected on active track transects in all habitat types within the LSA, with the highest density recorded in pine forest at 3.06 TKD. The next highest densities were recorded in mixed forest and mature conifer (i.e., spruce) at 1.30 and 0.87 TKD, respectively. While marten are reliant on complex habitats, mature forest cover, and a suitable prey base, they are sometimes generalist in nature. FMC observations across all habitats are likely the product of complex habitat, thermal and snow cover, and an abundance of prey items such as red squirrel and grouse.

Five marten observations were recorded in the FMC Incidental Wildlife Log (AAM, 2013, unpublished data). Observations were recorded near the gatehouse, the Down Valley Lower Gate, and the Faro Creek Diversion, and also on the haul road.

Fisher

Putative fisher tracks were detected once on active track transects (in conifer forest), resulting in an overall average track abundance of 0.01 TKD during the 2012 winter tracking survey (ELR, 2012). Three putative incidental observations of fisher tracks were also recorded in white spruce/willow and footprint habitats; they were identified primarily in mature conifer habitats (0.05 TKD) within the study area. Distinguishing fisher tracks from marten

tracks can be difficult; as there is an overlap in trail size between mature male marten and female fisher (there is a track width overlap between the species from approximately 3.5 inches wide to 4.25 inches wide). Track patterns tend to differ between the species, with fisher alternating between two, three, and four track patterns frequently, while marten tend to primarily use a two track bounding pattern. During the 2012 study, a combination of track size and pattern was used for identification; however tracks that could not be positively identified as fisher were classed as marten (if in the intermediate track width range). The identification of fisher tracks at the FMC is of interest, as this location is outside of the current known range of fisher in the Yukon Territory (Jung and Slough, 2011).

Fisher generally occur in mature forests with dense canopies and a high level of habitat complexity. Their detection in the LSA could suggest the presence of quality habitat (i.e., for reproductive denning) and a suitable abundance of prey items (also supported by the current study results). Fishers are also specialist predators on porcupine, which were detected in several habitats within the LSA.

Wolverine

While wolverines are expected to occur in the LSA, no signs of wolverine presence or activity were observed during the 2012 tracking survey (ELR, 2012). Wolverines have very large home ranges that can range from 100 to 500 km^2, and therefore the absence of track observations does not exclude their presence in or use of the LSA. Due to this large home range size, ground tracking surveys are not well suited to determining wolverine presence or density.

Over the 5-year record, two wolverine sightings were recorded in the FMC Incidental Wildlife Log (AAM, 2013, unpublished data). One individual was spotted along the haul road in June 2011 and the second individual was observed at the back of the mill in June 2012.

Ermine, least weasel and mink

Ermine (also known as short-tailed weasel) were detected during the 2012 winter track study on active track transects in six of the eight primary habitats, with the highest density being in coniferous forest at 1.24 TKD (ELR, 2012). The habitat type with the next highest density of ermine tracks was riparian shrub, with 0.54 TKD. Ermine were observed incidentally (i.e., observed during the study but not while on active tracking transects) ten times including a visual observation. Incidental observations were primarily made in white spruce/willow and non-riparian shrub habitats. Ermine were detected in six of the eight LSA habitat associations, with highest densities being in mature conifer and riparian shrub habitats and an overall track density for the site of 0.59 TKD. This figure again suggests the presence of suitable habitat and abundant prey species in the area.

Least weasel was detected only once as an incidental observation, in willow/dwarf birch shrub habitat.

Mink were detected only once on an active track transect and once incidentally, both occurring in mixed forest (Table 6J-6). The overall average track density recorded for mink was 0.01 TKD.

3.2.2.2 Canids

Grey wolf, coyote, and red fox were all detected during the 2012 winter tracking survey at low densities (ELR, 2012). Grey wolves were detected only once on an active track transect and four times as incidental observations. Collectively, these detections occurred in coniferous forest, in footprint areas, on the mine access road near the Vangorda Pit, and near the Grum waste rock piles. Grey wolves are known to utilize roads and linear corridors for movement through the landscape, and this behavior was observed at the Faro Mine site (tracks observed along the main haul road); however, wolf tracks were also observed in forested stands with pine and mature white spruce.

Neither foxes nor coyotes were detected on regular transects during the tracking survey. Coyotes were only detected four times as incidental observations; three times amongst waste rock piles near the mill site, and once near the prior freshwater reservoir. Red fox were only detected twice as incidental observations and both observations were made amongst the waste rock piles near the mill site. A low level of detection for these species was expected based on the level of tracking effort at the site. Incidental observations, primarily near disturbance areas, show that they are using the LSA area, although their movements and habitat use may be closely tied to

the existing footprint infrastructure. Coyotes and foxes are generalist feeders, and are likely taking advantage of prey species such as ptarmigan that were observed to be concentrated in areas of disturbance.

Wolf and fox sightings were the most common records among furbearer species in the FMC Incidental records. Of a total of 142 furbearer observations, 64 were wolf and 47 were fox observations (AAM, 2013, unpublished data). Wolves were observed in all months except February, but records were variable across the 5-year period. Red fox sightings occurred between February and November, and were variable among years. Both wolf and fox observations were from a range of locations at the FMC, including the haul and main access road, the pits and ponds, in the parking lot at the guard house, and in the Rose Creek diversion area. These furbearer species were the most commonly sighted but they are also the most conspicuous. Additionally, several observations occurred within a short period of time from each other suggesting multiple sightings of the same individual or individuals.

3.2.2.3 Felids

Four incidental Canada lynx observations were recorded during the 2012 winter tracking survey, however no detections were recorded on active track transects (ELR, 2012). Lynx tracks were observed in willow/dwarf birch, willow/white spruce, white spruce/willow, and footprint habitats. The incidental detections suggest that lynx are using the LSA area but at a relatively low density. Conversely, detections of hare tracks were relatively high, and suitable habitat was observed within the LSA area. During the 5-year period of FMC Incidental Wildlife reporting, lynx were observed four times; once in 2009 and three times in 2010.

3.3 Avian Species

Many areas surrounding the Town of Faro and the FMC offer suitable habitats for a wide range of avian species, including waterfowl, shorebirds, songbirds, upland game birds and raptors. EY (2003) estimates that approximately 160 avian species occur in the Faro and Ross River area out of the 279 species known to occur in the Yukon. CWS and USGS bird database queries produced a pooled list of 28 water bird and 39 land bird species (Tables 6J-6 and 6J-7, respectively) that have been observed in the Faro area (potentially within the FMC RSA). The most commonly observed species included white-winged crossbill, dark-eyed junco, common raven, Swainson's thrush, hermit thrush, gray jay and American robin. Lesser yellow legs and sandhill crane were also commonly sighted.

A total of 10 waterfowl species were observed during the 2013 waterfowl survey (Table 6J-7; ELR, 2013). Gartner Lee Limited (2008a) reported incidentally observing gulls near the tailings pond and as well as a Harlan's hawk (a dark morph of a red-tailed hawk; *Buteo jamaicensis harlani*) while conducting a vegetation classification study in 2007. Also incidentally observed during this study was a bank swallow colony, located along an exposed road cut on the access road to the CVD Pond water pump station. The FMC Incidental Wildlife Log records included several avian observations including bald eagle, swan, snowy owl, grouse, ptarmigan, common raven and sandhill crane (AAM, 2013, unpublished data).

Migratory species are protected under the *Migratory Birds Convention Act* and there are provisions in the Yukon *Wildlife Act* for non-migratory species; specifically Section 17 of the latter refers to the protection of non-migratory species eggs and nests. Four species observed onsite are considered to be of conservation concern:

- Bank swallow (*Riparia riparia*) - Threatened (COSEWIC)
- Harlequin duck (*Histrionicus histrionicus*) - Special Concern (COSEWIC and SARA Schedule 1)
- Horned grebe (*Podiceps auritus*)- Special Concern (COSEWIC)
- Trumpeter swan (*Cygnus buccinator*) - Specially Protected (Yukon *Wildlife Act*)

The olive-sided flycatcher (*Contopus cooperi*) has not been specifically observed onsite but has been recorded as occurring in the Faro area. It is listed by COSEWIC as a threatened species and is listed under Schedule 1 of SARA. The olive-sided flycatcher is associated with open areas containing or adjacent to mixed or coniferous mature forest with snags or tall live trees (COSEWIC, 2007). Open areas can include natural or anthropomorphic clearings, often near or adjacent to wetland areas. Tall trees are used for perching and coniferous trees are used for nesting.

Six avian species were observed during the winter tracking surveys conducted in March 2012, and included detections (i.e., signs or sightings) of common raven, boreal chickadee, common redpoll, gray jay, ptarmigan and

grouse (ELR, 2012). Ptarmigan and grouse were the second most abundant species group detected during the 2012 winter tracking survey, and were found among five of the eight primary FMC habitat types. Ptarmigan and grouse track density was highest in non-riparian shrub habitat at 10.56 TKD. Disturbance areas, mixed, and conifer forest habitats also had moderately high densities of 3.82, 2.43, and 2.25 TKD, respectively. Incidental observations were also made, including many visual observations. The majority of incidentals were observed in non-riparian shrub and footprint areas. Overall, 235 ptarmigan and grouse observations were made during the study (some of which were groups of several individuals), with the overall average density of tracks on transects being 3.00 TKD.

3.3.1 Waterfowl Observational Survey Results

A total of 60 person hours of observation time was spent at the FMC pits and ponds during September of 2013 (ELR, 2013, unpublished data). During this time, observers recorded a number of sightings of waterfowl using the various pits and ponds. In summary, a total of 40 individuals representing nine species were observed at the 11 sites during the fall survey period (Table 6J-8). The type and number of species observed are summarized in Table 6J-8. The locations of the assessed sites and waterfowl observations in the Faro Mine and Vangorda/Grum Areas are provided in Figure 6J-7a and Figure 6J-7b, respectively. All species observed were in their non-breeding plumage, and were observed diving, foraging, dabbling, drinking and resting in the various habitats in the FMC.

TABLE 6J-9
Waterfowl Observations for Faro Mine Pits and Ponds
Faro Mine Remediation Project

Pond/Pit Name	Species Observed (Common Name)	Species Observed (Common Name)	Number	Comments
Intermediate Dam (ID) Pond	American wigeon	Anas americana	3	Drinking and preening.
Sheep Pad Ponds (SPP)	Common goldeneye	Bucephala clangula	2	Actively diving and foraging.
	Harlequin duck	Histrionicus histrionicus	4	Actively diving and foraging.
Slot Cut in Grum Pit	Spotted sandpiper	Actitis macularius	1	Actively foraging along muddy shore.
Ponded Water on Tailings Facility	Herring gull	Larus smithsonianus	6	Observed to be preening in wetted area.
Cross Valley Pond	Harlequin duck	Histrionicus histrionicus	1	Observed diving, foraging near pump at southeast corner of pond.
Slot Cut in Grum Pit	Harlequin duck	Histrionicus histrionicus	4	Same birds as from SPP, observed diving and foraging.
Faro Pit	Red-breasted merganser	Mergus serrator	5	Resting on water.
	Horned grebe	Podiceps auritus	5	
	Surf scoter	Melanitta perspicillata	9	
	Barrow's goldeneye	Bucephala islandica	4	

3.3.2 Waterfowl Habitat Assessment

3.3.2.1 Habitat Descriptions

Habitat structure was considered at each pit and pond as it relates to value for waterfowl. As each of the assessed pits and ponds have been altered or constructed for the purposes of water holding and treatment for mine operation, their respective structures and vegetation composition were found to reflect this heavily altered state.

Well-established vegetation was observed at the RCD, Slot Cut in Grum Pit, and SPP. Ponds in the North Fork of Rose Creek below the access road are largely naturalized, with significant riparian vegetation, aquatic vegetation including algae, horsetails, various shrubs and forbs along the shores. The diversion reach is armoured with large rip-rap, creating a straight channel, though some pooling is created above the diversion reach where remnants of the original channel are present. Numerous patches of horsetail, willow and various grasses and sedges were observed at Slot Cut in Grum Pit. In addition, some willow has established in the riparian areas, as have some moss species along the coarse slope material.

Areas of grass, sedge and some emergent and aquatic vegetation were observed along the shores of the CVD Pond and Grum Settling Pond. Both ponds are constructed with armoured sidewalls that drop steeply into the pond (i.e., Grum Settling Pond) or gradually slope into the water (i.e., CVD Pond). Where silt and sediment have entered GSP from the adjacent Vangorda WTP Sludge Pond, the accumulation of fine material has allowed the establishment of some grasses and sedges. Riparian vegetation is sparse in the CVD Pond, but there are patches of emergent and aquatic vegetation where the gently sloping shores support mud and silt substrate allowing common horsetail (*Equisetum arvense*), milfoil (*Myriophyllum sp.*) and a variety of grasses and sedges to become established.

Limited vegetation establishment was observed at the remaining ponds, including the ID Pond, the Faro, Grum and Vangorda Pits, the Slot Cut in Grum Pit and the Little Creek Pond (LCP). The ID Pond is highly contaminated, preventing the successful establishment of any aquatic vegetation and allowing only limited riparian vegetation. Vegetation that is able to grow around the perimeter shows significant signs of stress. Faro, Grum, and Vangorda Pits were not sampled, as it was assumed for the purpose of this study that the depth of the pits would prevent contact with any sediment on pit bottoms. These pits were created as a by-product of mining extraction and their steep walls prevent vegetation establishment.

The Vangorda Water Treatment Plant (WTP) Sludge Pond is a constructed feature used for the storage of treated water from the Vangorda/Grum Area. This pond is heavily altered annually with the complete draining and dredging of sludge preventing the establishment of any riparian or aquatic vegetation. The LCP receives water from the Vangorda Waste Rock Dump and significant blackened vegetation exists around the entire perimeter of the pond. No aquatic vegetation exists, and the sparse horsetails present above the water line appear highly stressed.

3.3.2.2 Benthic Invertebrates

Based on preliminary invertebrate data available at the time of this report, benthic invertebrate diversity was markedly different between the ponds, and appears to relate to the degree of local disturbance. No invertebrates were found in the sediments from the ID Pond and LCP. Sampling results from the CVD Pond and the Grum Settling Pond yielded relatively low abundance and diversity when compared to what would be expected in natural unaffected wetlands. Samples from the SPP and the Slot Cut in Grum Pit did yield relatively higher abundance of invertebrates relative to the other sites sampled in the FMC, but still significantly lower in abundance compared to that which would be expected in an unaffected wetland or pond habitat.

3.3.3 Results of Metals Analyses

3.3.3.1 Sediment

Metals levels in sediment samples collected in the FMC Ponds in 2013 were compared to CCME Sediment Quality Guidelines for the Protection of Aquatic Life (CCME, 1995; ISQG and PEL, as described in Section 2.4.1, above). A summary of data for seven key metals (copper, chromium, cadmium, mercury, lead, arsenic, and zinc) is provided in Table 6J-9, including a comparison of metals levels with CCME guidelines. Bold text indicates those results that exceed the ISQG, while shaded results indicate that the detected level also exceeded the PEL.

Sediment samples from each of the ponds sampled exceeded the CCME ISQG or PEL sediment guideline levels for at least one metal. Sediment from the CVD Pond exceeded the ISQG limits for cadmium, chromium, copper, and mercury, and exceeded the PEL for lead, arsenic, and zinc. Sediment from the LCP exceeded the ISQG for chromium, cadmium and pH, the PEL for lead, arsenic, and zinc. Sediment from the ID Pond exceeded the PEL for copper, mercury, lead, arsenic and zinc, and exceeded the ISQG for pH. Sediment from the SPP exceeded the PEL

for lead, arsenic and zinc; and exceeded the ISQG for mercury and cadmium. Sediment from the Grum Settling Pond exceeded the ISQG for cadmium, lead, arsenic, and zinc. Sediment from the Slot Cut in Grum Pit exceeded the ISQG for lead, zinc and cadmium, and the PEL for arsenic. While not exceeded, chromium levels in the Slot Cut in Grum Pit were measured to be 36.4 milligrams per kilogram (mg/kg), with the ISQG being 37.3 mg/kg.

TABLE 6J-10

[a] Results in bold text indicate that the detected level exceeds the ISQG, and shaded results indicate that the detected level also exceeded the PEL.

[b] The pH range has been taken from the Water Quality Guidelines for the Protection of Aquatic Life as no guidelines for pH currently exist for sediment levels.

3.3.3.2 Vegetation

A summary of metals levels in aquatic and riparian vegetation collected at FMC ponds in 2013 is provided in Table 6J-10. Metal levels in the vegetation tissue samples were compared to sediment metals levels from the same pond to assess whether accumulation in aquatic and riparian plants may be occurring. Results where vegetation metals concentrations exceeded corresponding sediment metals levels are shaded in the table.

Copper and chromium levels were found to be elevated at the LCP. Elevated levels of cadmium were detected in vegetation from the CVD Pond, LCP, ID Pond, SPP, and Slot Cut in Grum Pit. Elevated levels of mercury in vegetation were only detected from the third sample location in the CVD Pond. Elevated lead concentrations in vegetation samples were detected at CVD Pond, ID Pond, LCP and SPP. Arsenic vegetation levels were elevated in samples from the CVD Pond, LCP, ID Pond, and the SPP. Zinc concentrations were elevated in vegetation samples from all ponds except the Grum Settling Pond and the Slot Cut in Grum Pit.

[a] Shaded results indicate instances where the concentration of a particular metal in aquatic or riparian vegetation exceeded that of sediment in the same pond or area.

3.3.3.3 Habitat Potential

Based on an assessment of waterfowl observations at the studied pits and ponds of the FMC, five of the FMC ponds were considered to have stop-over and feeding potential (CVD Pond, Pumphouse Pond, Grum Settling Pond, Slot Cut in Grum Pit, and SPP). Six other pits and ponds were considered to likely only provide stop-over potential (ID Pond, Faro Pit, Grum Pit, Vangorda WTP Sludge Pond, Vangorda Pit, and LCP). Habitat characteristics and habitat potential for each pit and pond studied is provided in Table 6J-11, while a summary of habitat data, metals information and habitat potential for the pits and ponds studied is provided in Table 6J-12.

TABLE 6J-12
Summary of Habitat Characteristics and Habitat Potential for FMC Pit and Ponds Assessed During the 2013 Waterfowl Study
Faro Mine Remediation Project

Name	Habitat Characteristics	Suitability and Potential
Faro Pit	Water accumulation resulting from ore extraction. No riparian, aquatic or emergent vegetation. Steep slopes and hard rock banks.	**Stop-over**: open water provides suitable stop-over habitats for migrating waterfowl. No opportunities for foraging identified.
Grum Pit	Water accumulation resulting from ore extraction. No riparian, aquatic or emergent vegetation. Steep slopes and hard rock banks.	**Stop-over**: open water provides suitable stop-over habitats for migrating waterfowl. No opportunities for foraging identified.
Vangorda Pit	Water accumulation resulting from ore extraction. No riparian, aquatic or emergent vegetation. Steep slopes and hard rock banks.	**Stop-over**: open water provides suitable stop-over habitats for migrating waterfowl. No opportunities for foraging identified.
CVD Pond	Armoured sides, some deposition of sediment, steep slopes, emergent and aquatic vegetation, moderately developed riparian in isolated areas.	**Feeding/Stop-over**: some mud and sand areas, gently sloping allows easy access to emergent and aquatic vegetation by ducks and geese. Benthic invertebrates present.

TABLE 6J-12

Summary of Habitat Characteristics and Habitat Potential for FMC Pit and Ponds Assessed During the 2013 Waterfowl Study

Faro Mine Remediation Project

Name	Habitat Characteristics	Suitability and Potential
ID Pond	Sloping sides, minimal riparian area, minimal emergent or aquatic vegetation, water quality influenced by tailings and sludge.	**Feeding/Stop-over**: no aquatic vegetation is present and riparian vegetation is highly stressed, so offers limited foraging opportunities. Tailings sludge creates mud flat-like feature, potentially attracting migrating waterfowl.
Rose Creek and Rose Creek Diversion (Pumphouse Pond)	Natural watercourse with well-established riparian area in non-diverted channel areas, riffle-pool morphology, significant emergent and aquatic vegetation.	**Feeding/Stop-over**: well-established riparian, emergent and aquatic vegetation is this structurally diverse aquatic habitat.
Vangorda WTP Sludge Pond	Constructed pond used in collection of treated water. Pond water is drained each Fall, with accumulated sludge dredged and placed in a sludge storage facility. Steep sides and no aquatic vegetation exist. Riparian vegetation is heavily altered and managed in order to allow safe access and maintenance.	**Stop-over**: aquatic and riparian habitat is heavily modified through annual dredging of sludge from pond. No emergent or aquatic vegetation, benthic community poorly developed. Open treated water provides suitable stop-over habitat for migrating waterfowl.
Grum Settling Pond	Semi-natural dug-out pond receiving treated water from Vangorda WTP Sludge Pond. Riparian vegetation is poorly developed due to artificial nature of pond; however, emergent and aquatic vegetation present.	**Feeding/Stop-over**: benthic invertebrates present, some emergent vegetation becoming established. Open water suitable for stop-over of migrating waterfowl.
Slot Cut in Grum Pit	Resulting from waste rock piles, receiving runoff from Grum waste rock above. Shallow, muddy pond with significant emergent and aquatic vegetation to southeast end. Minimal riparian vegetation present due to disturbed nature of area.	**Feeding/Stop-over**: mud flat and open water with well-established emergent vegetation and benthic invertebrate communities provides potential habitat for resident or migratory waterfowl.
SPP	Water accumulation from small drainage collects in north pond, flows into south pond through above-ground metal culvert.	**Feeding/Stop-over**: significant riparian, emergent and aquatic vegetation with well-established benthic invertebrate community provides potential habitat for resident or migratory waterfowl.
LCP	Heavily contaminated resulting from runoff from Vangorda waste rock piles upslope. Blackened vegetation around perimeter and in path of runoff. Sparse riparian vegetation around perimeter.	**Stop-over**: no emergent or aquatic vegetation, and does not consistently hold water. Provides low-value habitat for migrating waterfowl and contaminant level likely contributes to lack of forage availability.

[b] Based on analytical results from samples collected by ELR field staff during field surveys in September 2013

[c] Based on water quality sampling program data (C&M).

[d] Assumed to be present based on observations at site by ELR field staff during field surveys in September 2013.

[e] Not sampled; Assumed to be not present based on pit depth and composition of surrounding substrate (i.e., rock).

[f] Not sampled; Assumed to be not present due to annual dredging and composition of surrounding substrate (i.e., rock, gravel and sand).

3.4 Small Mammals

Small mammals are considered to be ecologically important as some species are considered furbearers (i.e., red squirrels) but most are prey species for land-based carnivores and raptors and support the basis for an ecosystem food web; small mammal species are defined accordingly within this report to include snowshoe hare and porcupine, in addition to species (e.g., small rodents, squirrels, and chipmunks) typically included within this group. Several small mammal species have been observed within the FMC LSA, none of which are listed by COSEWIC, and are discussed below.

A contaminant-related study that sampled from small mammal populations was conducted at the FMC between 2004 to 2005 and documented the presence of several small mammal species (Gartner Lee Limited, 2006). These species included northern red-backed vole (*Clethrionomys rutilus*), common shrew (*Sorex cinereus*), heather vole (*Phenacomys intermedius*), deer mouse (*Peromyscus maniculatus*), Siberian lemming (*Lemmus sibiricus helvolus*), and least chipmunk (*Tamias minimus*).

Both the 2012 winter tracking survey (ELR, 2012) and the FMC Incidental Wildlife Log (AAM, 2013, unpublished data) included observations (including signs or sightings) of snowshoe hare, porcupine, and red squirrel. Mice and vole sightings were also recorded in the log records. Small mammals (mice and voles) were detected in four of the eight primary habitat types during the winter tracking survey. They were most commonly observed in disturbance areas and in pine forest, with densities of 0.58 and 0.38 TKD, respectively. Small rodent tracks were also recorded twice during incidental observations, in non-riparian shrub and pine habitats.

The red squirrel was the most frequently detected species during the tracking survey, with an average track density of 6.15 TKD across all LSA habitats, and having particularly high densities in pine, mixed, deciduous, and riparian shrub habitats. Red squirrels generally have a preference for mature conifer forests (spruce and pine) as these habitats provide a more consistent supply of food (cones), thermal and visual cover, as well as a thick canopy for movement above ground. Their overall high population density is believed to be a factor of the abundance of pine forests within the LSA, and suggests that an excellent prey base is available for species groups such as raptors, mustelids, and canids.

The snowshoe hare was the third most abundant species group detected during the tracking survey with an overall average density of 2.90 TKD. Hare were detected most frequently in deciduous and pine forest habitats.

Four porcupine observations were made on active track transects, all of which were observed in non-riparian shrub, mixed, and coniferous forest habitats, with densities of 0.11, 0.09, and 0.09 TKD, respectively. Porcupine tracks were observed six times incidentally in non-riparian shrub, deciduous, riparian shrub, and pine habitats. Both tracks and feeding sign were observed.

3.5 Amphibians

Five species of amphibians are known to occur in the Yukon; however, based on the distribution of these species the wood frog (*Rana sylvatica*) is the only likely species to occur in the FMC area (EY, 2005). One wood frog was observed by a field crew in the Vangorda/Grum area while conducting a vegetation classification survey in July 2007 (Garner Lee Limited, 2008a). Wood frogs are not at risk at the territorial or federal level, and are not anticipated to be abundant at the FMC. There are no reptile species found within the Yukon (Canadian Amphibian and Reptile Conservation Network, 2012).

3.6 Invertebrates

One 'Species of Conservation Concern' polygon was found to occur within the FMC RSA using the YESAB Geolocator. The Yukon Conservation Data Centre results indicate that the polygon was established after a single specimen of a dragonfly species known as the Canada darner (*Aeshna canadensis*) was observed at this location. The Canada darner is ranked as critically imperiled in the Yukon by NatureServe (2013). The polygon is located in the Swim Lakes area, approximately 8.5 km east of the FMC LSA boundary. This species is ranked secure at the national level (NatureServe 2013) and is not listed by COSEWIC. Specimens of this species have not been observed in other habitats appropriate for the species elsewhere in southern Yukon (Randi Mulder, Yukon Conservation Data Centre; personal communication).

ACKNOWLEDGMENTS

Ecofor Consulting Ltd. (Ecofor) prepared this report on behalf of the Government of Yukon, Energy Mines & Resources, Assessment and Abandoned Mines.

James Mooney and Kevin Wilson (Owner) would like to thank Assessment and Abandoned Mines for the opportunity to conduct this project and for providing us with assistance. We would also like to thank the Ross River Dena Council field participants Dean Bolton and Ashley "AJ" Charlie.

Finally, we would like to thank the Ecofor staff and the Ross River Dena Council for their high quality of work.

Ecofor is solely responsible for any errors evident in this report. The opinions and/or recommendations presented herein are ours and do not necessarily reflect those held by the Heritage Branch of the Yukon Government.

MANAGEMENT SUMMARY

Cultural resources staff of Ecofor Consulting Ltd., (Ecofor) completed the fieldwork for this project between September 24th and September 26th, 2013 on behalf of the Government of Yukon Energy, Mines and Resources, Assessment and Abandoned Mines (AAM). Field staff included James Mooney and Holly Smith from Ecofor Consulting Ltd., and Dean Bolton and Ashley "AJ" Charlie of the Ross River Dena Council. Previous heritage overview assessment work for the Faro Mine Complex was completed by Ecofor (Mooney and Smith 2012). The purpose of the current project was to assess potential impacts to heritage resources through reconnaissance survey and selected shovel testing across the proposed borrow areas.

Eight areas were proposed for ground disturbing impacts associated with the Faro Mine Interim Works. These areas had been previously identified in the overview assessment to possess potential for heritage resources. The current field team conducted the Heritage Resources Impact Assessment and found seven (7) areas assessed in the field to contain significant potential for buried heritage resources. Each of these areas was shovel tested. One of these areas contained an isolated prehistoric lithic surface find (KcTq-1), and three contained prehistoric lithic scatters (KcTq-2, KcTq-3, and KcTq-4). Site KcTq-2 contained two lithic materials which were collected from the first 10 cm of soil and most likely from above the White River ash layer (or Tephra) (WRT). Site KcTqu-3 contained two lithic materials in the top 10 cm of soil. Site KcTq-4 consisted of lithic materials found directly under the WRT, and may present the Little Arm Phase. These three sites were flagged with a 30 m buffer of yellow "No Work Zone" flagging tape. The location of the single surface isolated find was marked by a single strand of yellow "No Work Zone" flagging tape. A modern horse corral and cabin were identified and recorded. A single log privy was also identified and recorded. Two isolated game hanging racks were noted in and near the current borrow pit edges.

No further heritage resources work is recommended for site KcTq-1. Impacts to the remaining three lithic sites (KcTq-2, KcTq-3, and KcTq-4) are recommended to be avoided. If avoidance is not possible then data recovery work is recommended. Data recovery should include limited shovel testing to better determine artifact distribution and density followed by 1 x 1 m block excavation. Approximately 4 - 6 square meters of excavation would be recommended for each site.

Impacts to the horse corral and cabin are recommended to be avoided. If the impacts to the horse corral and cabin cannot be avoided then consultation with owner(s) and/or trapline holder or big game outfitter is recommended. No further heritage resources work is recommended for the game hanging racks or the single log privy.

1.0 INTRODUCTION

1.1 Scope of Project

The proposed ground disturbing impacts are associated with the Faro Interim Mine Works. This proposed project is located within the Faro Mine Complex which is located approximately 22 km north of the community of Faro and 360 km northeast of Whitehorse and is located within the traditional territory of the Ross River Dena Council (RRDC) and the Liard First Nation (LFN) which are both members of the Kaska Nation. This general project area is within N.T.S. map sheets 105K/6 and very near the boundary to 105K/5. The property is accessible by road from Faro.

The intent of the Faro Mine Remediation Project is to remediate the land that is currently disturbed by the mine site. There are basically two areas of previous open pit operations consisting of the Faro Mine Area and the Vangorda Plateau Area (which included the Vangorda Pit and the Grum Pit). There is also one large tailings area known as the Rose Creek Tailing Area.

The current project proposes to assess possible impacts to heritage resources associated with eight areas proposed as borrow source locations, or proposed to have ground disturbing impacts. Impacts to heritage resources could include ground disturbances such as earth moving, borrow pit operations and disturbance of the area.

No previous heritage impact assessment fieldwork was conducted within this area however a heritage resources overview assessment was conducted for the larger project area in 2012 (Mooney and Smith 2012). Due to the relatively small size of the project the current fieldwork was completed in September 24th to 26th, 2013. The project incorporated First Nation participant throughout the fieldwork. The study areas of the past overview assessment and the current impact assessment are shown in Figure 1.

1.2 Personnel

Field crews consisted of Ecofor employees James Mooney and Holly Smith with field assistance provided by Dean Bolton and Ashley "AJ" Charlie of the Ross River Dena Council.

1.3 Report Format

Section 2 provides environmental setting of the project area. Section 3 discusses the culture history of the project area. Section 4 presents the methodology employed, including the inventory, site evaluation, and impact identification and assessment. Section 5 presents the results of the resource inventory conducted and recommendations. Section 6 summarizes the conclusions and recommendations for the project. Section 7 lists the references cited.

Five appendices are included at the end of this report. Appendix I contains the project mapping, Appendix II contains newly recorded archaeological site forms, Appendix III contains the artifact catalogues, Appendix IV contains copies of field notes, and Appendix V contains selected photo documents.

2.0 ENVIRONMENTAL SETTING

The target assessment areas fall within the Yukon Plateau North Ecoregion which is part of the Boreal Cordillera Ecozone (Smith, Meikle and Roots 2004).

2.1 The Yukon Plateau - North Ecoregion

This is the largest ecoregion entirely inside the Yukon and contains a large portion of the Tintina Trench. The ecoregion generally consists of relatively rolling highlands on an east-west orientation.

Mean annual temperatures are near -5°C. Mean temperatures for January range from below -30°C in the lower valleys to above -20°C over the higher terrain. This is drastically different by July as mean temperatures in the lower valleys are 15°C and drop to close to 8°C in higher terrain. Frost can occur at any time of the year but is less likely from mid-June to late July.

Precipitation is moderate with an increase in eastern higher elevation sections. Annual precipitation amounts range from 300 to 600 mm. The winter months have mean amounts of 20 to 30 mm while the summer months can expect rainfall amounts of 40 to 80 mm (Smith, Meikle and Roots 2004). Winds are generally light however may increase to moderate/high during unusually active weather systems or thunderstorms.

The vegetation of the Yukon Plateau–North ranges from boreal to alpine. Northern boreal forest exists at elevations up to 1,500 m (Smith, Meikle and Roots 2004). Open black spruce with a moist moss, or drier lichen understory is the dominant forest type in the boreal zone. Shrub and lichen tundra dominate the higher elevations. The alpine vegetation is characterized by low ericaceous shrubs, prostrate willows and lichens. In the subalpine areas, shrub birch, with scattered pine, white spruce, subalpine fir and a lichen understory, is extensive. Extensive shrub lands exist on valley bottoms subject to cold air drainage and at mid-elevations. Black spruce is the dominate tree type in the ecoregion however white spruce, occasionally with aspen or lodgepole pine, occur in warmer, better-drained areas and in forest fire burn areas.

The Yukon Plateau–North Ecoregion supports wildlife populations typical of Yukon's boreal forest mammals. Moose, woodland caribou, Stone sheep, Dall Sheep, grizzly bear, black bear, wolverine, and marten are all abundant. This ecoregion supports the greatest proportion of brown-coloured black bears in the Yukon, occurring between the Stewart and Pelly rivers. Lynx, beaver, chestnut cheeked vole, mule deer, coyotes, and red fox are also present in some sections of the Yukon Plateau-North (Smith, Meikle and Roots 2004). Of particular interest in the larger area are the Tay River Caribou herd, and an overlap of Stone and Dall Sheep, while Mountain goats are uncommon.

The glacial history of the Yukon Plateau North Ecoregion was dominated by the actions of the Cordilleran Ice sheet and local glaciers, while more recent glaciations were less extensive, and most current glacial features were left from the McConnell glaciation (Smith, Meikle and Roots 2004). However, some older features and glacial erratics are present from the older Reid and pre-Reid glaciations. Some uplands and valley floors were extensively eroded into "whalebacks" or rock drumlins by the glacial flow. The western edge of the ecoregion was approximately the terminus for the

ice sheet of the McConnell glaciation. As the ice retreated through regional stagnation and wasting it left behind kame and kettle topography and glacial lake deposits in many valleys (Smith, Meikle and Roots 2004).

Elevation within the overall mine site ranges from 1645 m Above Sea Level (ASL) in the northeast to roughly 915 m ASL in the lower valleys. The current main road in the project area follows the access road that was built to service the mine when it was in development. This road follows roughly both the Vangorda and Rose Creek drainages on its way out of Faro.

As noted above, the soils in the valleys of this ecoregion tend to be underlain by glacial parent materials. Soil development also reflects the presence of extensive discontinuous permafrost and a strong continental climate (Smith, Meikle and Roots 2004). Of interest is the presence of the Wounded Moose and the Diversion Creek paleosols. These two paleosols are buried soils formed a great deal of time before the current environmental conditions and may reflect past stable ground surfaces. The Wounded Moose paleosol developed on glacial surfaces of pre-Reid age and the Diversion Creek paleosol developed between the Reid and the McConnell glaciations. Both of these paleosols would predate the known cultural history in the Yukon.

Water availability is the one overwhelming environmental predictor of archaeological site potential. Proximity to water sources is an important indicator of archaeological potential as water is essential for survival. People normally live close to sources of water and will often use watercourses as travel routes.

A narrow drainage divide denotes the approximate boundary between the southeast quarter of the larger study area which is drained by Vangorda Creek and the northwestern three quarters which is drained by Rose Creek. Vangorda Creek flows generally southwest while Rose Creek flows to the northwest while most of its tributaries flow into it from the north east. The previously disturbed mine consist of the Faro open pit in the northwest, the Vangorda Plateau in the southeast (with the Vangorda and Grum pits) and the Rose Creek tailings storage facilities along the northwest valley floor of Rose Creek.

The bedrock geology of this ecoregion includes sections of two geological provinces of metamorphosed sedimentary rock. In the northern half of the ecoregion, variably deformed sedimentary rocks have been deposited on the outer continental shelf of ancestral North America, the Selwyn Basin.

The bedrock geology in the southeast part of the ecoregion includes siliceous sedimentary and volcanic rocks of the Yukon-Tanana terrane and metabasaltic flows of the Slide Mountain terrane but the origin of these materials is not as well known due to deformation before and during transportation onto the Selwyn Basin strate (Smith, Meikle and Roots 2004).

The southeast section of the ecoregion between Faro and Ross River also includes exposed river and stream cutbanks along the Tintina Trench (a 450 km fault) that contains rhyolite and olivine basalt which may have provided materials for prehistoric stone tool making. Also of interest in the northern Anvil Range are jet-black or gunsteel-blue weathering siliceous siltstone and conglomerate containing chert pebbles. These materials may also have been used for making stone tools.

The larger study area has been disturbed by a variety of actions. These previous disturbances can be grouped into four main categories: Faro Mine Area in the north; Rose Creek Tailing Area in the northwest; Vangorda Plateau (containing both Vangorda and Grum) in the southeast; and lastly the access roads between the pits and mine components. The Faro Pit is 1,675 m long, 975 m wide, and 335 m deep. The Vangorda Plateau consists of the Vangorda Pit which is 1,150 m long, 350 m wide, and 150 m deep, and the Grum Pit which is 1,100 m long, 700 m wide, and 200 m deep. The Rose Creek Tailings Area is approximately 4 km long, and up to 1 km wide with approximately 55 million tonnes of tailings. The access roads between the Vangorda Plateau and the Faro Mine Area consist of a heavier haul road just east of a lighter access road to the west. The mill and other infrastructure were located between the Faro Pit and the Rose Creek Tailings Area.

3.0 CULTURAL HISTORY

This study area has not been the subject of many cultural resource studies or investigations prior to the current efforts. Therefore, in order to build a context for the area's likely cultural resources, the prehistoric, proto-historic, and historic past land use of a larger area is summarized. While a good deal is known about the historic period, less is known of the prehistoric and proto-historic periods. The following is an overview of the culture history for the broader region including south-central and southwest Yukon and northern BC. Many researchers have reviewed the culture history of this broader area and presented the information using a variety of terms and temporal ranges (Clark 1981; West 1996; Workman 1978, Wright 1995, 1999).

3.1 Prehistoric Period (pre ca 11,000 B.C. to ca A.D. 1840s)

The earliest prehistoric occupation, which dates to early post-glacial times, is known as the Northern Cordilleran tradition (Clark 1983; Hare 1995). The earliest Northern Cordilleran tradition occupation known at present is a site located near Beaver Creek, dated to 10,670 radiocarbon years before present (B.P.)(Heffner 2002). The majority of sites appear to date older than 7,000 to 8,000 B.P. The Northern Cordilleran tradition, with some overlap, predates the introduction of microlithic technology from Alaska into the interior of the central and southern Yukon (Clark 1983; Hare 1995).

Little Arm Phase dates from 7,000 to approximately 4,500 B.P. (Clark and Gotthardt 1999; Workman 1978) and can be defined by the use of microlithic technologies. After about 4,500 B.P., there is less evidence of microblade use in the Yukon, and an increase in the use of notched projectile points and a variety of scraping and carving tools, labeled the Taye Lake phase in southwest Yukon, or more broadly in Yukon and Alaska, the Northern Archaic tradition (Hare 1995; Workman 1978). The most recent archaeological culture of southern Yukon is that of the Aishihik phase (Workman 1978). This phase is thought to be a cultural development from the earlier Taye Lake culture, although there are some significant differences in technology. The most notable is the introduction of the bow and arrow, replacing a type of throwing spear known as an atlatl (Hare, et al. 2004). These Aishihik Phase sites are found above the White River Volcanic ash layer (also known as Tephra) that is dated to about 1,250 radiocarbon years BP (Clague, et al. 1995).

3.2 Athabaskan Period (ca A.D. 500 to 1840s)

In the Athabaskan Period the project area is thought to have been populated by ancestors of the current Ross River Dena Council which may have been comprised of the Shu-tah Dene, Northern Tuchone and Kaska. A great deal of information concerning the Northern Tutchone people was recorded in oral traditions passed on through generations and recorded by various researchers (Dobrowolsky 1987, Gotthardt 1987, Legros 1999; McClellan 1981, McClellan et al., 1987). More information regarding the Kaska is presented below.

From a tool kit perspective, the Athabaskan period has been identified as a shift to stemmed projectile points, the increased use of bone and antler projectile points, and the use of the bow and arrow.

This late prehistoric period is defined by those archaeological components dating after the fall of the White River ash or Tephra (WRT). The Aishihik Phase has been evaluated as ranging from approximately A.D. 750 to A.D. 1750 and also includes the use of native copper tools, stemmed projectile points, and gorges. Also indicative of the Aishihik Phase are small stemmed Kavik points, end and side scrapers, and ground adzes (Hare 1995). The poor preservation of organic materials makes the task of diet reconstruction more difficult than at the coastal sites, but there is evidence of continued use of a variety of large and small mammals, fish, and birds. In the high elevations of the southern Yukon ice patches, examples of the transition from the older atlatl technology to the bow and arrow use has been clearly documented by recent finds (Hare at al. 2004). The shift to the new technology was a rather abrupt one at roughly A.D. 750 based on a good sample of dated atlatl dart shafts and bow and arrow remains.

3.3 Proto-historic Period (A.D. 1700s to ca A.D. 1840s)

The Proto-historic period, as presented here, also overlaps with late Athabaskan Period and can be defined by the appearance of non-native goods, other early trade items, and foreign (western or eastern) influences, but not the documented accounts of westerners themselves. Other indicators of the proto-historic period are the arrival of the first non-native diseases and information concerning non-natives. This period spans the time between the first introduction of non-native influences or artifacts, and the recording of first hand or primary written accounts. Unlike other cultural periods with more specific temporal ranges it is difficult and perhaps impossible to determine when the first ‘outside’ influences of Russian, Asian, European or other cultures began to impact First Nations people in the Yukon interior.

Some of these far reaching effects may have been passed along from Russian exploration in the early and mid 1700s (Veniaminov 1984) and other Asian and European (Andreev 1944, Quimby 1985) exploration and contact with coastal communities. The Chilkat Tlingit from the Northwest Coast travelled and traded with many interior First Nation peoples throughout this proto-historic period including the Kaska and the Northern Tutchone from the Dawson and Mayo areas and occasionally the Mountain Dene people from as far away as Fort Norman on the Mackenzie River. The Tlingit protected and controlled the trading routes into the interior and fiercely defended those routes when they were threatened. News of early non-native explorers and traders would have travelled inland along with foreign items such as metals, cloths, glass beads, and later tobacco and other goods.

In some of the earliest cases the impacts of these foreign cultures could have had significant impacts even without the presence of the foreigners themselves. Such is the case for what is called ‘drift-iron’ whereby metals and other materials from Asian or European shipwreck wash ashore. Historical accounts of shipwrecks have been reported in the mid 1700s but much earlier wrecks were possible. Metals and other foreign trade items have been derived from ship wrecks off what is now British Columbia, Southeast Alaska, and perhaps the Northwest Alaska as well. Of particular interest is the extent that Chinese exploration reached under the direction of Emperor Cheng Zu in the early 1400s.

3.4 Historic Period (ca A.D. 1840s to the Present)

During the early years of this period the Russians were expanding their exploration and trade network along the Pacific coast and up the major rivers of the Alaskan interior, while the British were exploring

eastward into what would become Canada's Northwest and Yukon Territories, as well as Alaska. In the 1840s, representatives of the Hudson Bay Company established trading posts near the study area. Frances Lake Post was established by the narrows of Frances Lake in 1840 while Fort Pelly Banks was constructed in the winter of 1842-43 on the Pelly River at the mouth of Campbell Creek. Fort Yukon was established by John Bell at the confluence of the Yukon and the Porcupine Rivers in 1847. The next year Robert Campbell established Fort Selkirk on the upper Yukon River and then relocated to an improved location in 1851. The Frances Lake post functioned primarily as a meat post and then as a staging post enroute to Fort Selkirk. These posts were plagued by starvation, poor supply and poor trade due to hostilities and feuding.

The location of Fort Selkirk was known to upset the Chilkat Tlingit who controlled the trade routes from the coast to the central Yukon. In 1852, a Chilkat Tlingit raiding party travelled inland and forced Robert Campbell and his crew to leave the trading post, which was consequently burned by the Northern Tutchone (Castillo 2012). The posts at Frances Lake and the Fort at Pelly Banks were abandoned by the Hudson's Bay Company by 1851-1852, while Fort Halkett remained open until 1865.

In 1867, US Secretary of State William Seward was able to focus increasing American interests, and he convinced the United States Senate to purchase Alaska from Russia. Soon after the purchase, the US Army sent Captain Raymond up the Yukon River on the first stern-wheel steamer to reach Fort Yukon (Grauman 1977). Raymond surveyed the location of Fort Yukon and proved that it was within US territory. The British sold the Fort to the US Government and relocated east across the 141st Meridian.

The inland fur industry continued to drive exploration and settlement into the late 1800s, but mining would shift the focus to the placer gold found in streams and alluvial deposits. Mining in the second half of the nineteenth century was a risky but often very lucrative enterprise. The impacts of mining would spread quickly and drastically change the project area.

Mineral prospecting and mining efforts in the second half of the nineteenth century were in some ways very dependent on the existing infrastructure of the fur trading and missionary efforts. As the competition for the inland fur trade grew, so would the number of stern-wheelers on the Yukon River. These steamers could better supply the small number of trading posts along the Yukon and its tributaries and reduce the risk of prospectors running short of supplies. Therefore more of the fur traders and other explorers turned their attention to search for gold and other minerals. Three key prospectors to the north were L.S. (Jack) McQueston, Al Mayo, and Arthur Harper. They wrote to miners in the United States to encourage them to come north. They also established outposts along the Yukon River, including Fort Reliance, established in 1874 near the confluence of the Klondike River (what would become Dawson City) (Wright 1976).

Harper and another man may have been the first to travel up the Fortymile in search of gold in 1881 (Buzzell 2003). They collected a very rich sample, but were unable to relocate the exact location. In 1886, McQueston, Harper, and Mayo built a post on the confluence of the Stewart and Yukon Rivers which provided supplies for additional prospectors. Also in 1886 Howard Franklin made a richer find on the Fortymile River. Others rushed in and these claims along the Fortymile River attracted miners from across Central and Eastern Alaska, and even Southeast Alaska. Fortymile was the first town to grow to over a thousand people by the mid 1890s (Buzzell 2003), and in 1887 the Stewart River post was deserted. Some prospectors that did not find easy success in Fortymile returned to the Stewart and

continued work in the area. In 1890, Harper re-established a trading post at the site of the old HBC post at Selkirk as interest in the area grows. This was followed by Jack Dalton who developed a series of existing First Nation trails from tide water at Haines Alaska, into Fort Selkirk.

Then, on August 16, 1896, George Carmack, Skookum Jim, and Tagish Charlie discovered a very rich claim on Bonanza Creek, a tributary to the Klondike River near Dawson. This discovery sparked one of the largest gold rushes in history.

It would take almost a year for the news of the Klondike gold fields to spread south, even to places relatively close by in southeast Alaska. Most of the prospectors and traders in the Alaskan and Yukon interior had already converged on the Dawson area during the winter and spring, and supplies ran dangerously low. That would quickly change in the summer of 1897 and spring of 1898 as new towns and supply posts sprang up along the Gold Rush routes to cash in on the increased demand.

The population of Dawson City grew very fast and in 1898 reached a peak of over 30,000. However the boom period did not last long and the vast majority of population moved on very quickly with the news of other discoveries and hopes of other bonanzas. The Gold Rush period saw greatly increased steamer traffic on the entire Yukon River drainage basin and across the interior. Just prior to the Gold Rush there were only a few steamers, while at its peak there would be hundreds of vessels working the rivers. These shallow draft steamers were supported by a network of wood camps, shipyards, and a large workforce which kept the river traffic moving. This network provided the infrastructure backbone for trading posts, fish camps, missionaries, and mail routes, while meeting the needs of the growing number of prospectors and traders.

As the world's attention was drawn to growing concerns in Europe in 1939, the Canadian Government began building a chain of airfields across the northwest under the Northwest Staging Route Program. Following the bombing of Pearl Harbor there was no doubt that Alaska and the Yukon would play a key role in the war, and a road needed to be built to link Alaska to the contiguous United States. It was quickly decided that the "Prairie Route" would be used, whereby key airfields would be linked from Great Falls, Montana to Fairbanks, Alaska. As part of the agreement Canada agreed to build and improve airstrips along the way including Watson Lake. In February 1942, the US War Department issued the directive to begin construction. These actions spurred on the building of approximately 2,446 km (1,520 mi) of new road through British Columbia and the Yukon Territory. Following the completion of the Alaska Highway the Canol Pipeline and Canol Road (North and South) were completed to allow the flow of oil from Norman Wells, NWT to Whitehorse in 1944. These two events increased access to the Traditional Territory of the Ross River Dean Council and were largely responsible for commercial and mining/industrial activities in recent decades, including construction of the Robert Campbell Highway (Tungsten Road) in 1961.

3.4 The Faro Mine

In the 1880's there was placer mining along the Pelly River however, there was never adequate amounts to trigger a Gold Rush in the area. Small amounts are taken from the creeks and sandbars along the Pelly River to this day, but most are hobby claims or small operations. However, the area around Faro is very rich in other ores and minerals. In 1953, prospector Al Kulan staked the Vangorda

Creek lead-zinc deposit with the assistance of Kaska prospectors Jack Ladue, Robert Etzel, Joe Etzel, Art John, and Jack Sterriah. At that time the deposit was considered too small and too remote to be mined (Town of Faro 2012).

When exploration of the ore body around Faro was conducted a few years later, it was realized they had hit upon a world class deposit of lead/zinc ore (galena). The Vangorda deposit was purchased by Kerr-Addison Mines Ltd. while Dynasty Explorations staked the Faro deposit in 1965. In the late 1960s preparations for full mine production began on the Faro deposit and the Town of Faro was established along the Pelly River, approximately 5 km from the LSA, in 1968. Faro Mine production began in 1969 and the mine was officially opened in 1970. There were over 100 people working in the area, and Dynasty had even built an airstrip on the claim site. Dynasty Explorations later joined forces with Cyprus Mines from Los Angeles to create Cyprus Anvil Mining Corp in 1975 (Faro Mine Remediation Project 2011).

Meanwhile the Kerr-Addison Mine Ltd. discovered the Grum deposit in 1973 and decided to sell both the Vangorda and Grum claims to Cyprus Anvil Mining Corp. in 1978. This collection of the Faro, Vangorda and Grum deposits benefitted Cyprus Anvil greatly. They quickly became the largest private sector employer in the Territory. In the 1970's the Faro Mine could produce up to 10,000 tonnes of ore per day. By the mid 1970's Faro was the largest lead/zinc mine in Canada (Faro Mine Remediation Project 2011); produced approximately 15% of the world's zinc/lead output; and, represented 20% of the Yukon's economy.

Mining continued intermittently between the Faro deposit and the Vangorda Plateau (the Vangorda and Grum deposits). The property changed hands multiple times and went through periods of operation and closure due to fluctuating metal prices. Until finally in 1998 the Anvil Range Mining Corp. declared bankruptcy and sought protection under Companies' Creditors Arrangement Act. The courts appointed an interim company to manage the environmental care and general maintenance of the property. In 2003, the territorial and federal governments officially stated the Faro Mine Complex will not reopen and entered into a joint agreement with the RRDC (on behalf of the Kaska Nation) and Selkirk First Nation to work together on developing a closure plan (Faro Mine Remediation Project 2011).

3.5 The Kaska Nation

The project falls within the traditional territories of the Ross River Dena Council (RRDC) and the Liard First Nation (LFN). Both first nations are part of the Kaska Nation. The Kaska Nation's traditional territory covers a large area of northwestern BC, southeastern Yukon and southern NWT. Within the Kaska traditional territory there are five First Nations communities: Dease River First Nation; Kwadacha Nation; Ross River Dena Council; Liard First Nation; and Daylu Dena Council. Each Kaska First Nation is represented by an elected Chief and Council as well as a Hereditary Chief.

Prior to European contact, traditional subsistence activities typically featured a seasonal round of winter hunting and summer fishing covering vast areas. In summer, families congregated at lakes and rivers, where fish and plants were collected, dried and stored. In late summer, small groups dispersed throughout the uplands and higher valley systems to hunt in clan-owned territories. Temporary camp sites, situated within a variety of ecological zones, were often reoccupied year after year in order to

exploit seasonally available resources (Honingmann 1981).

Contact with neighbouring Nations was vital to First Nations economies. Interior bands traded hides, furs and obsidian to coastal groups for fish oil, dentalium, woodwork and blankets. Trails were an intrinsic part of this economy and traditional subsistence as a whole. The principal ethnographic descriptions of the Kaska Dena are available in Black (1955), Jenness (1937) and Morice (1893, 1903, 1905). Additional information on past lifeways can be found in Honigmann (1981).

Ross River, near the confluence of the Ross and Pelly Rivers, is the modern focal point of the Ross River Dena Council. Originally First Nations people used the area as a seasonal camp and gathering place. By 1903, a trading post was established nearby and later when the American army completed the Canol Pipeline and Canol Road in 1944, they connected Ross River by road to the rest of the Yukon (Cohen 1992). In 1962, Ross River was relocated to its current site close to the Campbell Highway (Yukon Community Profiles 2012).

Watson Lake, Upper Liard and the adjoining settlements are home to the Liard First Nation. The amount of activity near Watson Lake was greatly increased when its airfield was established in 1939. This was part of the Canadian government's construction a chain of airports across north-eastern British Columbia and the Yukon as part of the lend-lease program. The new community was soon after used as a supply centre for the construction of the Alaska Highway in 1942.

3.6 Previous Heritage Investigations

In this case there are no previously recorded sites within or near the assessment areas, and no others recorded in the larger vicinity. The majority of archaeological investigations carried out in the broader area have been motivated by development activities, including mining/mineral exploration and road construction.

Ruth Gotthardt conducted heritage resource inventory in the upper Liard drainage including portions of the Robert Campbell Highway (1987) and also conducted work in the Francis Lake area (1993). Greg Hare conducted an overview assessment along a portion of the southern Robert Campbell Highway (1998). Christian Thomas conducted an assessment for proposed borrow pits for the Robert Campbell Highway (2007) and conducted an impact assessment for the same highway from km 10 - km 140 (2008).

A Preliminary Field Reconnaissance (PFR) was conducted by Ecofor in May 2012 for 28 proposed borrow pits along the Robert Campbell Highway. The focus of the PFR was to identify areas of heritage resource potential within these proposed borrow pits. Prior to fieldwork, previously identified archaeology sites and heritage resources location data were collected and included in field mapping. Field crew attempted to assess each block from the ground. Of the 28 targets, 15 were found to contain archaeology potential, 2 were inaccessible, and 11 were found to contain no heritage resource potential (Smith 2012). This assessment was used to recommend high potential areas for shovel testing that were used in a follow-up HRIA of Pit #7 also in 2012 (Mooney 2012).

In 2012, Ecofor Consulting Ltd. completed a Heritage Resources Overview Assessment for the Proposed Faro Mine Remediation Project (Mooney and Smith 2012) which identified likely resources to be found in the area and areas evaluated to contain potential for heritage resources.

4.0 METHODS

Field efforts were separated into two main tasks consisting of pedestrian transect survey to assess in-field potential, and sub-surface testing - where potential was rated as moderate to high.

Due to the relatively small size of the assessment areas each proposed target area was walked in relatively tight transect intervals of approximately 5 to 15 m apart. When areas or landforms were assessed in the field to posses moderate to high potential shovel testing was conducted. Shovel tests were located approximately 5 to 10 m apart. Shovel tests were a minimum of approximately 30 by 30 cm and were be excavated with shovel and trowel as needed into sterile sub soils. All soil matrix were screened though ¼" mesh. Artifacts identified were collected and bagged according to the shovel test unit and stratum, or arbitrary 5 cm vertical interval. The profile of positive shovel tests were recorded by depth below surface and natural and cultural soil strata. All shovel tests were backfilled and returned to as close to natural conditions as possible. If surface finds or subsurface cultural materials were identified additional shovel testing was conducted to assess the vertical and horizontal limits of the site, and to recover a sample of the material culture to assist in the assessment of the site use and cultural affiliation. All sites, isolates, and heritage resources were photographed and the site location will be recorded using a hand-held GPS unit, and a sketch map was prepared in the field. Sites were recorded using temporary site numbers and site data was recorded. Data included setting, access, vegetation, water system information, elevation, soils data including number of cultural strata, features present, and other comments. This information was submitted to Yukon Heritage Branch for site inventory and return of Borden Site number. The condition of sites was also assessed based on the amount of disturbance ranging from relatively intact to destroyed.

Historic and prehistoric sites were recorded and flagged in the field. Field work was completed by crews of three to four individuals (principal investigator, archaeological field technician, and First Nation Participants). A buffer area of 30 m around known historic and prehistoric sites was flagged with yellow "no work zone" ribbon as well as flagging at the centre of the site.

Interim and final reports, site forms, and artifact curation preparations met the Yukon Archaeological Sites Regulations Guidelines for Permit Holders.

If mummified or skeletal palaeontological remains were exposed, Yukon Palaeontology would have been contacted before disturbing them further.

If human remains were identified during operations, all work would have ceased in the area immediately and the R.C.M.P, First Nations, and Yukon Heritage Resources would have been notified.

4.1 Curation of Materials Collected

The Yukon Heritage Resources Unit will serve as the repository for the materials collected. Contact information of the Heritage Resources Unit is provided below.

4.2 Resource Definitions

A *Site* is an area or a place, or; a parcel of land which contains heritage resources or objects.

Historic Sites contain heritage resources that are greater than 45 years in age and posses significant heritage value. By convention, historic sites date to the period for which written records are available; in this case, the historic period commences with the arrival of the Hudson's Bay Company in the early-mid 19th century. Historic sites may include cabins, caches, camps, brush camps, and any other man-made structures, features or objects that date between about the 1960's and 1830-50.

Archaeological or Prehistoric Sites generally represent use before European contact and are found on or under the ground surface, and may consist of the remains of ancient camps, including hearths, animal bone and stone tools and debris. In this usage, an Archaeological Site equates to a Prehistoric Site (a site that dates to the period before written history). Note, however, that in heritage resource management usage, archaeological resources are viewed as resources that are in subsurface context (buried) and may also include historic period objects and features.

Proto-historic Sites can be viewed as basically prehistoric sites from a time period which includes the effects of foreign historic cultures but lacks the first hand written descriptions of that area. For example, in the Yukon the proto-historic period ends with the appearance of first hand written descriptions in the mid 1800s. However the proto-historic time period extends back thru time when foreign materials such as "drift-iron" from ship wrecks on the west coast, or foreign trade items were carried into the Yukon. Examples of foreign historic materials which predate the mid 1800s found in prehistoric contexts usually represent this proto-historic period.

5.0 RESULTS AND RECOMMENDATIONS

Field work was completed across the eight proposed areas of ground disturbance in one fieldwork session from September 24th to 26th, 2013. The field crew were accommodated at the Faro Studio Hotel.

These eight areas of planned disturbance within the Faro Mine Interim Works had been previously identified in the overview assessment to posses potential for heritage resources. The current field team conducted the Heritage Resources Impact Assessment and found seven (7) areas or landforms assessed in the field to contain significant potential for buried heritage resources. Each of these areas was shovel tested. One of these areas contained an isolated prehistoric lithic surface find (KcTq-1), and three contained prehistoric lithic scatters (KcTq-2, KcTq-3, and KcTq-4).

A modern horse corral and cabin were identified and recorded. A single log privy was also identified and recorded. Two isolated game hanging racks were noted near the current borrow pit edges. None of these historic resources were assessed to be over 45 or 50 years of age and therefore they were not recorded with the Yukon Historic Site Inventory. These resources were noted here since they are within and near possible impact areas and would be of concern to stakeholders.

No paleontological remains, grave sites or human remains were identified. All of the newly identified prehistoric sites were flagged with a 30 m buffer of yellow and black "No Work Zone" tape except the isolate from disturbed context KcTq-1.

Overall results mapping are augmented with shovel test location sketch maps is in Appendix I while site forms for archaeological sites are in Appendix II. Appendix III contains detailed artifact catalogues, while Appendix IV presents field notes. Appendix V presents selected images of each shovel test location and representative images of sample artifacts and historic resources. The results of these efforts are presented below in prehistoric as well as modern use areas that may be of concern to related stakeholders.

5.1 Prehistoric Resources

The current 2013 fieldwork focused on assessing eight areas proposed for borrow pit areas or ground disturbing activities. Most of the ground surface in these areas consisted of side slope, covered in black spruce with little to no potential for buried heritage resources. As noted above seven (7) smaller areas or landforms within the proposed target areas were assessed in the field to possess moderate to high potential for buried cultural resources. Each of these landforms were the subject of sub-surface shovel testing. The results of this testing is presented in Table 1 below as an overview (which also includes areas of negative testing) and secondly in a more detailed site by site description.

Table 1. Shovel Test Location Results.

STL #	Borden #	Total (+) Tests	Total (-) Tests	Archaeological Potential	Landform	Landform Size	Site Size
1	KcTq-2	2	15	High	Esker Ridge	5 x 70 m	5 x 15 m
2	KcTq-1	0	4	Low	N/A disturbed	5 x 5 m	surface find
3		0	5	Moderate - High	Small Knoll	5 x 20 m	-
4	KcTq-3	2	7	High	Esker/Bench	5 x 40 m	5 x 18 m
5		0	6	Moderate - High	Ridge	50 x 10m	-
6	KcTq-4	1	9	Moderate - High	Esker Ridge	5 x 30 m	5 x 10 m
7		0	5	Moderate	Rock Bench	5 x 10 m	-

Borden #: KcTq-2
STL #, Temporary Site #, and name: STL J1, Site J2, Seklla Site
Location: See Map 1 – Appendix I
Landform: Esker Ridge
Number of Negative and Positive Shovel Tests: 15 negative and 2 positive
Total Number of Lithic Materials: STP #1: 2 interior flakes and 1 modified flake; STP #8: 1 interior flake
Diagnostic Materials/Possible Cultural Affiliation: Prehistoric – Likely Post White River Tephra (possible Aishihik Phase)

Assessment: There was evidence of the White River ash or tephra (WRT) in the shovel tests and it appears this site may have been used after the fall of the WRT. The lithic materials identified were found in STP #1 near the high spot of the lower southern end of the ridge, and in STP #8 in the middle of the ridge. This narrow and relatively low ridge runs roughly north to south and overlooks the Rose Creek drainage to the west. This drainage flows northwest and then west into the Pelly River. Cultural materials were found between 0-10 cm below surface and likely found above the WRT in the first 5 cm of soil. The lithic remains identified likely represent a small, low to moderate density, scatter remaining from a temporary campsite or lithic reduction workshop which may reflect the post WRT and use in the Athabaskan Period and perhaps the Aishihik Phase.

Soil Description: STP #8 Organic Layer/I 0-5 cm rich organic and thin black loam, II = 5-10 cm of White River Tephra, III = 10-20 cm reddish brown to brown coarse sandy loam with approximately 25% gravel and cobbles.

Recommendations: The site is located just west of the edge of a proposed borrow pit but the 30 m buffer flagged around the site (as per direction from Yukon Heritage) is within the proposed pit and may be impacted by the proposed developments. Avoidance of the site is recommended. If avoidance of this site and its 30 m buffer is not possible then data recovery work is recommended. Data recovery

should include additional shovel testing to determine artifact distribution and density followed by 1 x 1 m block excavation. Approximately 4 - 5 square meters of excavation would be recommended.

Borden #: KcTq-1
STL #, Temporary Site #, and name: STL J2, Site J1, Rose Creek Site
Location: See Map 1 – Appendix I
Landform: N/A disturbed
Number of Negative and Positive Shovel Tests: 4 negative and 0 positive (only a surface find)
Total Number of Lithic Materials: Surface Find: utilized flake
Diagnostic Materials/Possible Cultural Affiliation: Prehistoric – undetermined

Assessment: This single isolated find was found in a disturbed push area from heavy equipment workings on the edge of an existing borrow area on a southwest facing slope. The remaining surface of the disturbed area and undisturbed ground surface around it were inspected but no additional materials were identified. The crew also opened four shovel tests in the most level closely related ground surface adjacent to the disturbed area but no additional materials were identified. The single lithic isolate may have been moved downslope from higher ground to the northeast. This isolate likely represents a small low density scatter remaining from a temporary campsite or lithic reduction workshop. No culturally diagnostic materials were identified and it is uncertain when these materials were deposited. The isolate was found on a disturbed surface which consisted of gravel and cobbles and coarse sandy materials.

Soil Description: The intact soils at this location were very similar to those at STL #1 and the WRT was present. Although no cultural materials were found in-situ a representative soil profile was made at STP #2. This consisted of organic Layer/I 0-5 cm rich organic and thin black loam, II = 5-10 cm of White River Tephra, III = 10-20 cm reddish brown to brown coarse sandy loam with approximately 25% gravel and cobbles.

Recommendations: The isolate was located within a proposed borrow pit, and on the edge of an existing borrow pit, and would be directly impacted by the proposed developments. The likelihood that this sloped landform would contain significant cultural materials is assessed as low to none. No further heritage resources management work is recommended.

Borden #: KcTq-3
STL #, Temporary Site #, and name: STL J4, Site J3, Keda Look Out Site
Location: See Map 1 – Appendix I
Landform: Esker Bench
Number of Negative and Positive Shovel Tests: 7 negative and 2 positive
Total Number of Lithic Materials: STP #1: 1 interior flake; and STP #4: 1 modified flake
Diagnostic Materials/Possible Cultural Affiliation: Prehistoric –Post White River Tephra (probable Aishihik Phase)

Assessment: This small landform consists of a bench at the southeast end of ridge line that overlooks Rose Creek. These lithic materials likely represent a low to moderate lithic scatter reflecting a temporary campsite or lithic reduction workshop. Cultural materials were found between 0-10 cm

below surface and above the WRT which supports an Athabaskan Period use and probable association with the Aishihik Phase.

Soil Description: STP #4 Organic Layer 0-5 cm scattered and thin rich organic duff, II = 5-19 cm White River Tephra, III = 19-25 cm reddish brown coarse sand with approximately 20% gravel.

Recommendations: This site is located on the west edge of a planned borrow pit area and would be impacted by proposed activities. Avoidance of the site is recommended. If avoidance is not possible then data recovery work under is recommended. Data recovery should include additional shovel testing to determine artifact distribution and density followed by 1 x 1 m block excavation. Approximately 4 - 6 square meters of excavation would be recommended.

Borden #: KcTq-4
STL #, Temporary Site #, and name: STL J6, Site J4, Whiskey Jack Site
Location: See Map 1 – Appendix I
Landform: Esker Ridge
Number of Negative and Positive Shovel Tests: 9 negative and 1 positive
Total Number of Lithic Materials: STP #5: 2 interior flakes
Diagnostic Materials/Possible Cultural Affiliation: Prehistoric – Little Arm Phase

Assessment: These materials were all found on the west facing side of a north-south ridge overlooking a tributary to Rose Creek. This ridge landform begins narrow in the north and widens in the south and only the northeast side is within the proposed borrow pit area. The lithic materials identified likely represent a small low density lithic scatter reflecting a temporary campsite or lithic reduction workshop. No culturally diagnostic materials were identified. However these materials were found between 10-15 cm below surface and 0-5 cm under the WRT which likely represent the Little Arm Phase.

Soil Description: STP #5 Organic Layer/I 0-3 cm, II = 3-12 cm of White River Tephra, III = 12-18 cm reddish brown coarse sandy loam, IV = 18-25 cm olive brown coarse sandy loam.

Recommendations: This site is located on the west edge of a planned borrow pit area and would be impacted by proposed activities. Avoidance of the site is recommended. If avoidance is not possible then data recovery work under is recommended. Data recovery should include additional shovel testing to determine artifact distribution and density followed by 1 x 1 m block excavation. Approximately 4 - 5 square meters of excavation would be recommended.

5.2 Modern Use Areas and Resources

The field crew also recorded a modern horse corral and cabin, a single log privy, and two game hanging racks. These modern resources are noted here due to expected interests of current stakeholders. The modern corral and cabin are located on the north side of an existing access road within a planned borrow pit area. The single log privy is also within a proposed borrow pit area. One of the game racks

is within a proposed borrow pit while the second is between them on the edge of an existing road (see Map 1 of Appendix I). Due to the relatively modern age of these resources they were not recorded with Yukon Historic Sites Inventory.

The modern cabin was constructed of milled lumber with a plywood exterior and an ashpalt shingle roof and the corral was built with rough cut round logs and spikes. This cabin and corral area appears to have been used for big game guiding and/or hunting in the late 1900s and early 2000s and would be impacted by borrow pit development. Impacts to the horse corral and cabin are recommended to be avoided. If the impacts to the horse corral and cabin cannot be avoided then consultation with owner(s) and/or trapline holder or big game outfitter is recommended.

The single log privy was constructed with a rough cut log and plywood and likely represents late 1900s and early 2000s construction and use. The single log privy would be impacted by borrow pit development. No further work is recommended for the single log privy.

The game hanging racks consist of rough cut round logs suspended in trees and fixed with nylon rope and spikes which likely reflect late 1900s and early 2000s construction and use. No further heritage work is recommended for these game racks.

6.0 CONCLUSIONS

The current field work was completed between September 24th and 26th, 2013. A total of eight areas were proposed for ground disturbing impacts associated with the Faro Mine Interim Works. These areas had been previously identified in the overview assessment to possess potential for heritage resources. The current field team conducted the Heritage Resources Impact Assessment and found seven (7) landforms assessed in the field to contain significant potential for buried heritage resources. Each of these areas was shovel tested. One of these areas contained an isolated prehistoric lithic surface find (KcTq-1), and three contained prehistoric lithic scatters (KcTq-2, KcTq-3, and KcTq-4). Site KcTq-2 contained two lithic materials which were collected from the first 10 cm of soil and most likely from above the White River ash layer (or Tephra) (WRT). Site KcTqu-3 contained two lithic materials in the top 10 cm of soil. Site KcTq-4 consisted of lithic materials found directly under the WRT, and may present the Little Arm Phase. These three sites were flagged with a 30 m buffer of yellow "No Work Zone" flagging tape. The location of the single surface isolated find was marked by a single strand of yellow "No Work Zone" flagging tape. A modern horse corral and cabin, and a single log privy were also identified and recorded. Two isolated game hanging racks were noted near the current borrow pit edges.

No further heritage resources work is recommended for site KcTq-1. Impacts to the remaining three lithic sites (KcTq-2, KcTq-3, and KcTq-4) are recommended to be avoided. If avoidance is not possible then data recovery work is recommended. Data recovery should include limited shovel testing to better determine artifact distribution and density followed by 1 x 1 m block excavation. Approximately 4 - 6 square meters of excavation would be recommended for each site.

Impacts to the horse corral and cabin are recommended to be avoided. If the impacts to the horse corral and cabin can't be avoided then consultation with owner(s) and/or trapline holder and big game outfitter is recommended. No further heritage resources work is recommended for the single log privy or the game hanging racks.

No paleontological remains, grave sites or human remains were identified. All of the newly identified prehistoric sites were flagged with a 30 m buffer of yellow and black "No Work Zone" tape. The location of the prehistoric isolate was marked with a single strand of "No Work Zone" tape but the area around it was not delineated.

If this project moves forward it is possible that further revisions in the proposed borrow pits may change. It is recommended that any areas of potential impact not previously assessed, are reviewed and assessed in the field prior to future impact. Impacts to recorded historic and prehistoric resources should be avoided were possible, or mitigation efforts should be completed prior to construction impacts.

YESAB	Yukon Environmental and Socio-economic Assessment Board

SECTION 1

Report Goals and Introduction

The Faro Mine Complex (FMC) started operations in 1969 and mining continued under various owners until the late 1990s, with the last owners declaring bankruptcy. At that time, the management of the FMC was assigned to an interim receiver. In 2003, the Government of Canada and the Government of Yukon (YG) determined the FMC would not be reopened and planning for its permanent closure and remediation was initiated. This process is still underway. However, there are activities that need to be carried out over the next 10 years prior to the remediation and closure of the FMC so that human health and the environment continue to be protected. These Interim Works are to undergo an assessment by the Yukon Environmental and Socio-economic Assessment Board (YESAB). The YG and the Government of Canada ("co-proponents") are in the process of developing an Interim Works Project Proposal (IWPP), which describes the environmental and socio-economic effects of the interim works, for submission to the Watson Lake Designated Office of YESAB in early 2014.

CH2M HILL Canada Limited (CH2M HILL) is leading and coordinating the development of this project proposal. Hemmera Envirochem Inc., along with our team of subconsultants, has been retained by CH2M HILL to prepare the socio-economic baseline and a socio-economic effects assessment for the IWPP. This report forms the former of those two documents. A summary of this baseline is also included in Section 6.3 of the IWPP.

A socio-economic effects assessment provides estimates of potential changes a project may have on demographics, housing, public services, and even community well-being, and can thereby help proponents and communities avoid or mitigate potential negative project effects and identify potential positive outcomes of projects and related activities.

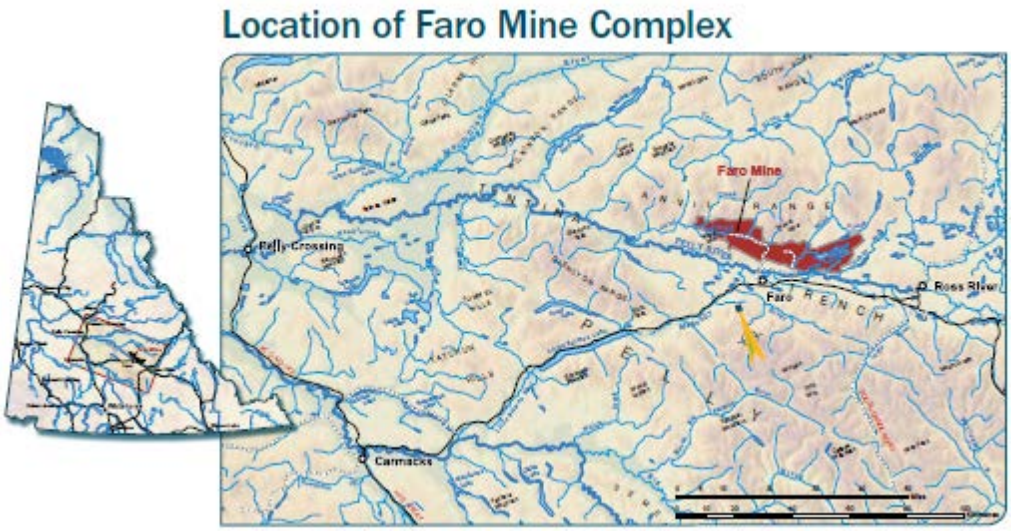
The first step towards completing a socio-economic effects assessment is to capture the conditions in the communities, or study areas, in a baseline report. The baseline conditions serve as a benchmark for measurement of potential changes in valued components (VCs) predicted to occur as a result of the project. For the purposes of this assessment, baseline conditions are considered to be the conditions in 2009 as this is the year that the co-proponents took over the day-to-day operational responsibility of the FMC from the receivers.

This report identifies the baseline conditions of the communities in the FMC study area. Further detail on the effects assessment methodology and the effects assessment itself are found in Section 7 of the IWPP.

SECTION 2

Faro Mine Context

2.1 Location



The location of the FMC is approximately 15 kilometres (km) north of Faro, located in south–central Yukon. The FMC is in the traditional territory of the Ross River Dena Council (RRDC), Liard First Nation (LFN), and Kaska Dena Council (KDC), and upstream from the traditional territory of the Selkirk First Nation (SFN) (YG, 2010a). See Figures 6L-1 and 6L-2 for maps showing the location of the FMC.

FIGURE 6L-1
Faro Mine Complex Location
Faro Mine Interim Works

Source: YG (2011); reproduced with YG's permission

FIGURE 6L-2
Faro Mine Location
Faro Mine Interim Works

Source: YG (2010); reproduced with YG's permission

The FMC is geographically bound to the north by the Anvil Range and lies directly along the Tintina Trench, in the Pelly River watershed.

The FMC comprises three key areas (YG, 2010a):

1. Tailings Area: This area is at the base of Rose Creek Valley and consists of 55 million tonnes of tailings deposited between 1969 and 1992. Three dams hold the tailings and a fourth dam stores water. The Rose Creek is diverted around this area.
2. Faro Mine Area: The mine area consists of a large (1,675 metres [m] by 975 m) open pit surrounded by approximately 250 million tonnes of waste rock. The Faro Creek is diverted around this facility.
3. Vangorda/Grum Area: Two additional large open pits (Vangorda and Grum) are surrounded by another 116 million tonnes of waste rock and overburden. Vangorda Creek is diverted around the Vangorda Pit.

The detailed layout of these three areas is shown in Figure 6L-3.

FIGURE 6L-3
Faro Mine Complex Layout

2.2 Local History

2.2.1 Pre-mining

The Faro Mine area was first prospected in 1953 by Al Kulan. He staked the Vangorda lead-zinc deposit and some drilling was carried out between 1953 and 1955, but little happened in the area until the early 1960s when the area was the subject of a detailed exploration program led by Dr. Aaro Aho. By 1965, the Faro Mine Area had clearly become an economical deposit, and in January 1970, the mine was officially opened by the Cyprus Anvil Mining Corporation (Macpherson, 1978).

2.2.2 Mining

From the original opening in 1970, the FMC operated until 1982, when production stopped because of low metal prices and high operating costs. Stripping carried on for a short time, but then all operations halted by the end of 1984. Near the end of 1985, the assets of Cyprus Anvil were purchased by Curragh Inc., who re-commenced operations at the FMC in spring of 1986. Mining continued until 1993 when it stopped again because of low metal prices, and Curragh entered into receivership. Anvil Range Mining purchased the assets of Curragh in order to re-open the FMC in 1995. Anvil Range Mining operated for a brief time, but ultimately the resource was effectively at the end of life. In early 1998, Anvil Range applied for creditor protection, and in April 1998, an interim receiver was appointed to maintain the site (YG, no date).

The FMC processed between 5,000 and 9,300 tonnes of ore per day (YG, 2010b). In 1989, the FMC was the sixth largest zinc producer in the world, supplying 3 percent of the western world's zinc and 5 percent of its lead concentrates. The FMC accounted for 20 percent of the Yukon's economy during its peak production (YG, no date).

2.2.3 Site Maintenance and Remediation Planning

From 1998 to 2008, care and maintenance work was carried out by the court-appointed interim receiver, Deloitte and Touche. In March 2009, YG took over this responsibility.

In January 2003, the federal and territorial governments agreed that the FMC would not reopen and planning for a permanent closure plan would need to occur. At that point, the two governments entered into an agreement with the RRDC and the SFN to jointly develop closure objectives for the site. These closure objectives define the intended outcomes of the remediation plan and guide the closure planning process. The closure objectives for the FMC are (YG, 2010):

1. Protect human health and safety.
2. Protect and, to the extent practicable, restore the environment including land, air, water, fish and wildlife.
3. Return the mine site to an acceptable state of use that reflects pre-mining land use where practicable.
4. Maximize local and Yukon socio-economic benefits.
5. Manage long-term site risk in a cost effective manner.

Occurring in parallel to the closure planning objectives work, over 100 technical studies and assessments have been conducted at the FMC to help inform YG and its contractors of site characteristics. In 2005, based on these technical studies, 12 sample closure alternatives were created representing the range of options that could be considered (YG, 2011a). The sample closure options were then reviewed by an Independent Peer Review Panel, as well as discussed with First Nations, federal and territorial governments and stakeholders (YG, 2011a). Based on these reviews the 12 options were narrowed down to five final options in 2006. The five final options were evaluated by the federal, territorial, and First Nations governments, who agreed on one preferred option for the final remediation plan (YG, 2011a).

Currently the detailed engineering and design for the preferred remediation option are being developed. Once that is complete, a project proposal will be submitted to the YESAB Executive Committee for an assessment, as well as undergo regulatory licences and permits processes.

2.3 Faro Mine Interim Works

The Interim Works (IW) involves works and activities that are required to protect people and the environment from the ongoing effects associated with the legacies of mining activities at the FMC, and to manage risks associated with those legacies, until the full remediation plan is in place. The environmental and socio-economic assessment for the IW considers the consolidated effects of all undertakings and accessory activities during this interim period.

The following three areas make up the IW environmental and socio-economic assessment scope:

- Site operations (further described in the Project Proposal Section 5.3): The Site operations are the ongoing site activities required to prevent the FMC from adversely affecting persons, property or the environment. It will also counteract, mitigate and remedy adverse effects that do occur.
- Site investigations (further described in the Project Proposal Section 5.4): Developing the Faro Mine Remediation Project and design of remediation and closure elements requires extensive site investigation programs. These programs will take place across the FMC throughout the proposed IW. It will comprise a range of land use activities that may be associated with site investigation programs such as soil and rock sampling, collecting vegetation samples, and test pitting, among other activities.
- Down Valley Interim Hydraulic Upgrades (further described in the Project Proposal Section 5.5): The Down Valley Interim Hydraulic Upgrades relate to the improvement of flood routing capacity for the Down Valley Tailings Facility, where some aspects of the facility do not meet the minimum standards specified in the Canadian Dam Association Dam Safety Guidelines. Activities under this component involve raising the capacity of the spillway, relocating infrastructure, and other improvements.

A fourth element of the IW scope is the ancillary activities (e.g., worker accommodation and borrow source investigation and development). These may relate to one or more of the three main areas. While these are considered to be ancillary to the IW work itself, they may have a substantive effect on socio-economic considerations of the proposed project. The detailed list of ancillary activities is as follows (Section 5.6 of the Project Proposal describes ancillary activities in greater detail):

- Maintaining site security by providing an ongoing site presence, establishing security facilities and programs, and managing site access as needed to secure the FMC and manage health and safety risks
- Maintaining and operating an office and gatehouse building at the FMC
- Providing emergency response capabilities and responding to emergencies
- Implementing preventative maintenance programs
- Maintaining buildings, site infrastructure, and utility systems (e.g., electrical distribution system maintenance and a waste-oil heating system)
- Maintaining stationary and mobile equipment
- Expanding existing borrow sources to supply aggregate and construction materials for care and maintenance, water treatment plant construction, and Down Valley Interim Hydraulic Upgrades activities
- Providing onsite accommodations for site workers, including temporary camps (e.g., construction activities, field investigation programs)
- Maintaining and operating employee housing within the Town of Faro (Faro)
- Procuring supplies and energy sources for the FMC (e.g., lime for water treatment, materials for water treatment plant construction, and fuel)
- Transporting goods and equipment to and from the FMC (e.g., providing the materials listed herein and removing hazardous waste)

- Using existing solid waste disposal facilities at the FMC
- Managing special wastes (this includes operating a waste-oil heating system)
- Withdrawing and using fresh water for domestic purposes
- Using, maintaining, and repairing existing septic systems at the FMC
- Performing additional ancillary activities to complete the IW activities

SECTION 3

Methodology

3.1 Values-based Approach

The assessment team has employed a values-based approach for this IW project. That means the things that people care about (the "values") that could be affected by the IW were identified and considered. As a first step, a list of socio-economic values was identified. These values were determined based on an analysis of existing socio-economic information. Also included were indicators for each value that may be measured quantitatively or qualitatively. These indicators provided the basis for the research plan for the socio-economic baseline and effects assessment.

Baseline data collection focused on understanding the conditions of individuals, communities, and businesses as they are related to the following socio-economic VCs:

- Economy and employment
- Community stability and well-being
- Infrastructure and services
- Land use and access
- Culture and heritage

Table 6L-1 describes each of these VCs, their indicators, and the rationale for including them. The socio-economic effects assessment provides predictions on how the IW activities might affect these valued components (see Section 7.3.6 of the IWPP).

TABLE 6L-1
Socio-economic Valued Components and Indicators
Faro Mine Interim Works

Valued Component	Indicators	Rationale for Inclusion
Economy and Employment	Business development Economic diversification Employment opportunities and income Education and training	The IW may stimulate local economies, and has the potential to increase employment, and develop skills, training and education in local communities. This value evaluates the community's ability to adapt to economic growth, effects of increased disposable income, distribution of costs/benefits among affected people (adverse effect/income equity), and effects on local and regional cost of living.
Community Stability and Well-being	Demographics Cultural well-being Social cohesion	The influx of temporary workforce during each project component may influence community makeup, including demographics and mobility such as effects of migration (in and out), changes in social and cultural makeup of communities, influence on individual, family and community health.
Infrastructure and Services	Roads and traffic Housing Health services Emergency services Community infrastructure	Potential influx of temporary workforce may cause strain on community infrastructure, housing, and emergency and health services. Increased traffic due to the IW construction and maintenance may affect local road safety and cause wear to road infrastructure.

TABLE 6L-1
Socio-economic Valued Components and Indicators
Faro Mine Interim Works

Valued Component	Indicators	Rationale for Inclusion
Land Use and Access	Traditional Land Use Hunting and Fishing Recreation Tourism Forestry	Potential effects on existing land use due to the IW, to First Nations traditional land use (for hunting, trapping and gathering), as well as effects to access for commercial and recreation land users due to Project construction/maintenance.
Culture and Heritage	Traditional Culture and Use Heritage Resources Culture	Potential effects to First Nations traditional culture, use, heritage, archaeological and spiritual resources; and effects on traditional language, education, laws and traditions due to the Interim Works construction and maintenance.

3.2 Baseline Data Limitations

The socio-economic effects assessment predicts the potential changes in the condition of the socio-economic VCs as they could change due to the IW activities. The potential changes are predicted from a set of baseline conditions. The conditions of the values can change over time. So, for the purposes of the assessment, a time is chosen for when the baseline conditions are measured. For the purposes of the IWPP, the year of the baseline conditions has been selected at 2009. This is the year that the co-proponents took over the responsibility of the FMC from the receivers.

This socio-economic conditions report is based on available secondary data for the four communities, and the affected First Nations. It provides descriptions generated from statistics from a variety of sources such as YG, and Statistics Canada, as well as information gathered from First Nations and community websites and documents.

Socio-economic data are generally less frequently available compared to environmental data. Best efforts have been made to gather relevant data from 2009 on for purposes of describing community conditions; however, not all Census data from 2011 has been released. Where data from the 2011 Census was available it has been used, but data from the 2006 Census comprises most of the description of the VCs for each community. Where available, data describes trends over time. While Census data is the primary source for VC descriptions, it has limitations with respect to small communities. Data from the Census is subject to a confidentiality procedure known as random rounding in which the numbers are rounded up or down to a multiple of five or ten in order to prevent associating statistical data to any one individual. The data also may be subject to suppression depending on the topic and the size of the community. For the purposes of the baseline conditions report, most of the census data is from Census 2006. The graphs may represent data from 2005 or 2006 depending on the question. Publication of data sets from the Census takes a period of years so the graph sources may be from a publication date later in time, such as 2008.

Primary community research to verify VCs, verify secondary data, and fill data gaps was not conducted. Given the limited scope and duration of the activities in the IWPP and guidance provided by YESAB as it relates to a Designated Office-level evaluation, the assessment team considers secondary data are satisfactory for this socio-economic effects assessment. However, care must be taken when drawing conclusions on socio-economic effects in communities when the baseline conditions are derived from secondary data.

3.3 Socio-economic Study Areas

For the purposes of this socio-economic conditions report and subsequently the socio-economic effects assessment to be prepared for the IWPP, the communities described are Faro, RRDC (primarily in Ross River), LFN

(primarily in Watson Lake), KDC, and SFN (primarily in Pelly Crossing). These were chosen through a combination of those Affected First Nations identified in the Devolution Transfer Agreement, and the community (Faro) located closest to the FMC.

The Affected First Nations impacted by the FMC identified in the Devolution Transfer Agreement are (Government of Canada, 2001):

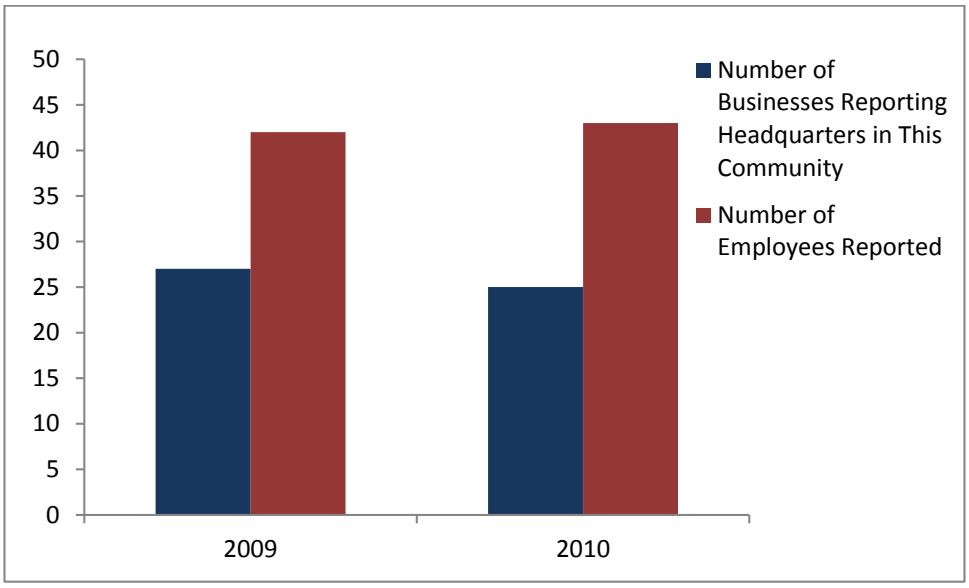
1. Ross River Dena Council (based in the community of Ross River; Traditional Territory to be all of Kaska Traditional Territory, encompassing FMC.)
2. Liard First Nation (based in the community of Watson Lake; Traditional Territory to be all of Kaska Traditional Territory, encompassing FMC.)
3. Kaska Dena Council (Umbrella organization representing interests of Kaska people in Yukon and BC; Traditional Territory encompassing FMC.)
4. Selkirk First Nation (based in the community of Pelly Crossing; the FMC upstream of its Traditional Territory.)

Faro was created as a result of the FMC in 1969, and it is the closest community to the FMC.

Secondary data related to all VCs were collected for each of these First Nations and communities, wherever possible. Secondary data as it relates to the KDC is represented through their members who are citizens of the RRDC or the LFN.

SECTION 4

Baseline Conditions of the Valued Components



4.1 The Town of Faro

During Faro's peak, it had the second largest population in the Yukon at just under 2,000 inhabitants in 1981. However, the most recent (as of June 2013) population estimates based on the Yukon Health Care Registration state it is home to 392 people (Yukon Department of Health and Social Services, 2013). This significant decline in population was a result of the closure of the FMC. Given its once large population, Faro boasts some extensive community facilities for a town of 300, including an airport, elementary and secondary schools, a recreation centre, a health centre, a post office, and a nine-hole golf course.

4.1.1 Economy and Employment

Faro is home to 25 businesses, which altogether employed 43 people (YG, 2011c). As Figure 6L-4 shows, numbers of businesses and employees in Faro have remained relatively consistent for 2009 and 2010. It should be noted that the figure below (6L-4) represents the number of businesses headquartered in Faro and the number of people those businesses employ. The labour force accounts in later graphs represent the total labour force for Faro, including businesses without local headquarters.

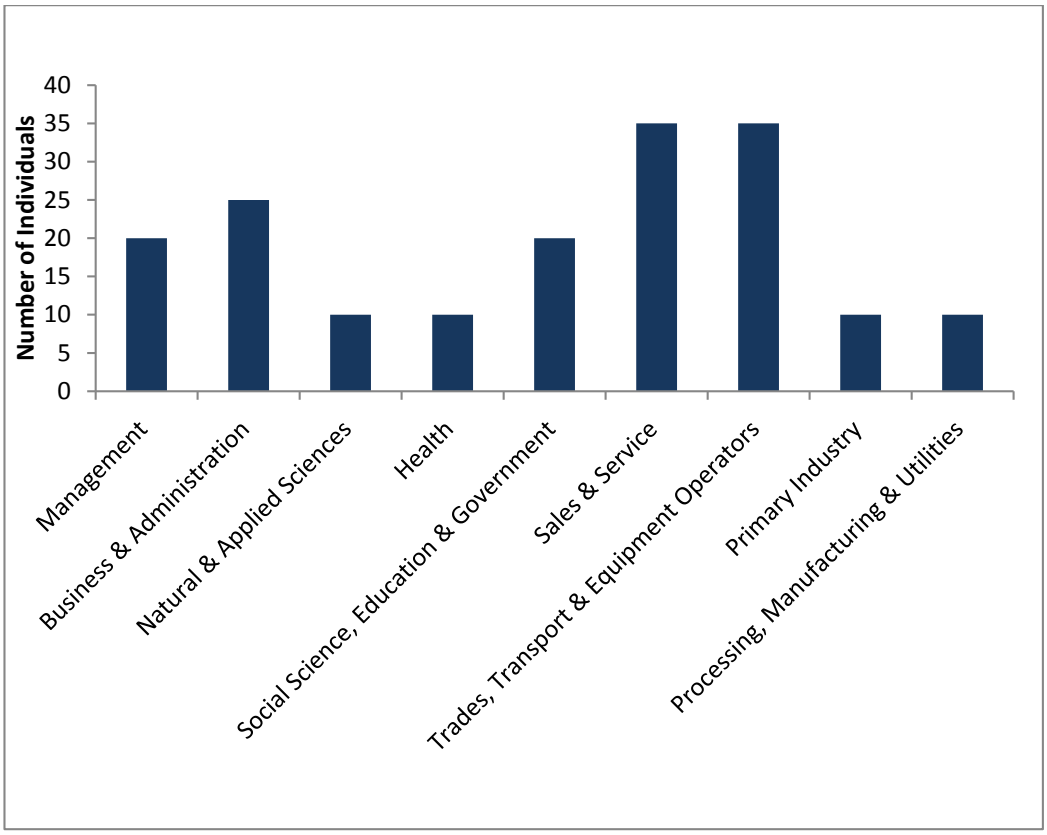


FIGURE 6L-4
Faro: Business and Employees in 2009 and 2010
Faro Mine Interim Works

Source: YG, Bureau of Statistics 2013.

Labour force by occupation shows sales and service, and trades, transport and equipment operators as the most reported occupations (Figure 6L-5). The labour force includes employed and unemployed individuals who are those without work, are available for work, and are actively seeking work.

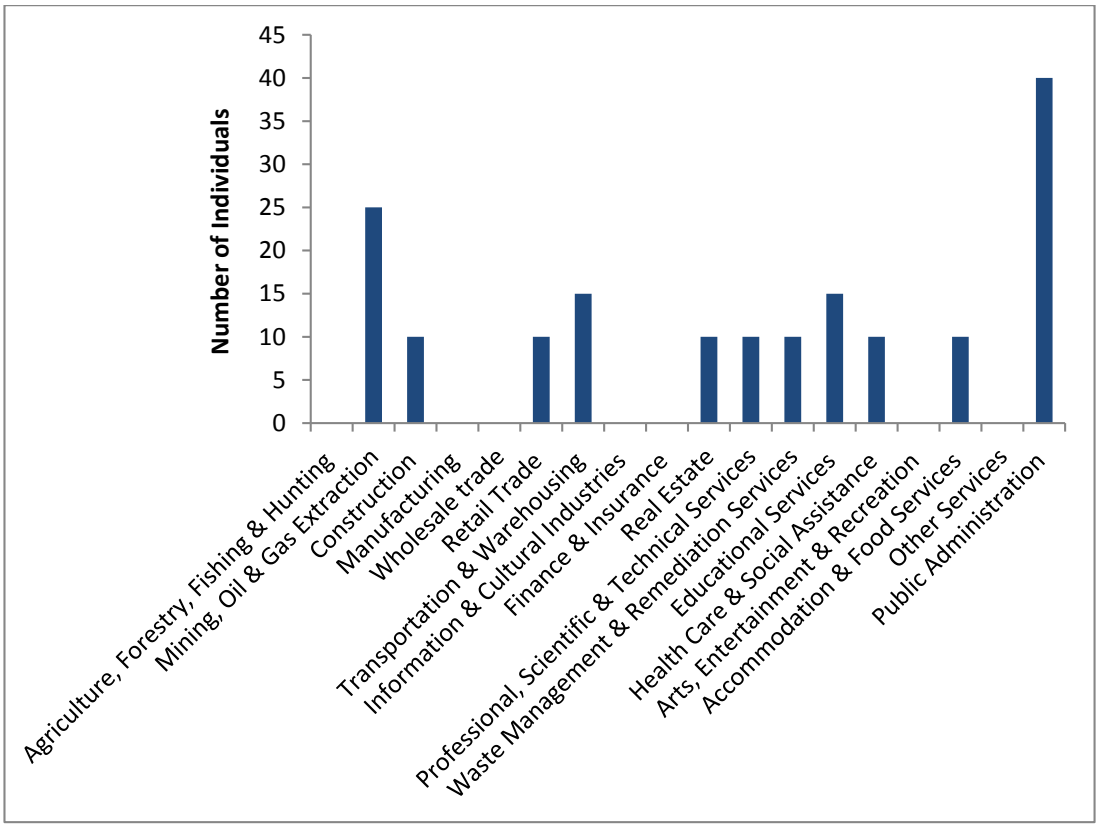

FIGURE 6L-5
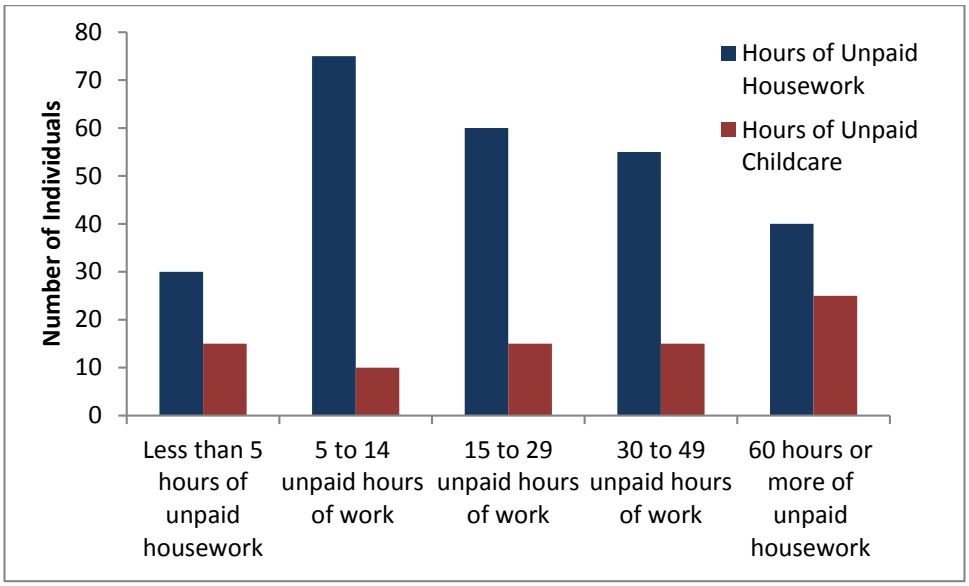
Faro: Labour Force by Occupation from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

In terms of largest labour force by industry in Faro, public administration accounted for 22 percent of the overall labour force (185 individuals) in 2005 (Figure 6L-6).

FIGURE 6L-6
Faro: Labour Force by Industry from Census 2006
Faro Mine Interim Works



Source: Statistics Canada, 2008.

The mining sector was the second largest labour force segment, accounting for 14 percent of the overall labour force (185 individuals). The labour force participation rate for Faro was 67 percent in 2005 (Statistics Canada, 2008). The main employers in Faro are government accounting for 22 percent of labour force. The private sector provides employment in the construction, mining, service industry, and tourism fields. Faro is also home to a multitude of small home-based businesses and artisans (YG, 2013c).

The following figures show the number of individuals by hours of unpaid work per week including housework and childcare (Figure 6L-7), and senior care (Figure 6L-8). In regards to unpaid work in 2005, of the total Census population sample (280 individuals), more than one quarter reported spending 5 to 14 hours weekly doing unpaid housework. The number of individuals indicating 15 to 29 hours and 30 to 49 hours weekly of unpaid housework was relatively equal at approximately 20 percent each. Fourteen percent of respondents reported 60 or more hours of unpaid housework.

Number of weekly unpaid hours spent providing childcare was much less than unpaid housework. Approximately 4 percent of the total respondents (280 individuals) claimed performing 5 to 14 hours weekly of unpaid childcare, while 5 percent of respondents equally indicated 15 to 29 and 30 to 49 unpaid hours. Nine percent of individuals reported 60 or more hours weekly dedicated to childcare. This is corroborated by the population data in Section 4.1.2, which shows Faro has a relatively older demographic profile.

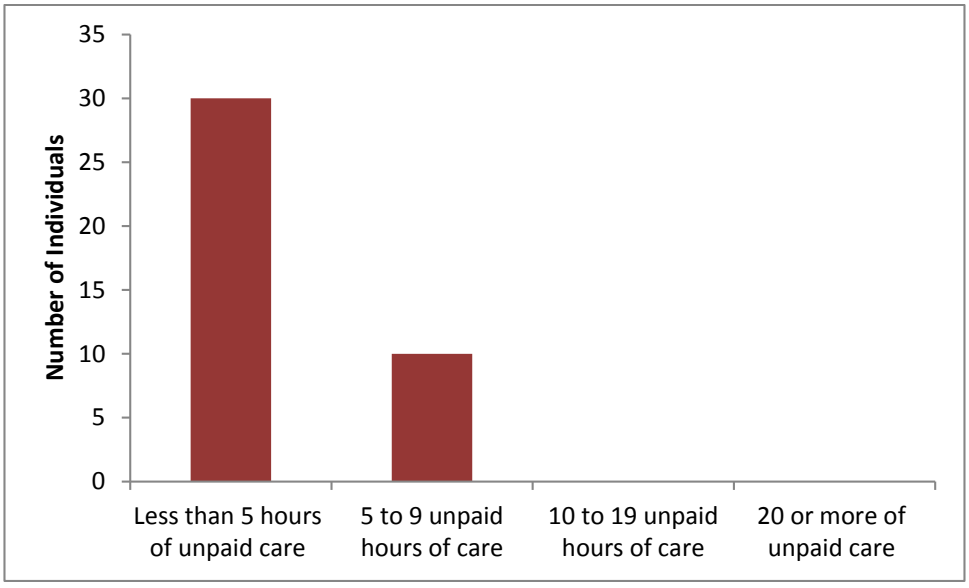


FIGURE 6L-7
Faro: Population by Weekly Hours Spent Doing Unpaid Work (Housework and Childcare) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

As shown below (Figure 6L-8), few individuals reported providing care or assistance to seniors without pay. Of the total survey respondents (280 individuals), 11 percent reported less than five unpaid hours weekly for senior care and even fewer (4 percent) reported spending 5 to 9 hours for unpaid care per week.

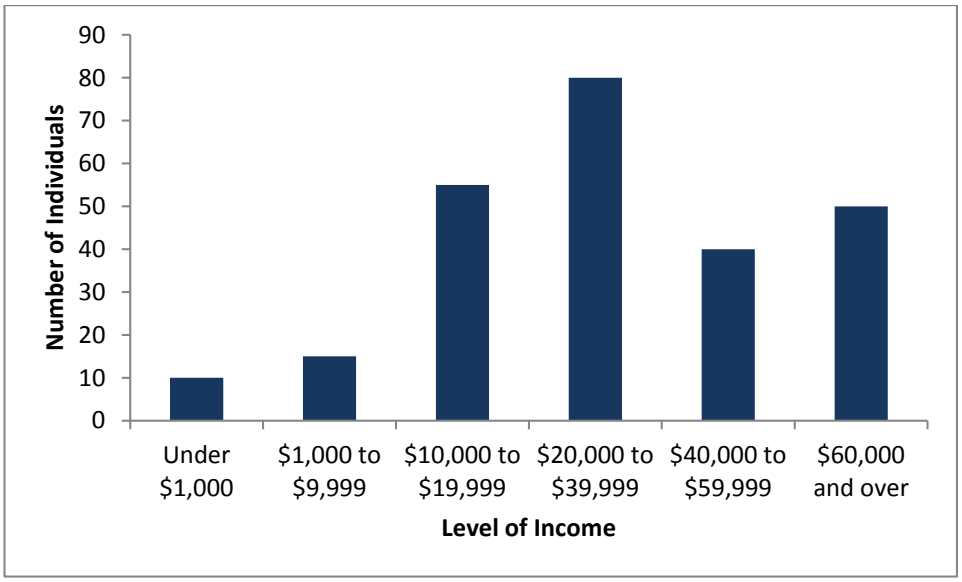

FIGURE 6L-8
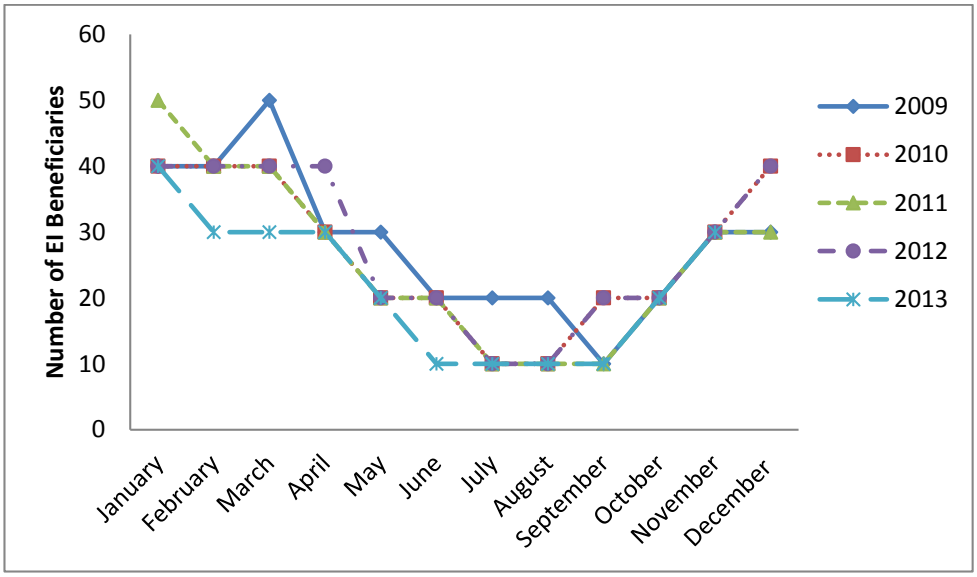
Faro: Population by Weekly Hours Spent Doing Unpaid Work (Senior Care) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

In 2005, the average annual individual pre-tax income for residents of Faro was $34,232; the average annual household income was $59,628 for the same year as shown in Figure 6L-9 (Statistics Canada, 2008).

FIGURE 6L-9
Faro: Annual Individual Pre-tax Income from Census 2006
Faro Mine Interim Works

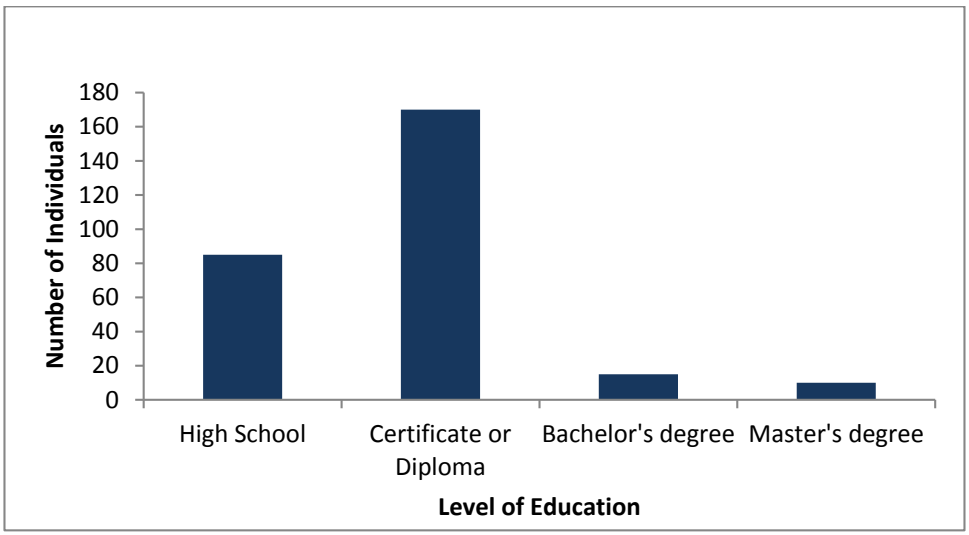


Source: Statistics Canada, 2008

According to the Canada Revenue Agency, a total of 290 tax returns were filed by Faro residents for the 2009 tax year, of which 190 included taxable income. Total income reported on all returns was $11.4 million in 2009 (Canada Revenue Agency, 2011).

Individuals receiving regular employment insurance (EI) benefits—which excludes benefits associated with sickness, maternity, fishing, work sharing, adoption, parental, regular, training, job creation, and self-employment assistance—have remained relatively stable between 2009 and 2013. As observed in Figure 6L-10, the greatest number of EI benefits occurs during the winter months between November and April. Lower EI levels during the summer months may be attributed to increased employment associated with the busier tourism industry, field research, and environmental work that typically occurs during the warmer months. Recently, there has been a slight decrease in the number of EI beneficiaries during the winter months.

FIGURE 6L-10
Faro: Employment Insurance Beneficiaries from 2009 to 2013
Faro Mine Interim Works

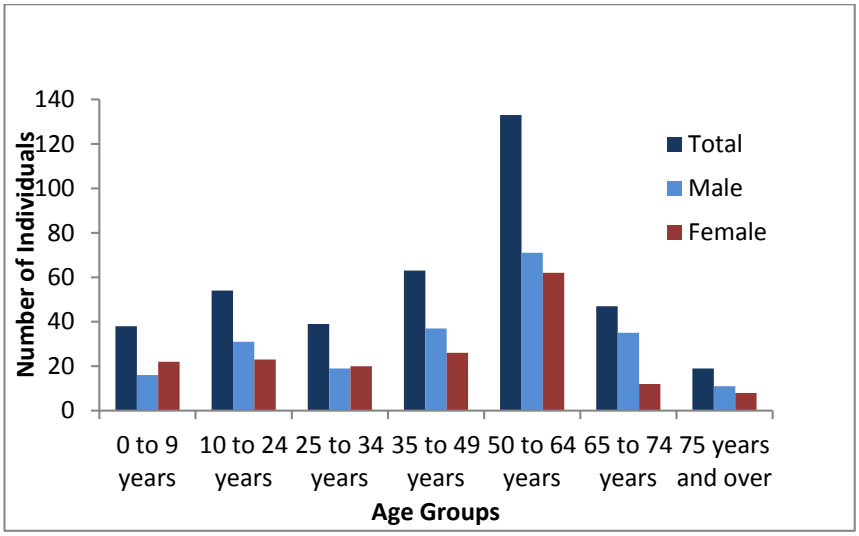


Source: Statistics Canada, no date.

The Consumer Price Index measures the cost of living experienced by communities in Canada. Relative to Whitehorse, in 2012 Faro residents spent $1.11 for every dollar that was spent in Whitehorse on household goods and supplies, and in 2013 that rose very slightly to $1.17 (YG, 2013c). In addition to shopping online and by phone, Faro residents often travel to Whitehorse for shopping. People in Faro supplement groceries by hunting, fishing and harvesting from the hinterland surrounding their community (YG, 2013c).

The highest levels of educational attainment in Faro are shown in Figure 6L-11.

FIGURE 6L-11
Faro: Education Levels from Census 2006
Faro Mine Interim Works



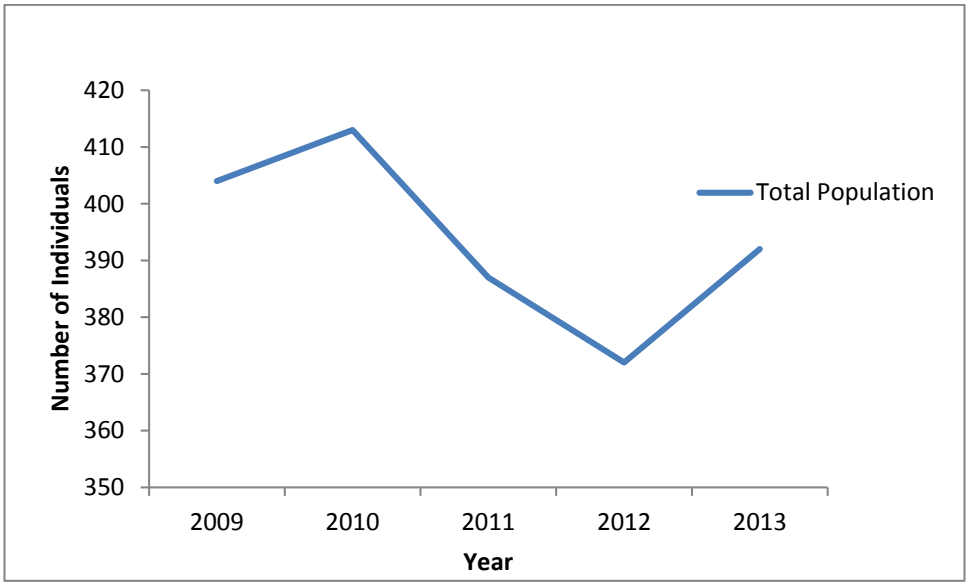
Source: Statistics Canada, 2008.

Of the 275 individuals aged 15 years and older, the 2006 Census data reported 95 had completed a certificate or diploma in the trades or other non-university programs. A total of 25 individuals reported having a Bachelor's or Master's degree as their highest level of schooling (Statistics Canada, 2008).

4.1.2 Community Stability and Well-being

Figure 6L-12 shows population estimates by age and sex from the Yukon Health Care Registration from June 2013.

FIGURE 6L-12
Faro: Population by Age and Sex in 2013
Faro Mine Interim Works



Source: YG, Department of Health & Social Services and Yukon Bureau of Statistics, 2013.

Of the 392 residents in Faro as of June 2013 there were 219 males and 173 females (YG, 2013a). In general, Faro has an aging population, especially as compared to other communities in the study area (YG, 2013a).

Figure 6L-13 shows a slight decline in population from 2010 to 2012. However, between 2012 and 2013, the population rose.

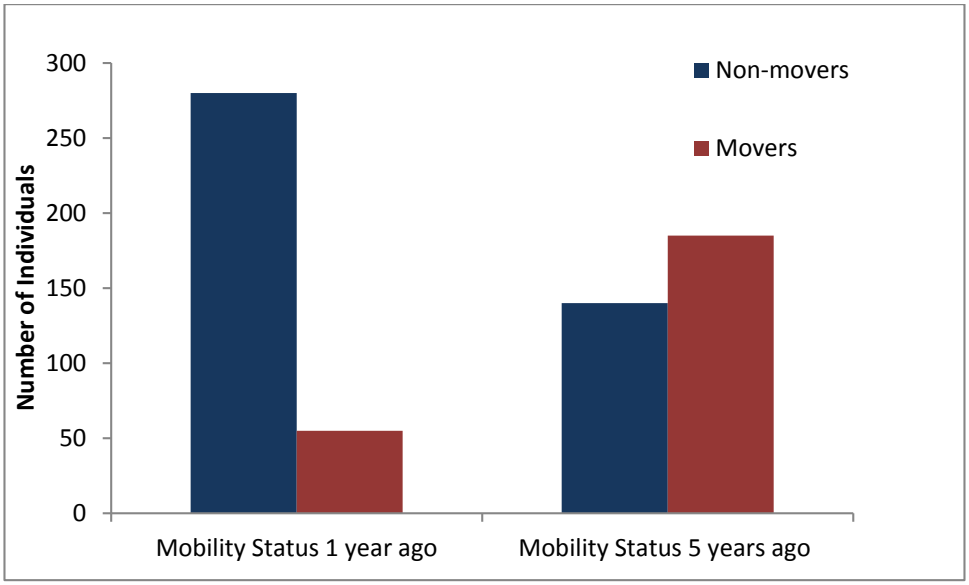


FIGURE 6L-13
Faro: Total Population from 2009 to 2013
Faro Mine Interim Works

Source: YG, Department of Health & Social Services and Yukon Bureau of Statistics, 2013.

As Figure 6L-14 shows, most people in Faro are non-movers, reporting no moves within the previous year, which signifies a very stable population base. Mobility status from 5 years ago indicates if a respondent moved within the last 5 years.

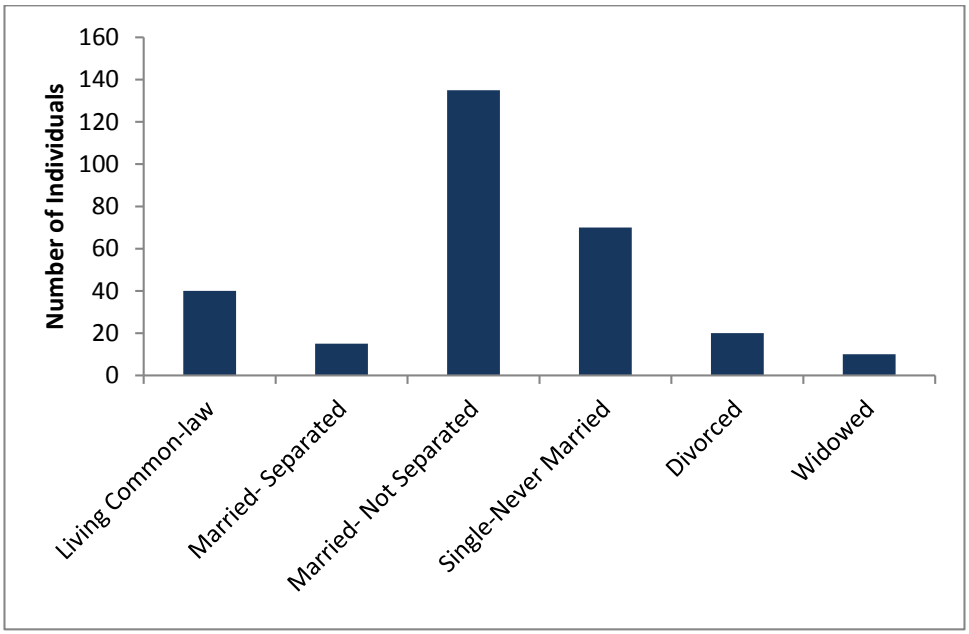

FIGURE 6L-14
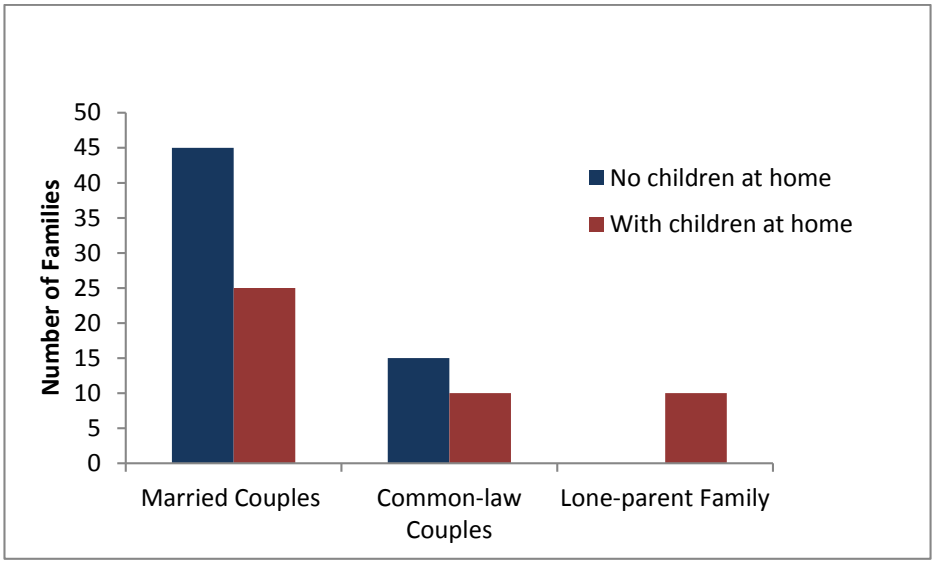
Faro: Mobility Status from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.



Faro has a large number of homes with married or common-law couples, with no children living at home (Figures 6L-15 and 6L-16) (Statistics Canada, 2012a).

FIGURE 6L-15
Faro: Marital Status from Census 2011 [1]
Faro Mine Interim Works

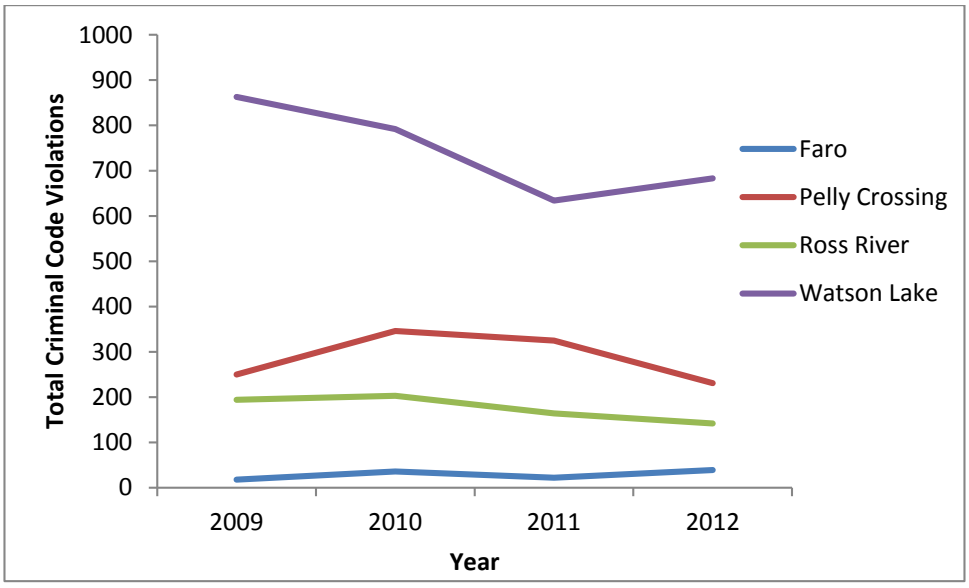
FIGURE 6L-16
Faro: Family Structure from Census 2011
Faro Mine Interim Works



Source: Statistics Canada, 2012a.

[1] Statistics Canada provides the following classifications of marital status: "Living common-law includes persons who are living with person of the opposite sex or of the same sex as a couple but who are not legally married to that person. Married-separated includes persons currently legally married, but who are no longer living with their spouse and have not obtained a divorce. Married includes persons whose opposite- or same-sex spouse is living, unless the couple is separated or a divorce has been obtained. Also included are persons in civil unions. Single includes persons who have never married (including all persons less than 15 years of age). It also includes persons whose marriage has been legally annulled who were single before the annulled marriage and who have not remarried. Widowed includes persons who have lost their legally-married spouse through death and who have not remarried" (Statistics Canada, 2012b).

As Figure 6L-17 shows, in comparison with other communities in the Yukon, Faro has very low rates of crime (YG, 2012).

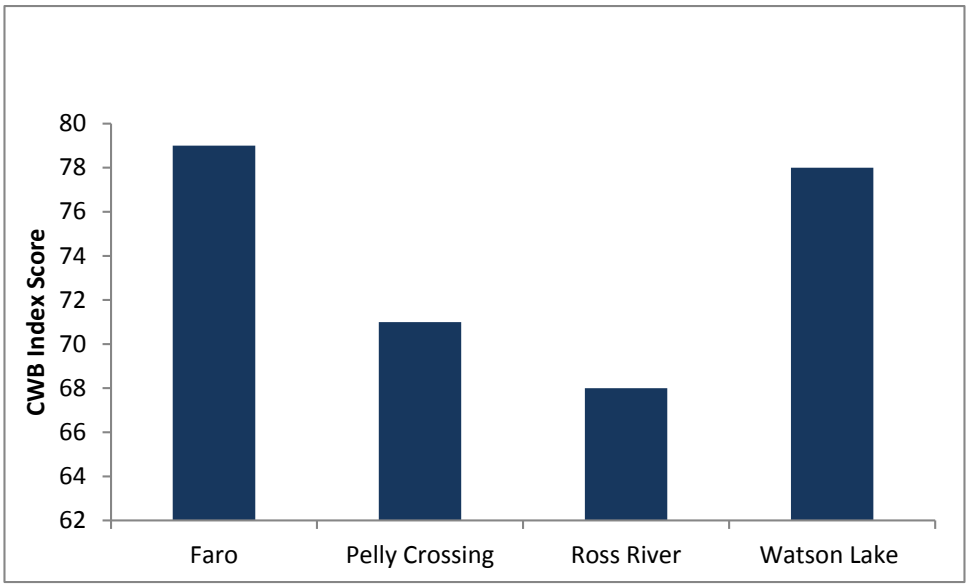


FIGURE 6L-17
Community Crime Rates: 2009-2012
Faro Mine Interim Works

Source: Yukon Bureau of Statistics, 2012.

The Community Well-Being score is a number generated by Aboriginal Affairs and Northern Development Canada (AANDC) which reflects data on income, education, housing conditions and labour force activity. It can range from a low of 0 to a high of 100. Figure 6L-19 presents the Community Well-Being score for all communities in the study area in 2006, indicating that Faro and Watson Lake had higher scores.

FIGURE 6L-19
Community Well-Being Index Score in 2006
Faro Mine Interim Works

Source: AANDC Community Well-Being Database. 2006

4.1.3 Infrastructure and Services

Faro has high-speed internet over telephone lines, as well as landlines and cell phone service provided by Northwestel. Yukon Energy Corporation provides customer electricity directly in Faro.

Faro has a kindergarten to grade 12 school with a 2012 enrollment of 39 students and 52 students enrolled as of September 2013 (YG, 2013c). Yukon College has a local community campus and coordinator, and courses are offered on-line or via teleconference facilities. The community library is co-located with the Del Van Gorder School, with free internet and computer access.

Faro is located approximately 358 km northeast of Whitehorse and 179 km east of Carmacks on the Robert Campbell Highway. The Faro Airport, located adjacent to Johnson Lake 3.5 km from Faro, has a 4,000-foot gravel runway and there is also a nearby float-plane base at Johnson Lake (YG, 2013c).

Faro has a nursing station staffed by two nurses on call 24 hours a day, as well as 24-hour access to Yukon HealthLine 811. The Yukon Children's Dental Program comes to Del Van Gorder School on a regularly scheduled basis. More complex medical and dental treatment is handled in Whitehorse, or, depending on the specialty required, outside of Yukon. In emergency situations patients are medevac'd out of Faro to the nearest appropriate facility.

Faro has a 24-hour ambulance service staffed by volunteers, which also services the community of Ross River. It also has a Royal Canadian Mounted Police detachment and volunteer fire services.

There are approximately 425 dwellings (2011) in Faro, which are a mixture of single family, multi-units, and mobile homes, as well as a country residential subdivision within the municipal boundary (YG, 2013c).

Faro is surrounded by natural beauty in the form of lakes, rivers and mountain ranges, and is home to abundant and rare wildlife, such as the Fannin Sheep, as well as migratory species like the Sandhill Cranes. The remaining community members have made great efforts in recent years to further tourism development for the community as a means to decrease dependence on the cyclical resource development sector as their main economic driver (YG, 2013).They have also been successful in attracting new community members interested in the natural environment and the arts (Miyagawa, 2004).

Faro has an active recreational community in both summer and winter. Local recreational facilities include softball, squash, a seasonal pool, ice rink, and carpet bowling. Faro also has a nine-hole golf course, a gym and weight room in the recreational centre, several playgrounds, and an arboretum. Hiking trails are well established, as are wildlife-viewing stations for cranes and sheep. The Dena Cho Trail and Van Gorder Falls trail provide outdoor hiking and skiing opportunities. Johnson Lake and Fish Eye Lake provide space for outdoor recreation, including swimming, water-skiing, fishing, and boating. Johnson Lake also supports a float-plane base and canoe-rental facility (YG, 2013c).

Faro is an incorporated municipality, so is responsible for delivering services to properties and residents within its boundary, such as fire protection, water, and road maintenance. Area residents living outside the municipal boundary are serviced by YG. Faro typically has an elected Mayor and four Councillors; the current government is identified in Table 6L-3.

TABLE 6L-3
Faro Mayor and Council (2014)
Faro Mine Interim Works

Name	Role
Mel Smith	Councillor
Heather Grantham	Councillor
Deborah Carreau	Deputy Mayor
Mike McMahon	Councillor

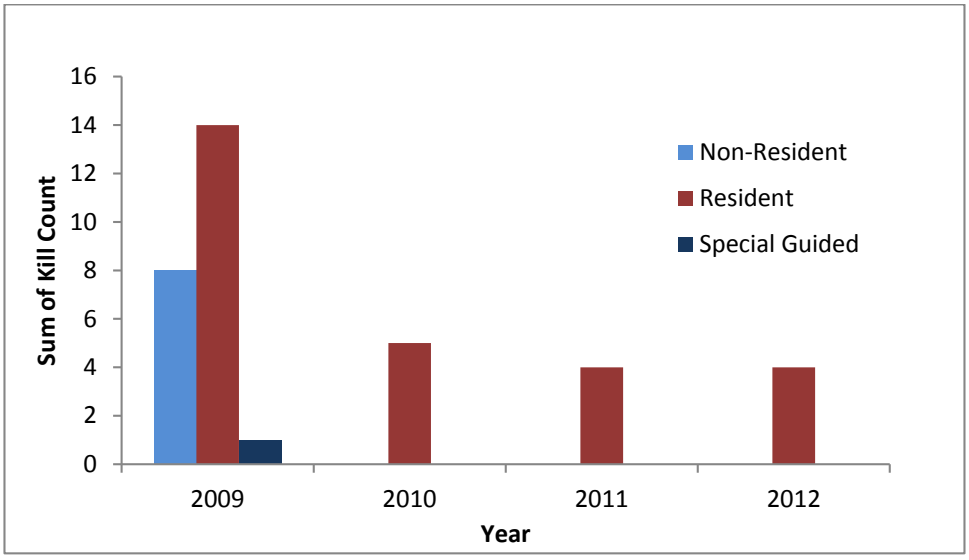
4.1.4 Land Use and Access

Timber harvest occurs in the area around Faro, primarily for personal and commercial home heating fuel (YG, 2011b). The Mount Mye Timber Harvest Plan identifies a timber harvest area to the east of the FMC (YG, 2011b). The area is part of the historic Faro burn of 1969. It is anticipated that 5,000 cubic metres of timber can be harvested from the area. To access the timber harvest area, permit holders must travel on the Blind Creek mining road and some parts of the identified timber harvest areas overlap with the FMC reserve.



There is wildlife harvest (particularly moose and caribou by resident hunters) (Figures 6L-20 and 6L-21) in Game Management Subzones (GMS) 445 and 446 (Figure 6L-22), which are accessed through the FMC.

FIGURE 6L-20
Moose Harvest in GMS 445 and 446, 2009 to 2012
Resident, Non-Resident, and Special Guided (does not include First Nations harvest)

Source: Yukon Government Department of Environment, no date

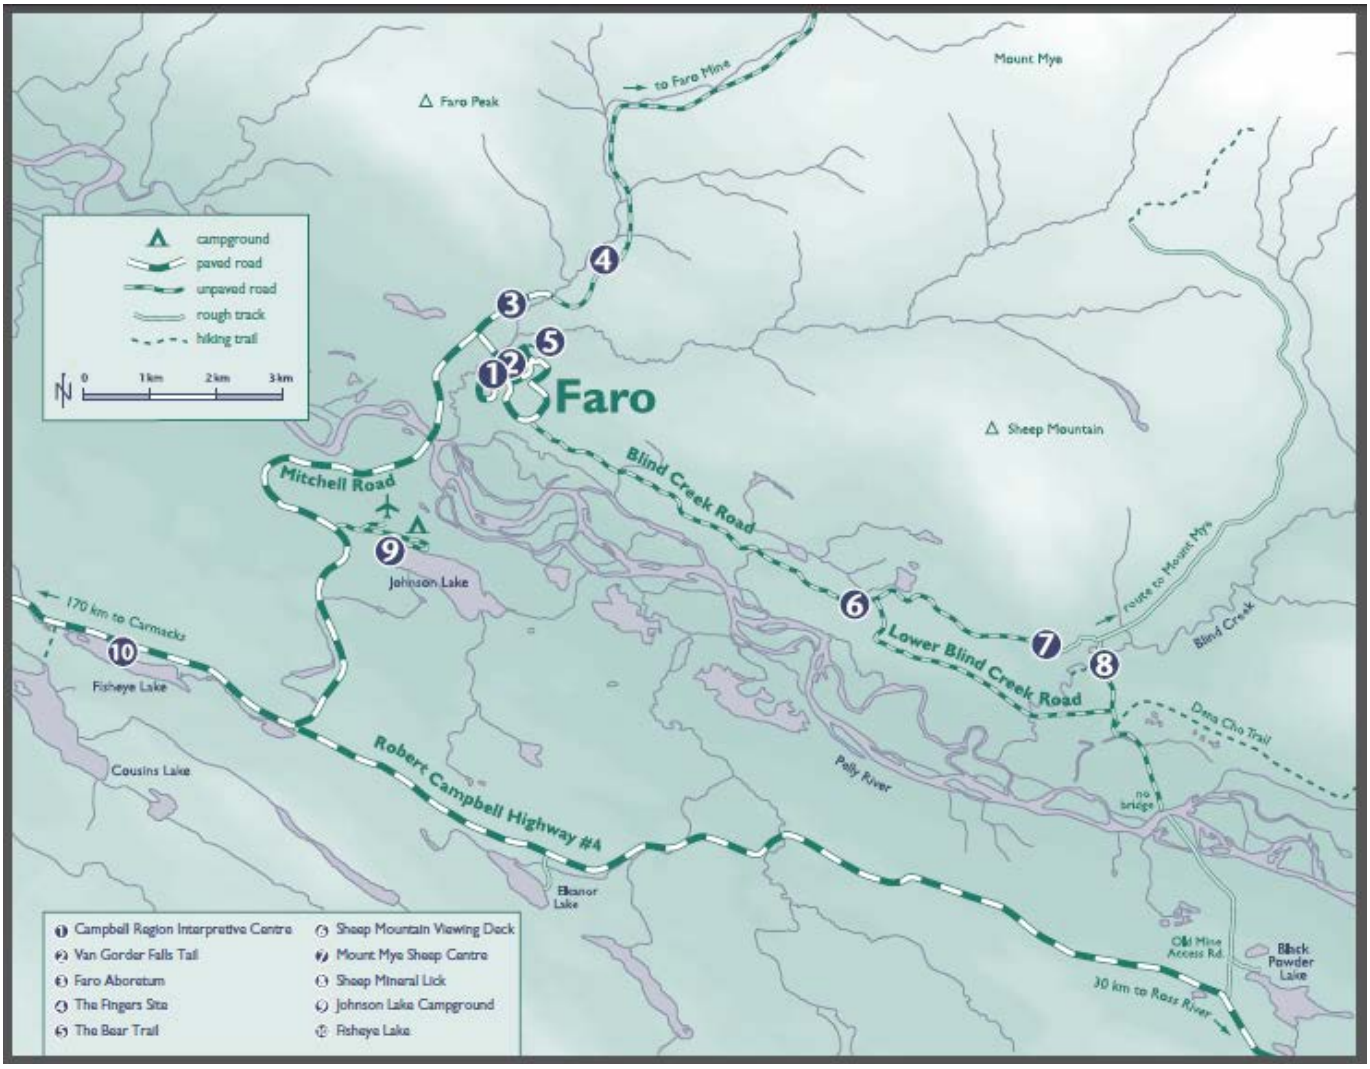
FIGURE 6L-22
Faro Area Game Management Subzones 442 to 446
Faro Mine Interim Works



Source: Yukon Fish and Wildlife Management Board Website, 2013

Moose hunters have been asked to voluntarily limit their harvest in the area since 1999, for reasons unrelated to the FMC. However, harvest rates for licensed hunters remain high and consistently are over standard harvest management thresholds (Yukon Fish and Wildlife Management Board, 2013). YG is currently considering further moose harvest management regulations in all game management subzones in the Faro area, which may have an effect on the number of harvesters that access the FMC in the future.

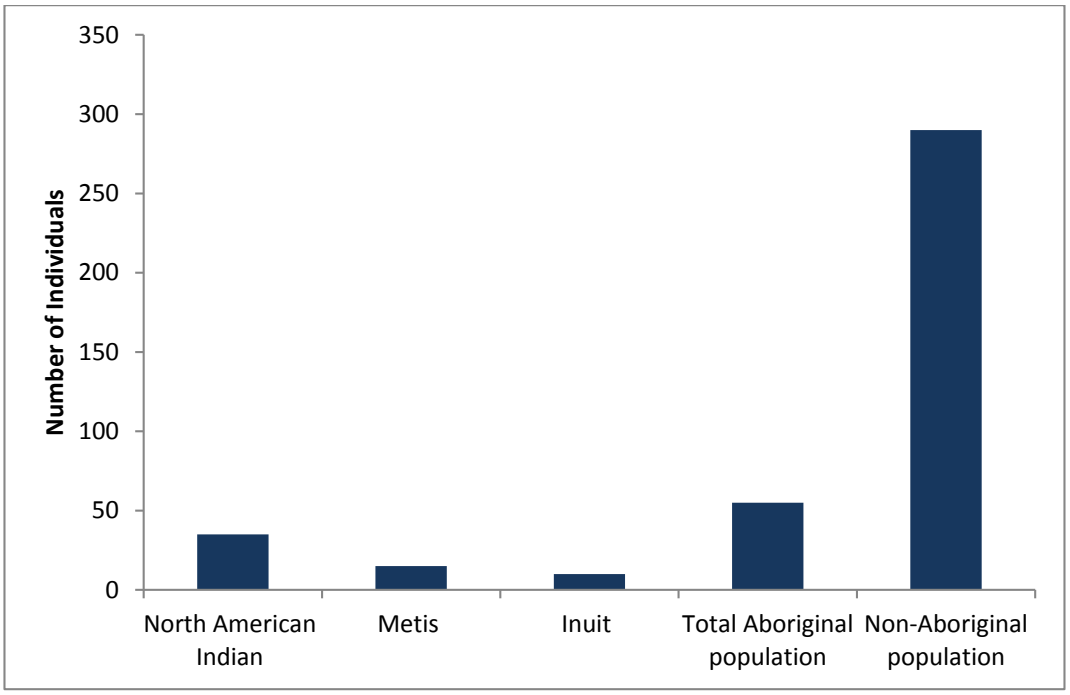
There are several hiking and mountain biking trails designated around Faro. The Dena Cho Trail is a 65-km multi-use trail that has been established using traditional travel routes between Faro and Ross River. Trail-based activities are widely promoted as a recreation and tourism opportunity in the region (Town of Faro, 2007).

Yukon has a wildlife-viewing plan that identifies viewing areas close to the FMC (Figure 6L-23) (YG 2013c).

FIGURE 6L-23
Tourism Sites in the Faro Area
Faro Mine Interim Works

Source: YG, 2011

The Mount Mye Sheep Centre has a heated cabin and viewing platform for viewing sheep on Mt. Mye. Each May, Faro hosts a Crane and Sheep viewing festival during the annual migration of the Sandhill cranes. This has become a major event for the community and draws visitors from around the territory to view the cranes as they migrate up the Tintina Trench (Town of Faro, 2013).



Tourism has become a major focus of the community and is identified as a priority in Faro's Integrated Community Sustainability Plan (Town of Faro, 2007). At present, there are at least six bed and breakfasts and one hotel in Faro (Town of Faro, 2013). All advertise wilderness experiences as a major reason to visit the Faro region. Faro is also home to the Yukon's Campbell Region Visitor's Centre, providing services to local visitors and housing a small museum covering the region's natural and human history (Town of Faro, 2013).

4.1.5 Culture and Heritage

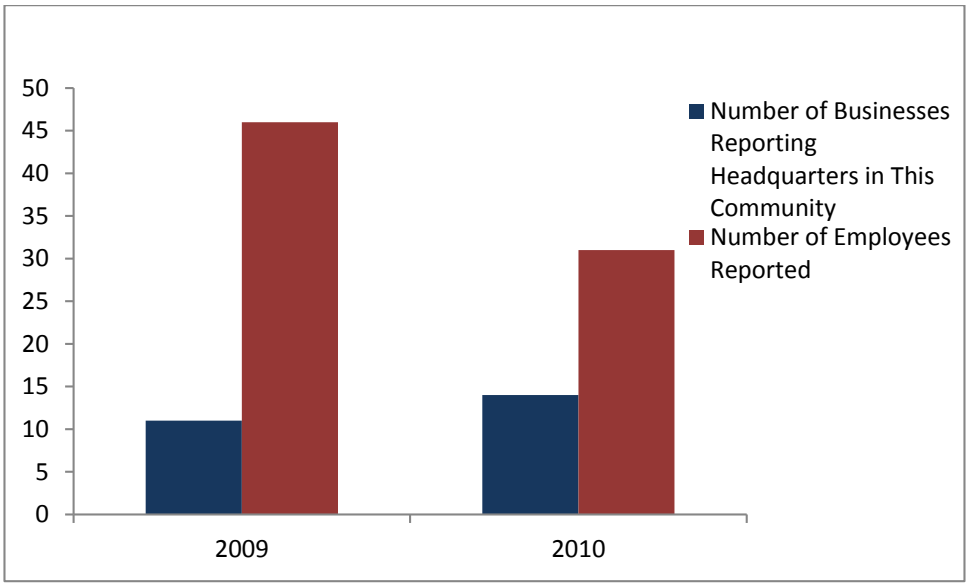
Faro was created to service the FMC in 1969. As such, its history and heritage is very much tied to the mining industry. The community has strongly felt the boom and bust with each opening and closing of the FMC. While on-going operations at FMC and further mineral exploration in the area is important to providing economic stimulus to Faro, there has been a concerted effort in recent years to develop small home-based businesses, and tourism opportunities, such as the Crane and Sheep viewing festival.

The figure below identifies the Aboriginal population of Faro (Figure 6L-24).

FIGURE 6L-24
Faro: Aboriginal and Non-Aboriginal Population from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

Most Faro residents speak English. Although hosting a small Aboriginal population within the Town itself, Faro is located in the traditional territory of the RRDC of the KDC (see section 4.2).



4.2 Ross River Dena Council

The confluence of the Ross and Pelly Rivers was traditionally used as a summer gathering spot for the people of the RRDC. In 1901, a fur trading post was established and created the community of Ross River. The community of Ross River is primarily home to members of the RRDC.

4.2.1 Economy and Employment

In 2010, Ross River was home to 14 businesses, which altogether employed 31 people (Figure 6L-25) (YG, 2011c). It should be noted that the Figure 6L-26 represents the number of businesses headquartered in Ross River and the number of people those businesses employ. The labour force accounts in later graphs represent the total labour force for Ross River, including businesses without local headquarters.

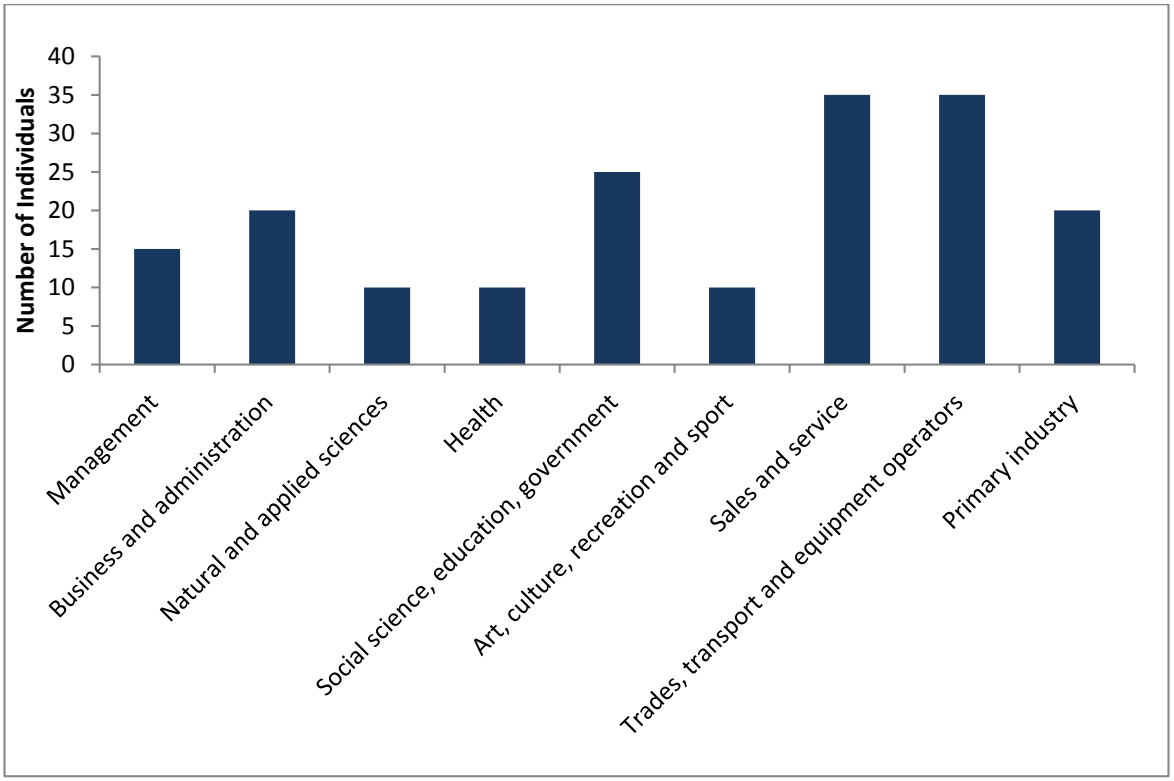


FIGURE 6L-25
Ross River: Business and Employees in 2009 and 2010
Faro Mine Interim Works

Source: YG, Bureau of Statistics, 2011c and 2010d.

Similar to Faro, sales and service, and trades, transport and equipment operators make up the majority of occupations in the labour force in Ross River (Figure 6L-26). The labour force includes employed and unemployed individuals who are those without work, are available for work, and are actively seeking work.

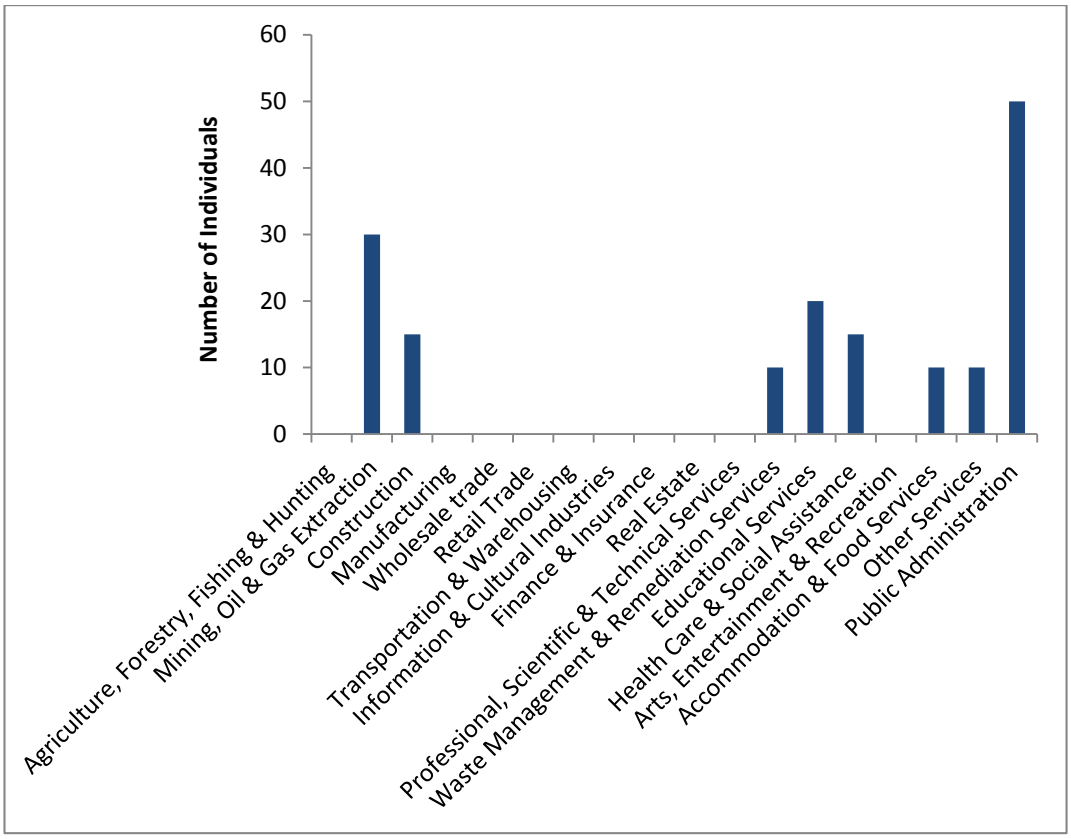

FIGURE 6L-26
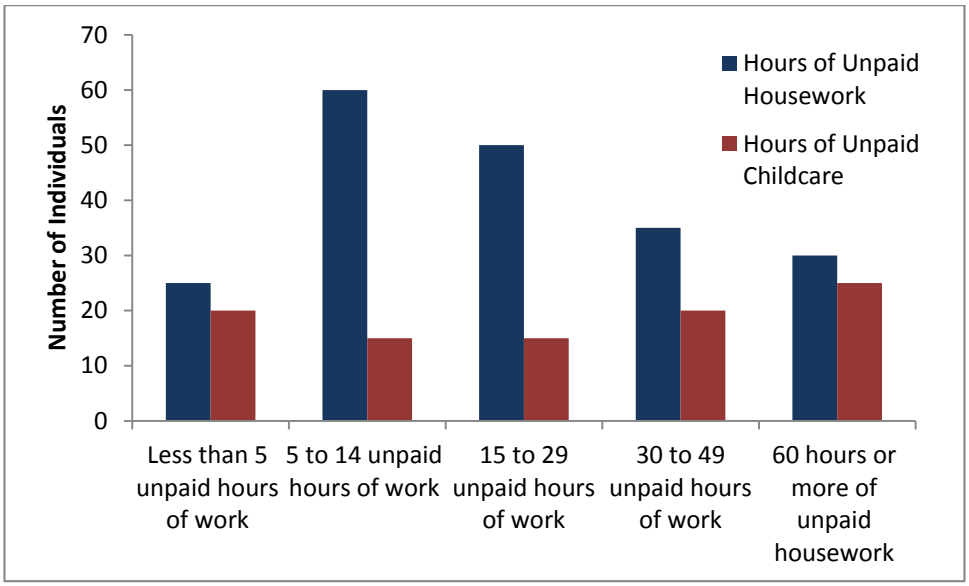
Ross River: Labour Force by Occupation from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

In terms of labour force by industry in 2005, public administration accounted for 31 percent of the overall labour force (165 individuals) (Figure 6L-27).

FIGURE 6L-27
Ross River: Labour Force by Industry from Census 2006
Faro Mine Interim Works



Source: Statistics Canada, 2008.

Following public administration, the mining sector was the second largest labour force segment, accounting for 19 percent of the overall labour force (165 individuals). The labour force participation rate for Ross River was 72 percent in 2005 (Statistics Canada, 2006).

The following figures show the population by hours spent doing unpaid work per week including housework and childcare (Figure 6L-28) and senior care (Figure 6L-29). In regards to unpaid housework, in 2005, more than one quarter of the Census population sample (230 individuals) reported spending 5 to 14 hours weekly doing unpaid housework. Twenty-two percent of individuals indicated 15 to 29 unpaid hours weekly. The number of respondents reporting 30 to 49 hours weekly of unpaid housework was similar to those indicating 60 or more hours of unpaid housework at 15 and 13 percent, respectively.

Number of weekly unpaid hours spent providing childcare was less than hours of unpaid housework. Of the total number of survey respondents (225 individuals), 9 percent indicated 30 to 59 hours of unpaid care and 11 percent reported doing 60 or more hours weekly. The total number of respondents who indicated performing 5 to 14 hours and 15 to 29 hours of unpaid childcare was equal at seven percent each.

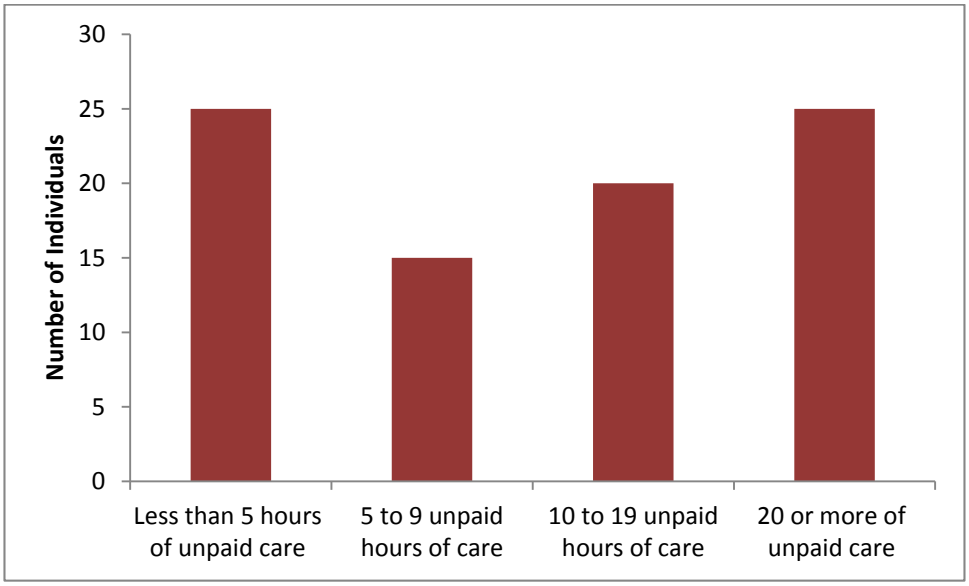


FIGURE 6L-28
Ross River: Population by Weekly Hours Spent Doing Unpaid Work (Housework and Childcare) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

In terms of providing unpaid assistance or care to seniors, 11 percent of the total survey respondents (230 individuals) reported less than five hours weekly, which was equal to the number of individuals who reported 20 or more unpaid hours weekly. Seven percent stated 5 to 9 hours and nine percent indicated 10 to 19 hours for such care without pay.

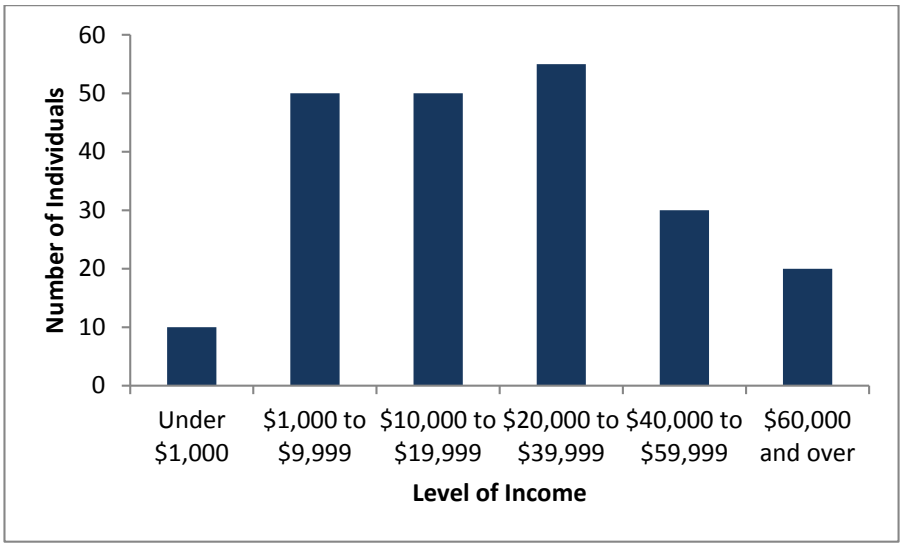

FIGURE 6L-29
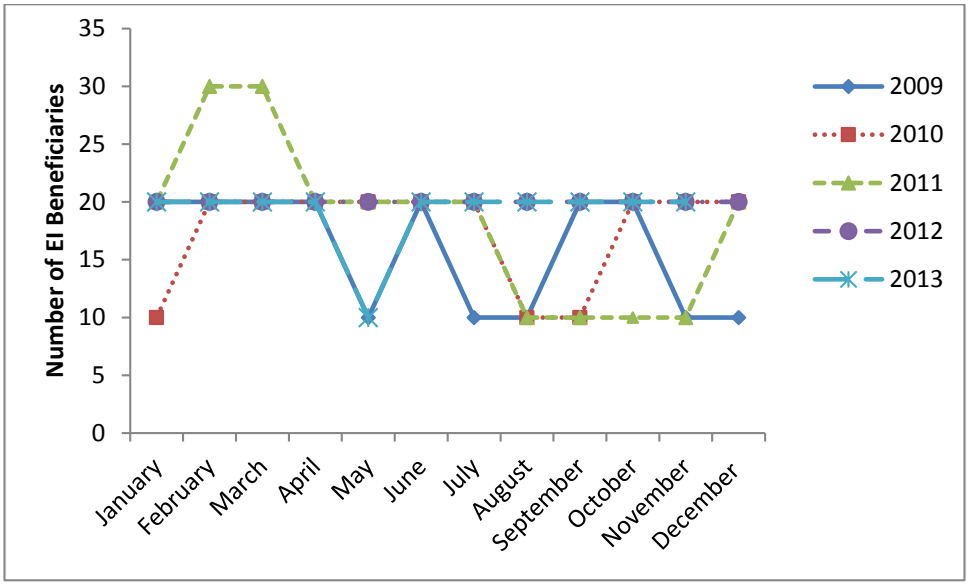
Ross River: Population by Weekly Hours Spent Doing Unpaid Work (Senior Care) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

Figure 6L-30 shows in 2005, the average annual individual pre-tax income for residents of Ross River was $26,061; average annual household income was $44,069 for the same year (Statistics Canada, 2008).

FIGURE 6L-30
Ross River: Annual Individual Pre-tax Income from Census 2006
Faro Mine Interim Works

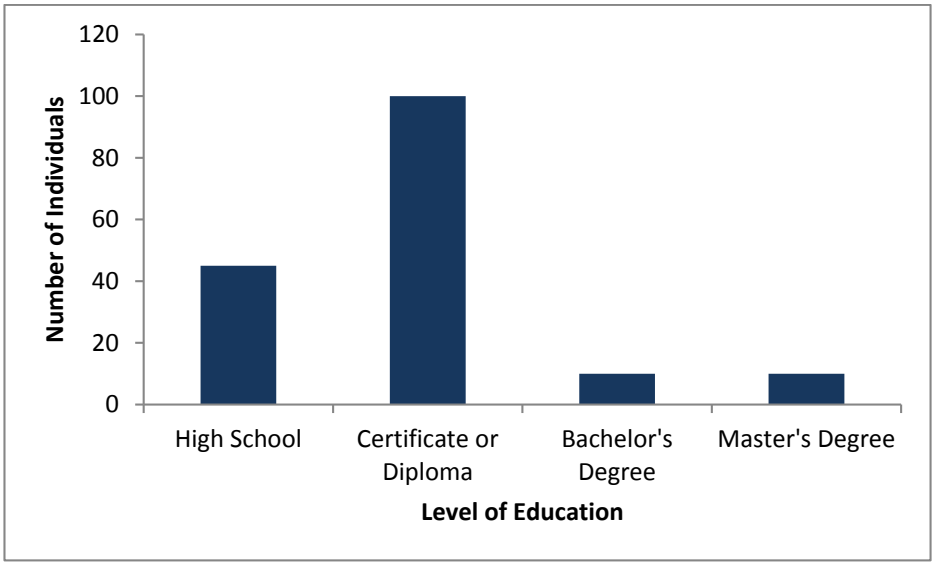


Source: Statistics Canada, 2008.

According to the Canada Revenue Agency, a total of 250 tax returns were filed by Ross River residents for the 2009 tax year, of which 130 included taxable income. Total income reported on all returns was $7.7 million in 2009 (Canada Revenue Agency, 2011).

The number of individuals receiving regular EI benefits, which excludes benefits associated with sickness, maternity, fishing, work sharing, adoption, parental, regular, training, job creation, and self-employment assistance, have remained stable during recent years (2012 and 2013). As shown in Figure 6L-31, with the exception of 2011, the number of EI beneficiaries over the years has observed slight fluctuations ranging between ten and 20 individuals in any given month.

FIGURE 6L-31
Ross River: Employment Insurance Beneficiaries from 2009 to 2013
Faro Mine Interim Works



Source: Statistics Canada, no date.

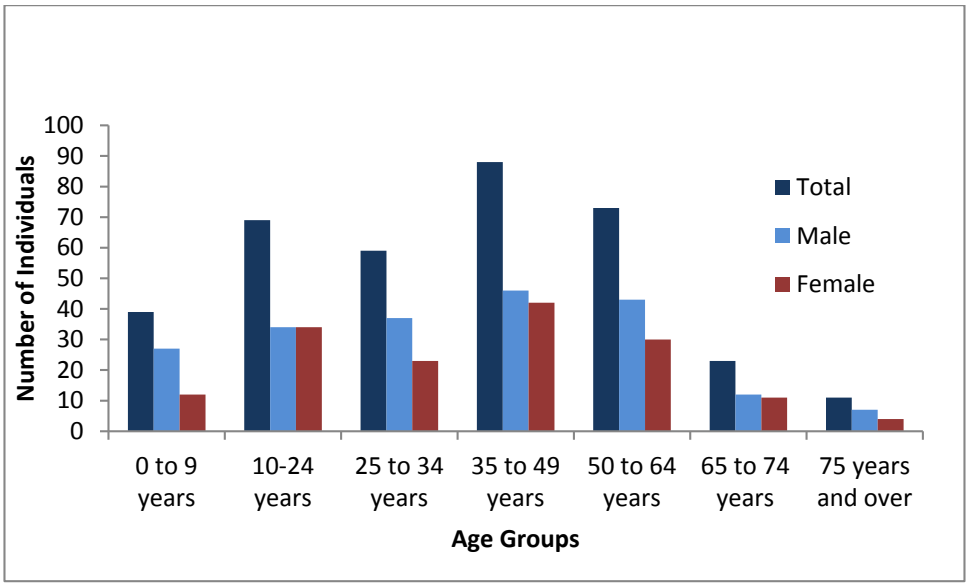
The Consumer Price Index measures the cost of living experienced by communities in Canada. In 2013, Ross River residents spent $1.21 for every dollar that an individual would spend on similar goods and supplies in Whitehorse (YG, 2013e).

In Ross River, as in many rural Yukon communities, many people travel to Whitehorse (a distance of 410km) for the bulk of their household goods and provisions or order goods online or by phone. Supplementing groceries by country-harvested foods, such as game, berries and fish, is also an important aspect of household economics (YG, 2013e).

In terms of educational attainment in Ross River, of the 230 individuals who were aged 15 years and older in 2006, 100 had completed a certificate or diploma (Figure 6L-32).

FIGURE 6L-32
Ross River: Education Levels from Census 2006
Faro Mine Interim Works

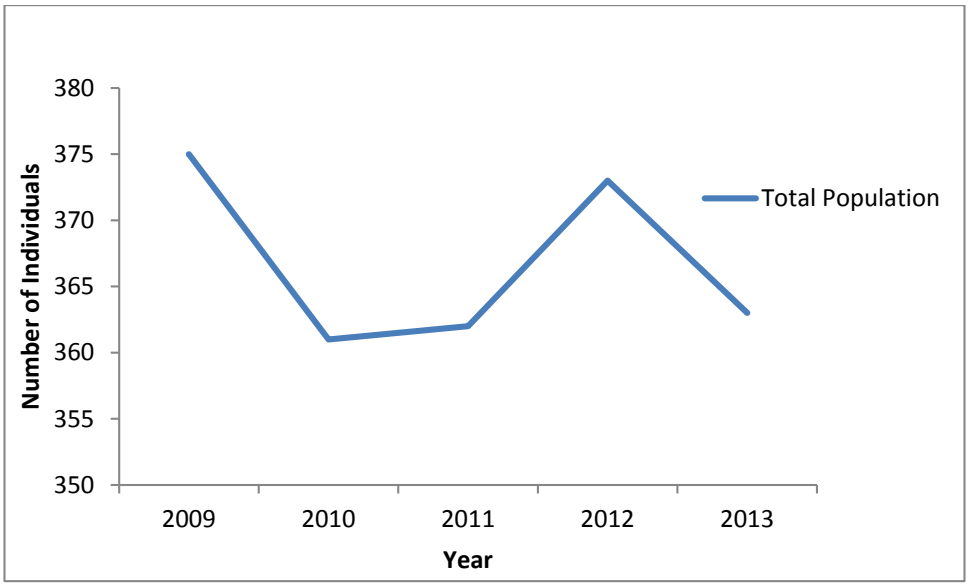
Source: Statistics Canada, 2008.



A total of 20 individuals reported having a university Bachelor's or Master's degree as their highest level of schooling (Statistics Canada, 2008).

4.2.2 Community Stability and Well-being

Estimated number of residents based on the 2011 Census is 352, but recent estimates (as of June 2013) based on the Yukon Health Care data puts it at 363 (Figure 6L-33) (YG, 2013a).



Age and sex data from the 2011 Census has been suppressed because of small sample size, but records from the Yukon Health Care Registration show in June 2013, there were 363 residents in Ross River, 206 male and 156 female (Figure 6L-34).

FIGURE 6L-33
Ross River: Population by Age and Sex in 2013
Faro Mine Interim Works

Source: YG, 2013a.

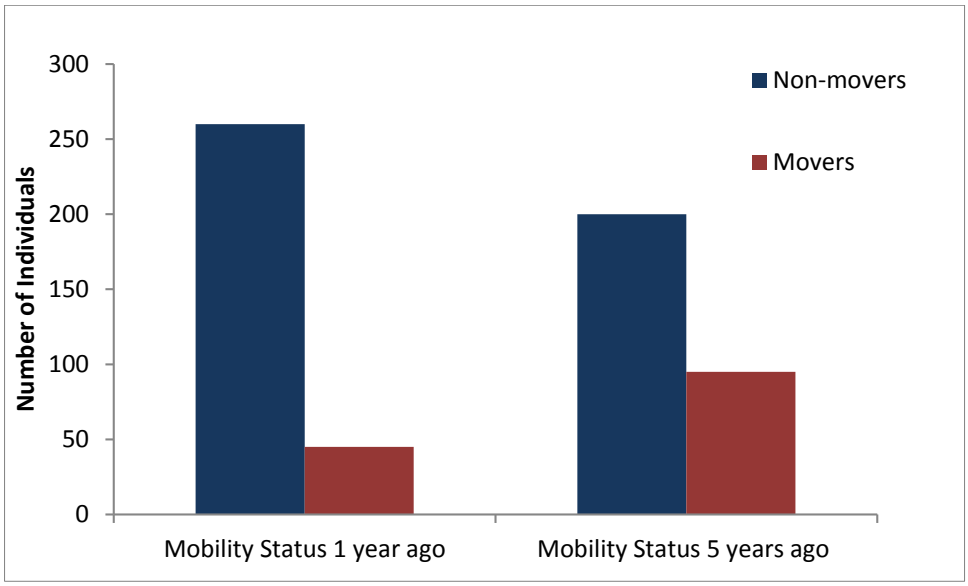


FIGURE 6L-34
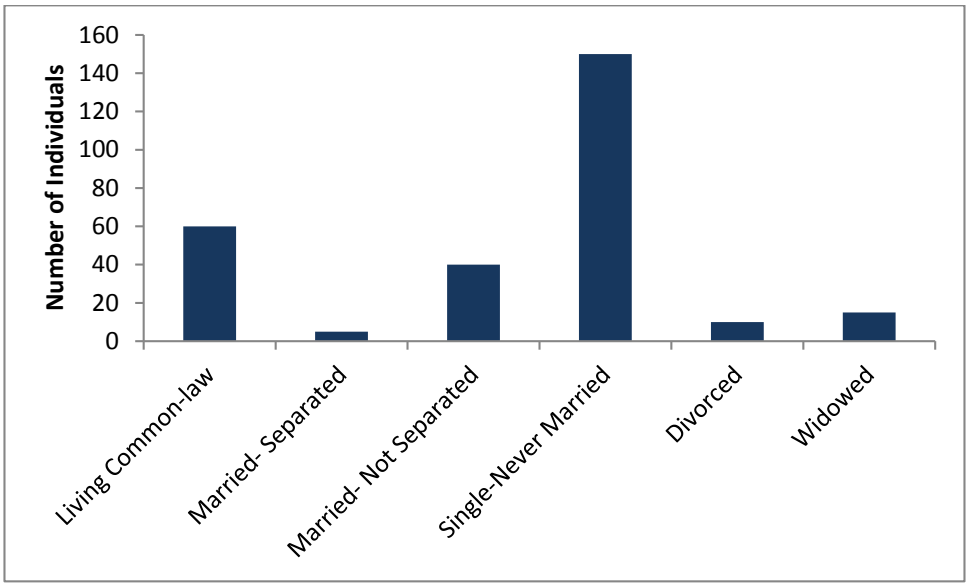
Ross River: Total Population from 2009 to 2013
Faro Mine Interim Works

Source: YG, 2013a.

As found in the 2006 Census, Ross River has a very stable population base with approximately 84 percent of the total survey respondents (310 individuals) reporting no moves within the previous year (Figure 6L-35). Mobility status from 5 years ago indicates if a respondent moved within the last 5 years.

FIGURE 6L-35
Ross River: Mobility Status from Census 2006
Faro Mine Interim Works



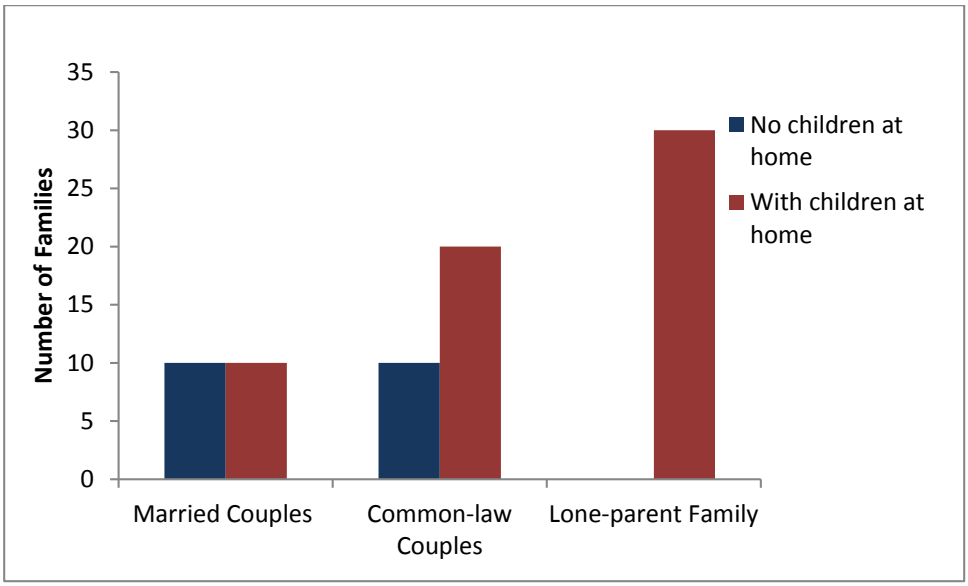
Source: Statistics Canada, 2008.

As shown below in Figure 6L-36, the majority of residents are single. Most Census data reflecting household make-up has been suppressed because of limited sample size.

FIGURE 6L-36

Ross River: Marital Status from Census 2006 [2]

Faro Mine Interim Works



Source: Statistics Canada, 2008.

Figure 6L-37 shows family structure for the community from the 2006 Census. Of the 80 respondents, 37 percent were single parents (lone-parent family), while one quarter of common-law couples reported having children at home. Married couples equally reported having children and not having children at home.

[2] Statistics Canada provides the following classifications of marital status: "Living common-law includes persons who are living with person of the opposite sex or of the same sex as a couple but who are not legally married to that person. Married-separated includes persons currently legally married, but who are no longer living with their spouse and have not obtained a divorce. Married includes persons whose opposite- or same-sex spouse is living, unless the couple is separated or a divorce has been obtained. Also included are persons in civil unions. Single includes persons who have never married (including all persons less than 15 years of age). It also includes persons whose marriage has been legally annulled who were single before the annulled marriage and who have not remarried. Widowed includes persons who have lost their legally-married spouse through death and who have not remarried" (Statistics Canada, 2012b).

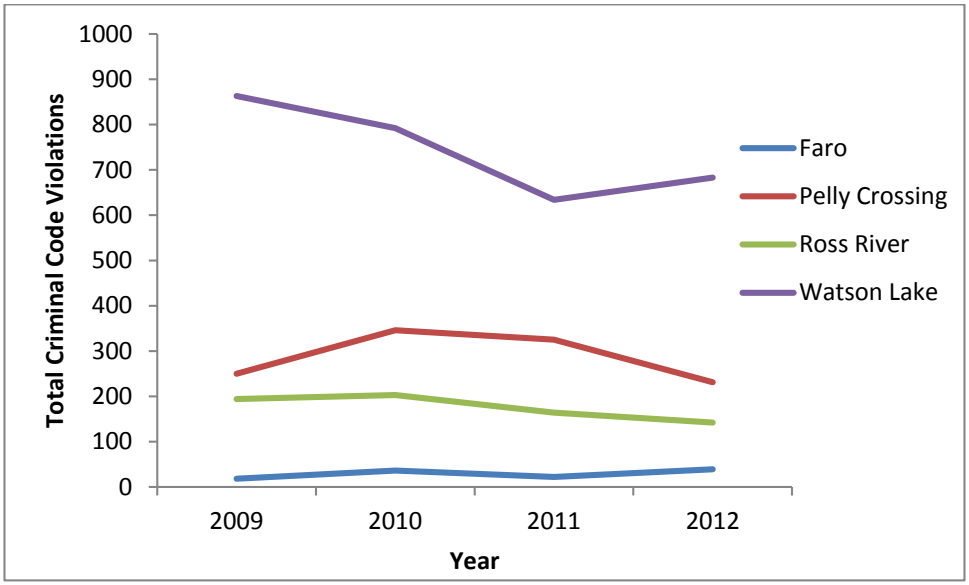


FIGURE 6L-37
Ross River: Family Structure from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

Figure 6L-38 indicates 142 Criminal Code violations were reported in Ross River in 2012. This is comparable with other communities of its size in the Yukon.

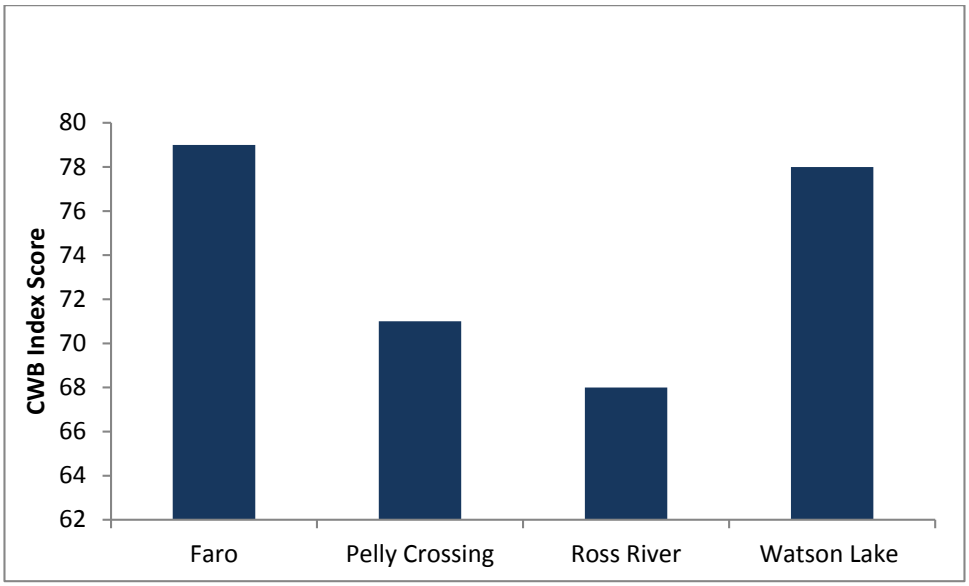

FIGURE 6L-38
Community Crime Rates: 2009-2012
Faro Mine Interim Works

Source: YG, 2012

The Community Well-Being score is a number generated by AANDC which reflects data on income, education, housing conditions and labour force activity. It can range from a low of 0 to a high of 100. Figure 6L-39 identifies the Community Well-Being score for all communities in the study area in 2006. Ross River has the lowest Community Well-Being score of all the communities.

FIGURE 6L-39
Community Well-Being Index Score in 2006
Faro Mine Interim Works

Source: AANDC Community Well-Being Database, 2006.

4.2.3 Infrastructure and Services

Ross River is linked to communities outside via high-speed internet, cellular service, and landline telephone service (YG, 2013e). Yukon Electrical purchases grid power from Yukon Energy Corporation, a Crown corporation of the Yukon Government, for distribution to its customers in Ross River (Yukon Electrical, 2013).

The Ross River School is a Kindergarten to Grade 10 school, with the 2012 enrollment at 48 and 2013 enrollment at 43 (YG, 2013e). Most students are members of the RRDC, and as such, the curriculum incorporates many aspects of traditional values. Yukon College has a community campus, which assists with courses online or through teleconferencing. The public library is shared with the public school and also offers internet and computer access (YG, 2013e).

After a devastating fire burned down the community arena in 2011, resource development companies operating in the region quickly began fundraising for the replacement of the recreation centre. With further funding assistance from the YG, construction began in 2012, and was completed in 2013. The new facility includes a hockey arena and multi-purpose areas designed for recreation and sport programming. The recreation centre was officially opened to the public on January 14, 2014 (YG, 2014).

Ross River is the gateway to the North Canol Road, a popular destination for adventure tourists looking for a scenic drive in one of the most remote regions in the country. A summer cable ferry transports vehicles from Ross River to the North Canol (YG, 2013e).

Ross River has a nursing facility for all residents, staffed by two nurses on call 24 hours a day. The Yukon Children's Dental Program provides dental services, community visits are scheduled through the Ross River School. Additional services and support are provided to members of the RRDC through the RRDC Health and Social Services Department (YG, 2013e).

In Ross River, ambulance services are volunteer run and provided out of Faro, which is 74 km away. There is a Royal Canadian Mounted Police detachment located in Ross River, as well as volunteer fire services (YG, 2013e).

According to the 2011 National Household Survey, there are 130 private dwellings, mostly single detached homes. Yukon Housing Corporation provides 14 social housing units and 12 staff units in Ross River, as well as programs and services which assist with home renovations, construction of rental units, mortgages, and financing (YG, 2013e).

Ross River is located 409 km northeast of Whitehorse via Carmacks on the North Klondike and Robert Campbell Highway. It is 74 km east of Faro, on the Robert Campbell Highway. Both highways are all weather and paved. There is a gravel airstrip maintained year-round, located adjacent to town. As an unincorporated municipality, Ross River's services to its residents and business are delivered by the YG. This includes water and wastewater services, landfill operations, and municipal road maintenance (YG, 2013e).

4.2.4 Land Use and Access

The FMC is located within the traditional territory of the Ross River Dena, who are part of the KDC. The RRDC does not have a settled land claim agreement. However, they identify a large portion of the central and eastern Yukon as being part of their traditional lands. RRDC and LFN claim overlapping traditional territories.

The area around the FMC was traditionally used by local First Nations primarily as a hunting and gathering location (Weinstein, 1992). However, for families who traditionally used the Mt. Mye/Blind Creek area, their harvesting and other land-use activities moved to other locations when the mine was developed (Weinstein, 1992). At this time, there is one RRDC Site-specific claim (RRDC S-11B) within the FMC Reserve.

The Dena Cho Trail, a 65-km multi-use trail between Faro and Ross River traces old travel routes used by local First Nations. This trail is promoted as a tourism and recreation activity in the area.

There is active trapping in the area around the FMC. Trap line number 405 is a group trap line managed by the RRDC and used by First Nation members.

4.2.5 Culture and Heritage

The RRDC is one of the five members of the KDC and is based in the community of Ross River. The Ross River Dena are currently one of the three Yukon First Nations without a settled land claim or self-government agreement. As such, they are administered as an Indian Band under the Indian Act. The governance structure includes a Chief, Deputy Chief, and three Councillors (Table 6L-4).

TABLE 6L-4
Chief and Council of the Ross River Dena, 2014
Faro Mine Interim Works

	Jenny Caesar
	James Dick
	Yvonne Moon

Source: KDC, 2014

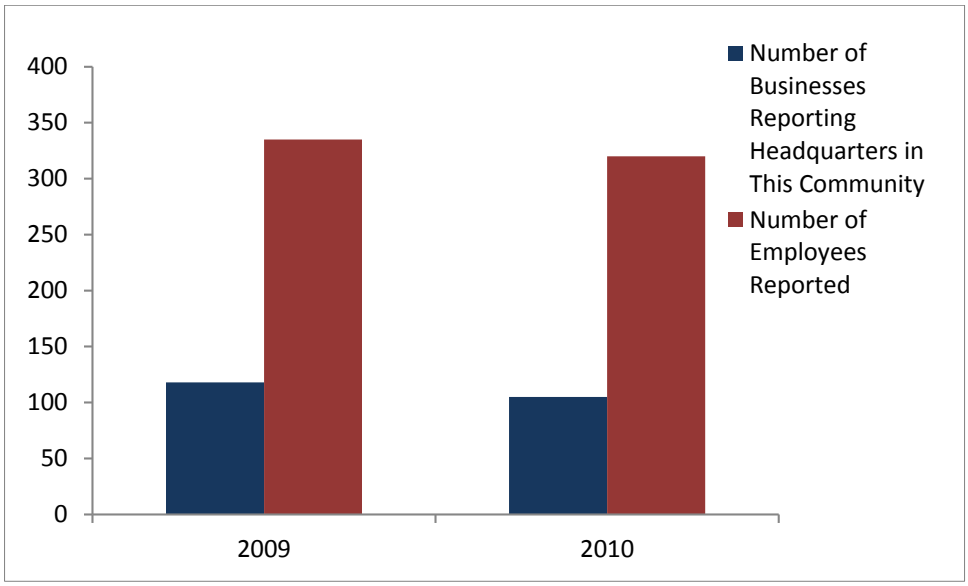
The area surrounding the community of Ross River was used traditionally for seasonal harvesting and camping by the people of the Ross River Dena, and it is still used as a source of wildlife for hunting, trapping and fishing. The Ross River Dena are also known for their exceptional drumming and singing, and host stick gambling events at Coffee Lake, a historical gathering place.

As noted previously, Ross River has a large Aboriginal population. Figure 6L-40 shows the breakdown of the Aboriginal population by identity.

FIGURE 6L-40
Ross River: Aboriginal and Non-Aboriginal Population from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

The traditional language of the Ross River Dena is primarily Kaska, although a number of citizens are also Slavey speakers. English is currently the predominant language.



4.3 Liard First Nation

Watson Lake is home to the LFN, a member of the KDC. References to the community of Watson Lake often include the Town of Watson Lake and the adjoining settlements of the LFN, including Upper Liard, Two-Mile Village, and Two and a Half Mile Village. The Town of Watson Lake was established in 1939 during the development of a chain of airports across the North by the Canadian government, and its presence was further enhanced by the construction of the Alaska Highway in 1942. Watson Lake is known as the "Gateway to the Yukon" since it is the first community encountered when driving north into the Yukon via the popular Alaska Highway. Watson Lake is the third-largest community in the Yukon, behind Whitehorse and Dawson City.

4.3.1 Economy and Employment

Figure 6L-41 represents the number of businesses and employees reported in the community. As indicated, in 2010 Watson Lake was home to 105 businesses, which altogether employ 320 people (YG, 2011c). It should be noted that the figure below (6L-43) represents the number of businesses headquartered in Watson Lake and the number of people those businesses employ. The labour force accounts in later graphs represent the total labour force for Watson Lake, including businesses without local headquarters.

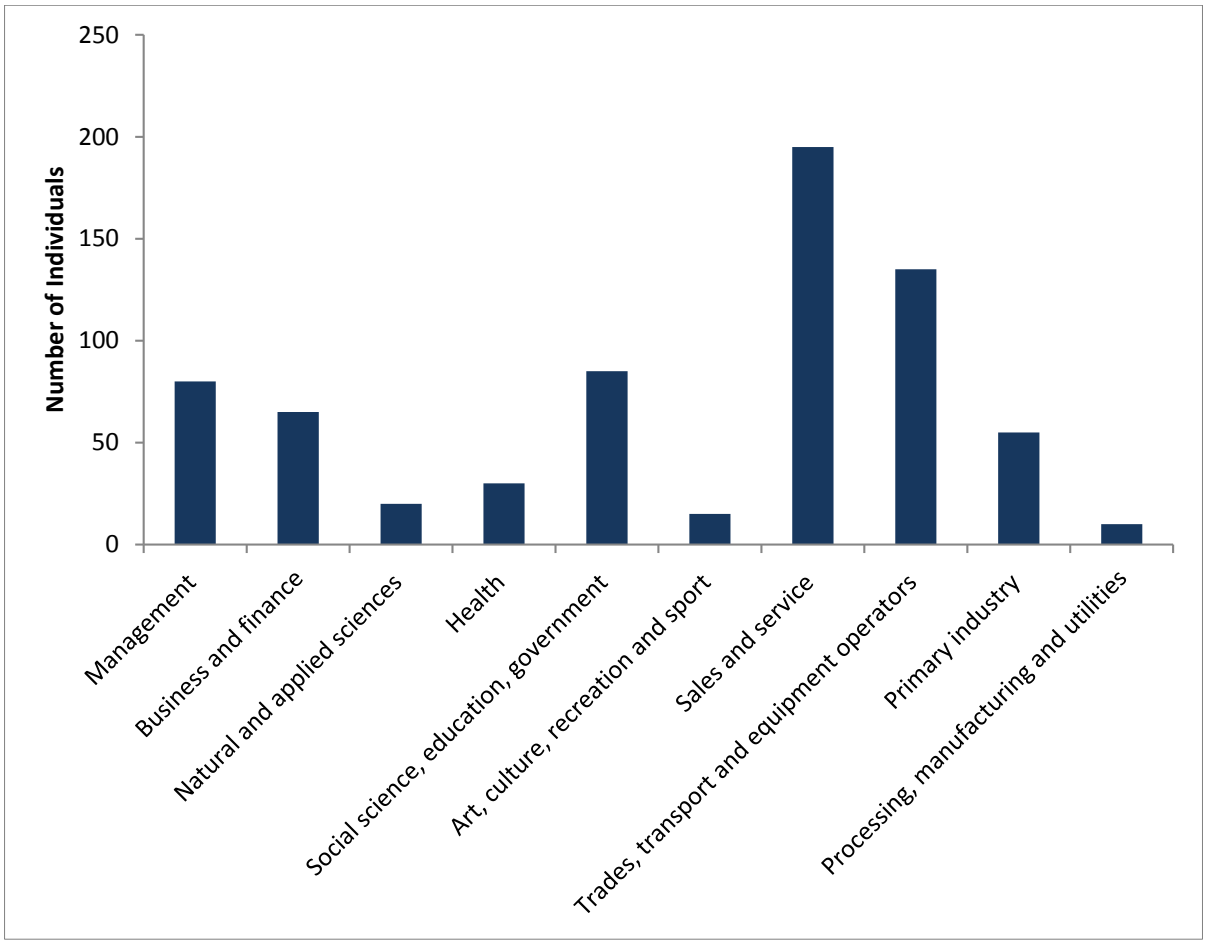


FIGURE 6L-41
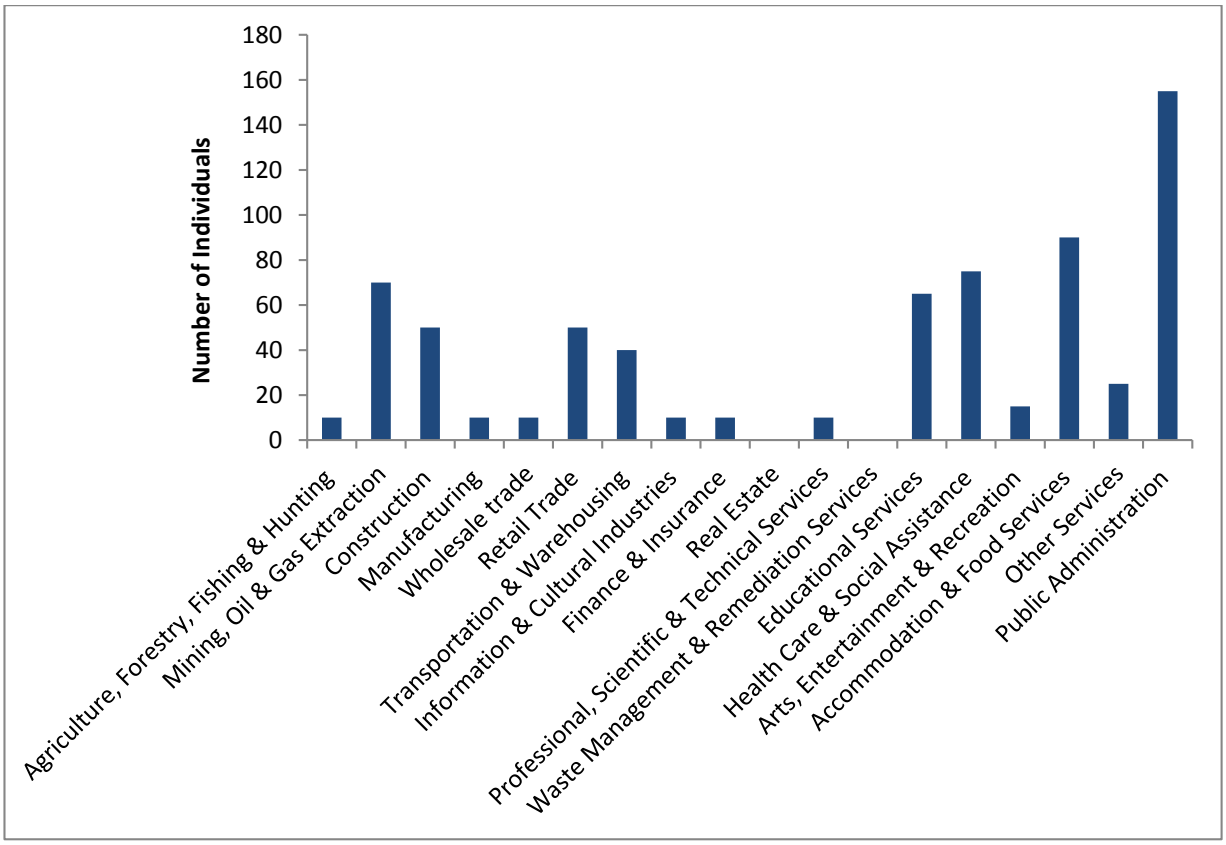
Watson Lake: Business and Employees in 2009 and 2010
Faro Mine Interim Works

Source: YG2011c and 2010d.

Sales and service makes up the greatest number of occupations in the local labour force (Figure 6L-42). The labour force includes employed and unemployed individuals who are those without work, are available for work, and are actively seeking work.

FIGURE 6L-42
Watson Lake: Labour Force by Occupation from Census 2006
Faro Mine Interim Works

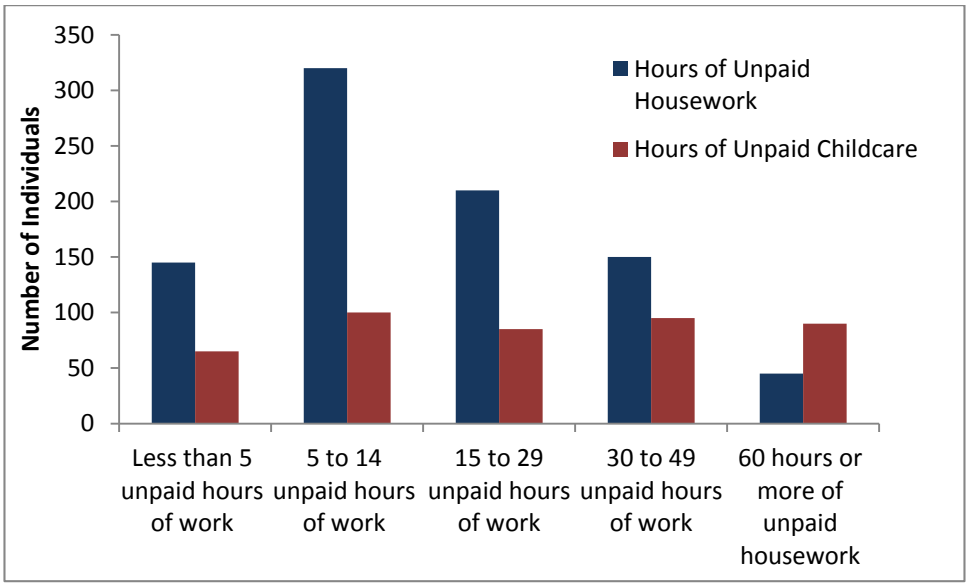


Source: Statistics Canada, 2008.

In 2005, the largest labour force industry was public administration, accounting for 22 percent of the overall labour force (725 individuals) (Figure 6L-43). Accommodation and food services were the second largest labour force segment, accounting for 13 percent of the overall labour force. The labour force participation rate for Watson Lake was 76 percent in 2005 (Statistics Canada, 2008).[3]

[3] Census information presented for Watson Lake is a combination of multiple census subdivisions to provide a more representative estimate of the regional statistics.

FIGURE 6L-43
Watson Lake: Labour Force by Industry from Census 2006
Faro Mine Interim Works



Source: Statistics Canada, 2008.

The following figures show the number of individuals by hours spent doing unpaid work per week, including housework and childcare (Figure 6L-44), and senior care (Figure 6L-45). In regards to unpaid housework, in 2005, 34 percent of the Census population sample (955 individuals) reported spending 5 to 14 hours weekly doing unpaid housework. Twenty-two percent of individuals indicated 15 to 29 hours and 16 percent stated 30 to 49 hours of unpaid housework. Five percent of respondents reported 60 or more hours of unpaid housework.

Number of weekly unpaid hours spent providing childcare was less than unpaid housework. Of the total survey respondents (960 individuals), approximately 10 percent reported 5 to 14 hours of unpaid childcare, while 9 percent of respondents indicated 15 to 29 hours and ten percent stating 30 to 49 hours. Nine percent of individuals reported 60 or more unpaid hours weekly dedicated to childcare.

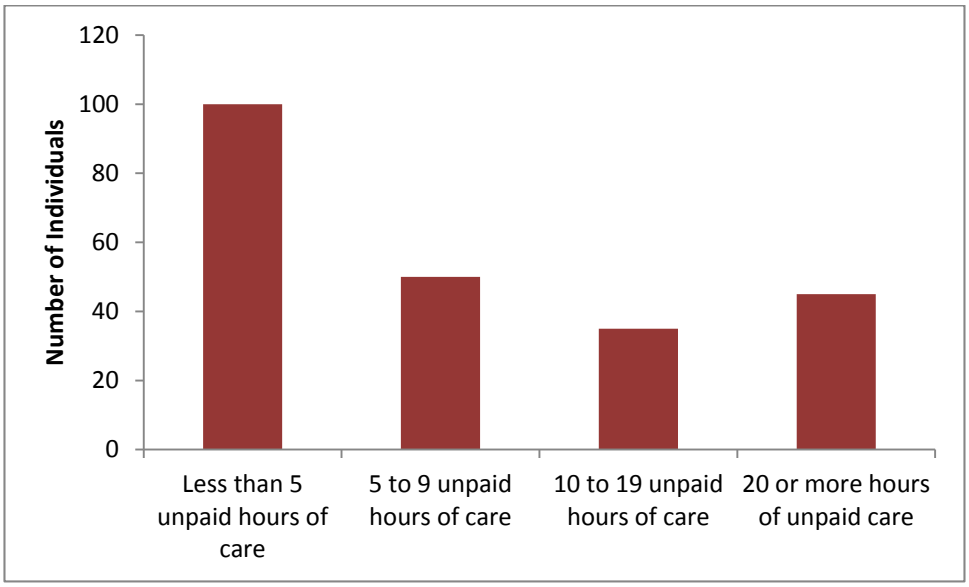


FIGURE 6L-44
Watson Lake: Population by Weekly Hours Spent Doing Unpaid Work (Housework and Childcare) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

Figure 6L-45 shows number of unpaid hours dedicated to providing assistance or care to seniors. Of the total survey respondents (960 individuals), 10 percent reported less than five hours of unpaid care and even less (5 percent) reported 60 or more hours per week.

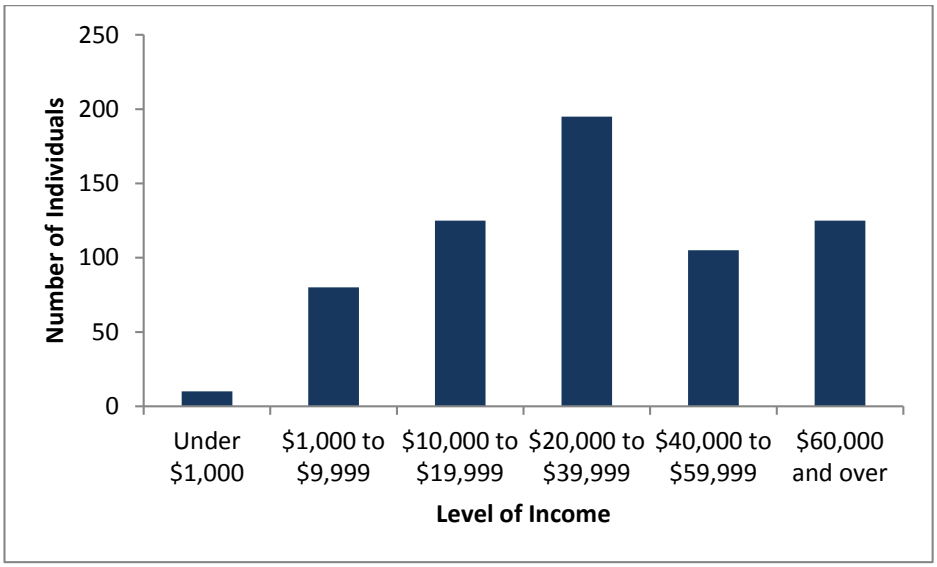

FIGURE 6L-45
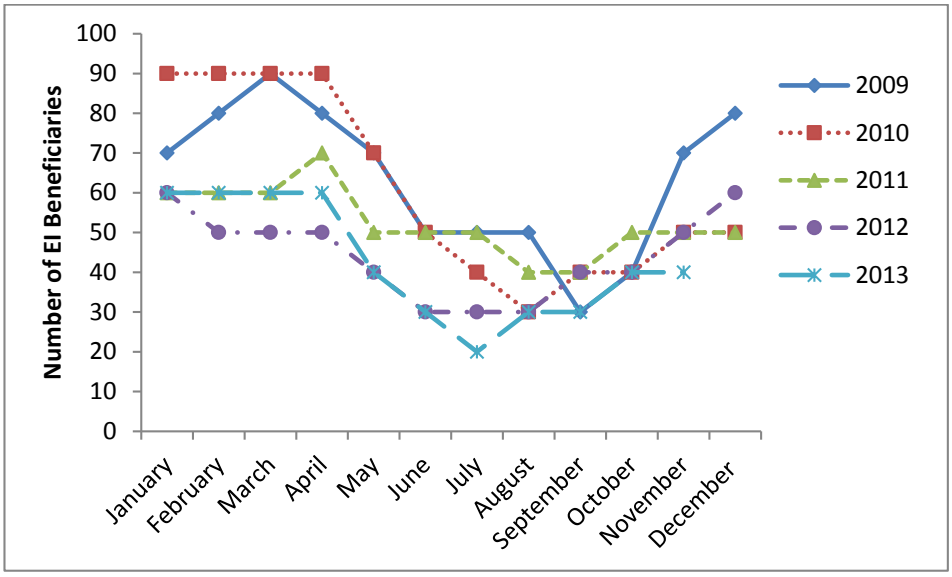
Watson Lake: Population by Weekly Hours Spent Doing Unpaid Work (Senior Care) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

As Figure 6L-46 shows, in 2005, the annual average individual pre-tax income for residents of Watson Lake was $30,284; the annual average household income was $56,340 for the same year (Statistics Canada, 2008).

FIGURE 6L-46
Watson Lake: Annual Individual Pre-tax Income from Census 2006
Faro Mine Interim Works

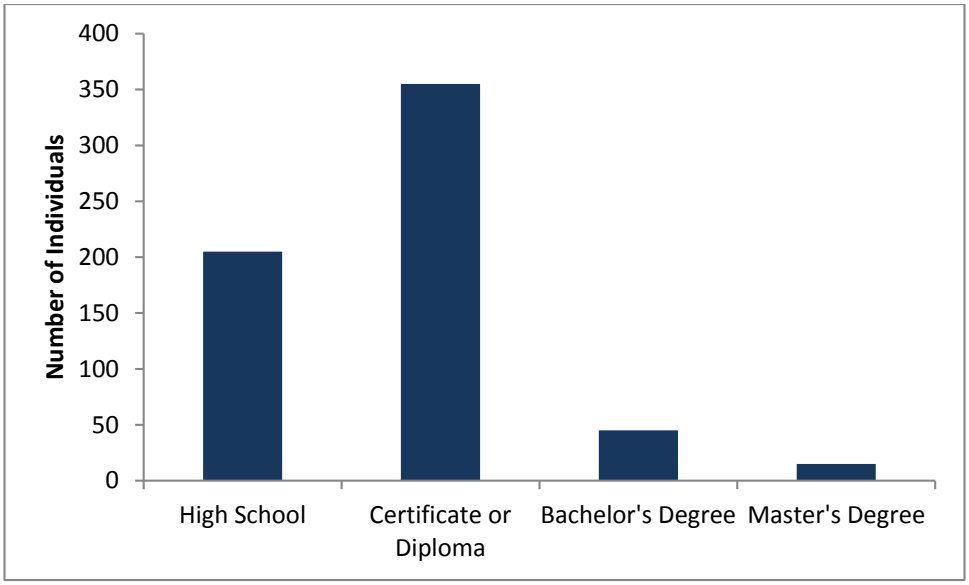


Source: Statistics Canada, 2008.

According to the Canada Revenue Agency, 1,010 tax returns were filed by Watson Lake residents for the 2009 tax year, 610 of which included taxable income. Total income reported on all returns was $34.6 million in 2009 (Canada Revenue Agency, 2011).

Figure 6L-47 shows the number of individuals receiving regular EI benefits, which excludes benefits associated with sickness, maternity, fishing, work sharing, adoption, parental, regular, training, job creation, and self-employment assistance. Number of EI beneficiaries have decreased since 2009 with July of 2013 having the lowest EI insurance levels recorded during the 5-year period. The greatest number of EI benefits occurs during the winter months between November and April. Similar to the other communities, the lower EI levels during the summer months may be attributed to increased employment associated with the summer tourism industry, field research, and environmental work that typically occurs during the warmer months. In comparison to 2009, the number of EI beneficiaries in 2013 decreased by approximately 30 percent.

FIGURE 6L-47
Watson Lake: Employment Insurance Beneficiaries from 2009 to 2013
Faro Mine Interim Works



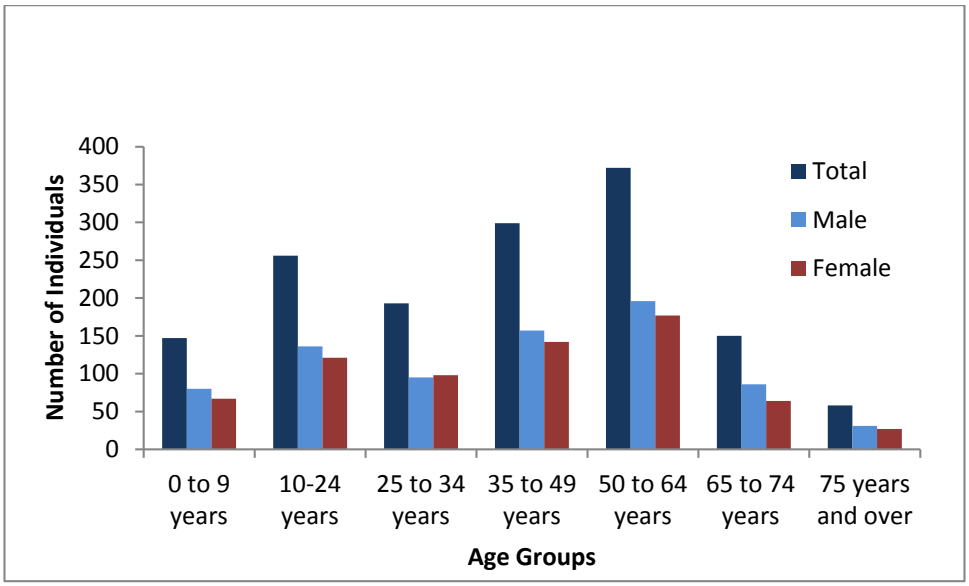
Source: Statistics Canada, no date.

The Consumer Price Index reported that on average for every dollar spent on purchases of goods and groceries in Whitehorse, the same products in Watson Lake would be purchased at a rate of a $1.15 (April 2013) (YG, 2013f).

The Town of Watson Lake has recently completed a *Strategic Plan for Revitalization of the Watson Lake Economy* (Town of Watson Lake, no date), to ensure the community is well positioned in future years to take advantage of opportunities across all business sectors.

In terms of educational attainment in Watson Lake, of the total survey respondents (965 individuals) aged 15 years and older in 2006, 355 had completed a certificate or diploma (Figure 6L-48). A total of 60 individuals reported having a Bachelor's or Master's degree as their highest level of schooling (Statistics Canada, 2008).

FIGURE 6L-48
Watson Lake: Education Levels from Census 2006
Faro Mine Interim Works



Source: Statistics Canada, 2008.

4.3.2 Community Stability and Well-being

According to recent 2013 estimates, Watson Lake has a population of 1,474, representing 780 males and 694 females (Figure 6L-49) (YG, 2013a).

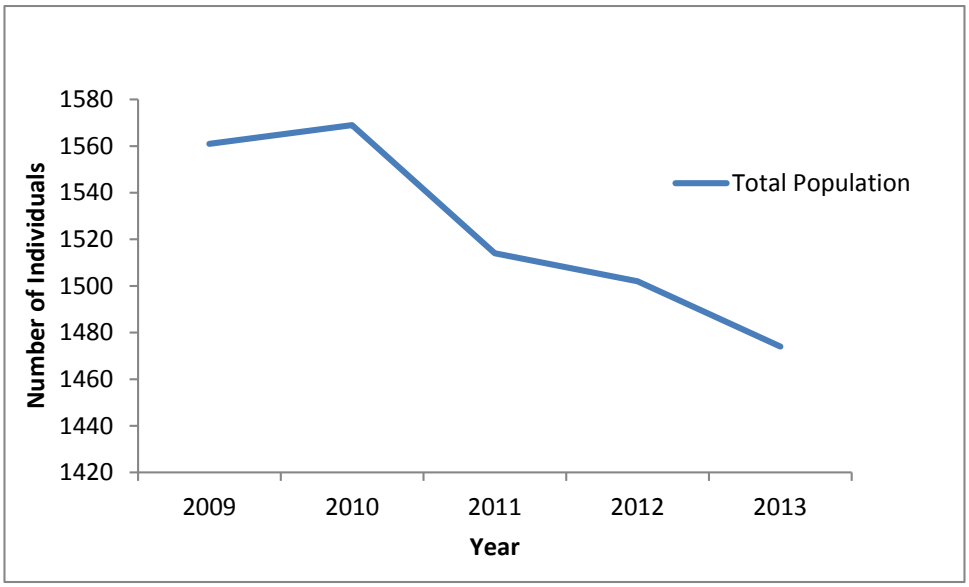


FIGURE 6L-49
Watson Lake: Population by Age and Sex in 2013
Faro Mine Interim Works

Source: YG2013a.

Since 2010, there has been a gradual decline in population (Figure 6L-50).

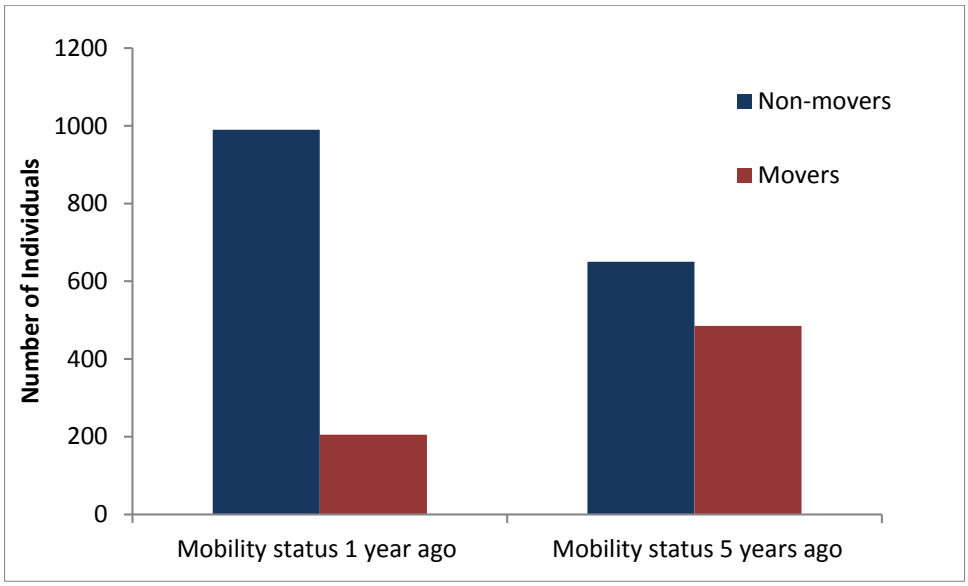

FIGURE 6L-50
Watson Lake: Total Population from 2009 to 2013
Faro Mine Interim Works

Source: YG, 2013a.

The majority of Watson Lake residents are non-movers, over 82 percent of survey respondents (1195 individuals) having lived in Watson Lake for over a year and 54 percent for over 5 years in the 2006 Census (Figure 6L-51). This reflects a relatively stable population base, but more transient than other small communities such as Ross River and Faro.

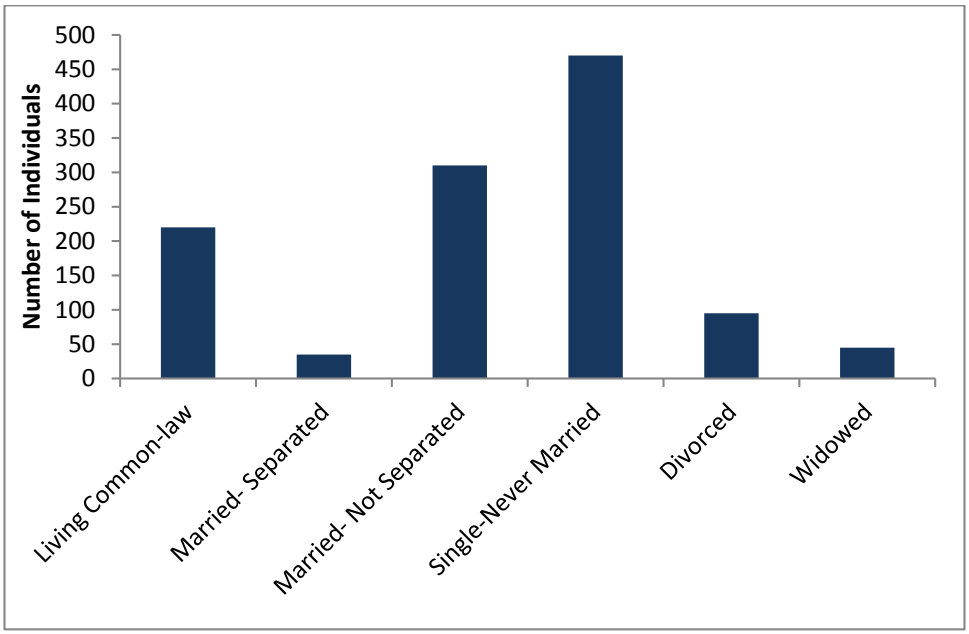

FIGURE 6L-51
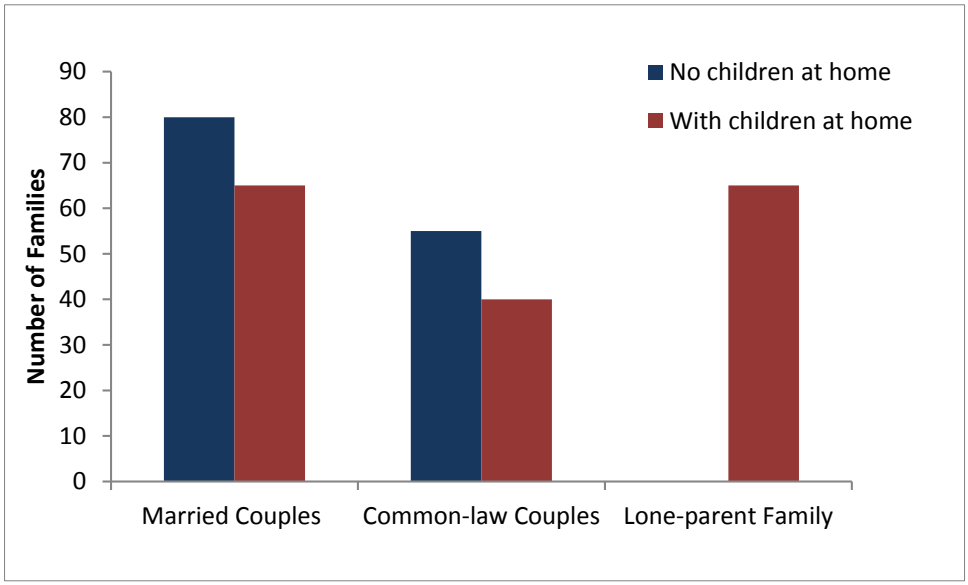
Watson Lake: Mobility Status from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.



Nearly half of survey respondents (910 individuals) were single. Watson Lake has a high number of married and common-law couples with the majority of households without children (Figures 6L-52 and 6L-53).

[4] Statistics Canada provides the following classifications of marital status: "Living common-law includes persons who are living with person of the opposite sex or of the same sex as a couple but who are not legally married to that person. Married-separated includes persons currently legally married, but who are no longer living with their spouse and have not obtained a divorce. Married includes persons whose opposite- or same-sex spouse is living, unless the couple is separated or a divorce has been obtained. Also included are persons in civil unions. Single includes persons who have never married (including all persons less than 15 years of age). It also includes persons whose marriage has been legally annulled who were single before the annulled marriage and who have not remarried. Widowed includes persons who have lost their legally-married spouse through death and who have not remarried" (Statistics Canada, 2012b).

As Figure 6L-54 shows, Watson Lake has the second highest number of criminal code violations in the Yukon, at 683 reported in 2012 (YG, 2012).

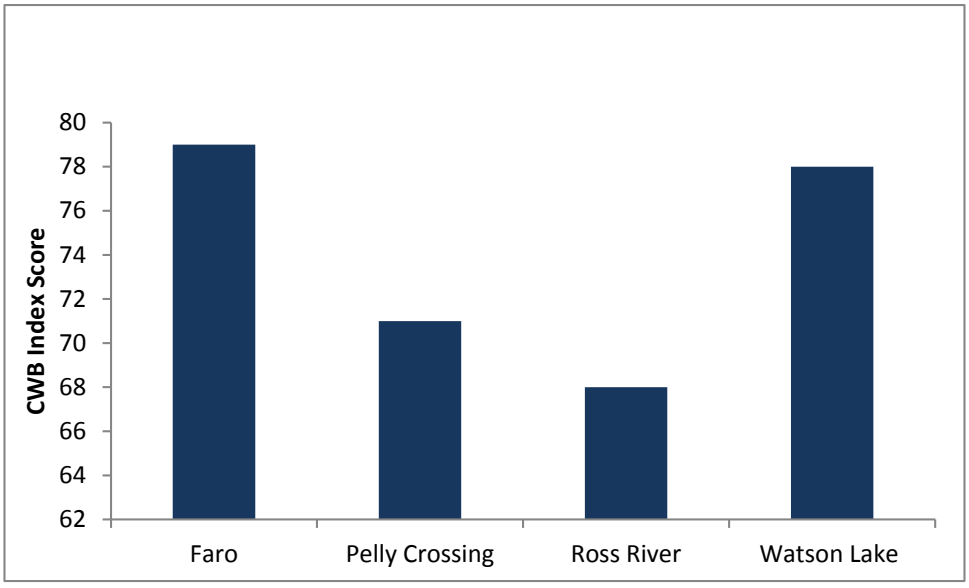

FIGURE 6L-54
Community Crime Rates: 2009-2012

Source: YG, 2012.

The Community Well-Being score is a number generated by AANDC which reflects data on income, education, housing conditions and labour force activity. It can range from a low of 0 to a high of 100. Figure 6L-55 identifies the Community Well-Being score for all communities in the study area in 2006. Watson Lake's score is 78 (AANDC, 2006).

FIGURE 6L-55

4.3.3 Infrastructure and Services

Watson Lake is an incorporated municipality with an elected Mayor and four councillors (Table 6L-5). The municipality is responsible for providing programs and services to its citizens, and the YG provides services to residents living outside of the municipal boundary.

TABLE 6L-5
Watson Lake Mayor and Council, 2013
Faro Mine Interim Works

Source: Town of Watson Lake, 2013

Watson Lake has an airport with a 5,500-foot asphalt runway capable of handling a 737 aircraft. Planes, buses, and taxis all operate in Watson Lake (YG, 2013f).

Watson Lake has two schools. Johnson Elementary School serves Kindergarten to Grade 7. Watson Lake Secondary School has grades 8 to 12. Most students at both of these schools are members of the LFN. Yukon College is located in a wing of the secondary school and provides some courses, as well as equipment for distance learning (YG, 2013f).

The Watson Lake Library is within the Town of Watson Lake Administration Building (YG, 2013f).

Watson Lake has a 24-hour Ambulance service, after regular business hours it is staffed by volunteers. The Royal Canadian Mounted Police have a detachment with one sergeant, one corporal, and seven constables. The fire department has one staffed fire chief and many volunteers. Watson Lake has a new medical facility, which was opened by YG in August 2013. It provides the community with emergency services, six in-patient beds, as well as diagnostic services. The Watson Lake Seniors Complex has a 12-unit seniors housing complex (YG, 2013f).

The Town of Watson Lake has a recreation centre, including a heated pool for summer use, an arena, a fitness centre, and a curling rink. There is also a skateboard park, a golf course, and a small ski hill near the community (YG, 2013f).

High-speed internet, cellular, and landline service is provided by Northwestel. Yukon Electrical generates and distributes its own electricity in Watson Lake (Yukon Electrical, 2014).

Four hundred and sixty homes were reported in the 2011 Census. Yukon Housing offers 46 social units and 34 staff units (YG, 2013f).

4.3.4 Land Use and Access

The FMC lies within the traditional territory of the Kaska Dena, of which the LFN is a member. As such, the traditional use of lands in the region could also be associated with LFN. At this time, LFN has not settled its land claim agreement and has not identified any specific lands near the mine site. Similar to the RRDC, the LFN does not have a land claim settlement or self-government agreement.

4.3.5 Culture and Heritage

The LFN is another Yukon member of the KDC. They are based out of Watson Lake, Yukon, with many of their members also living in Upper Liard, Yukon or Lower Post, British Columbia. An election was held in

December 2013, and the new Chief is Daniel Morris and the Councillors are Roy Dick, Don Magun, Cynthia Porter, and Timothy Stewart (Table 6L-6) (KDC, 2013).

Of the total survey respondents (1205 individuals), 52 percent is comprised of Aboriginal peoples (Figure 6L-56).

FIGURE 6L-56

4.4 Kaska Dena Council

The KDC was formed in 1981 to provide a voice for the five-member First Nations who share a historical relationship and a traditional territory spanning the British Columbia-Yukon border (KDC, 2013). The KDC has a Board of Directors which includes six Directors and three elected officers (Table 6L-7).

TABLE 6L-7

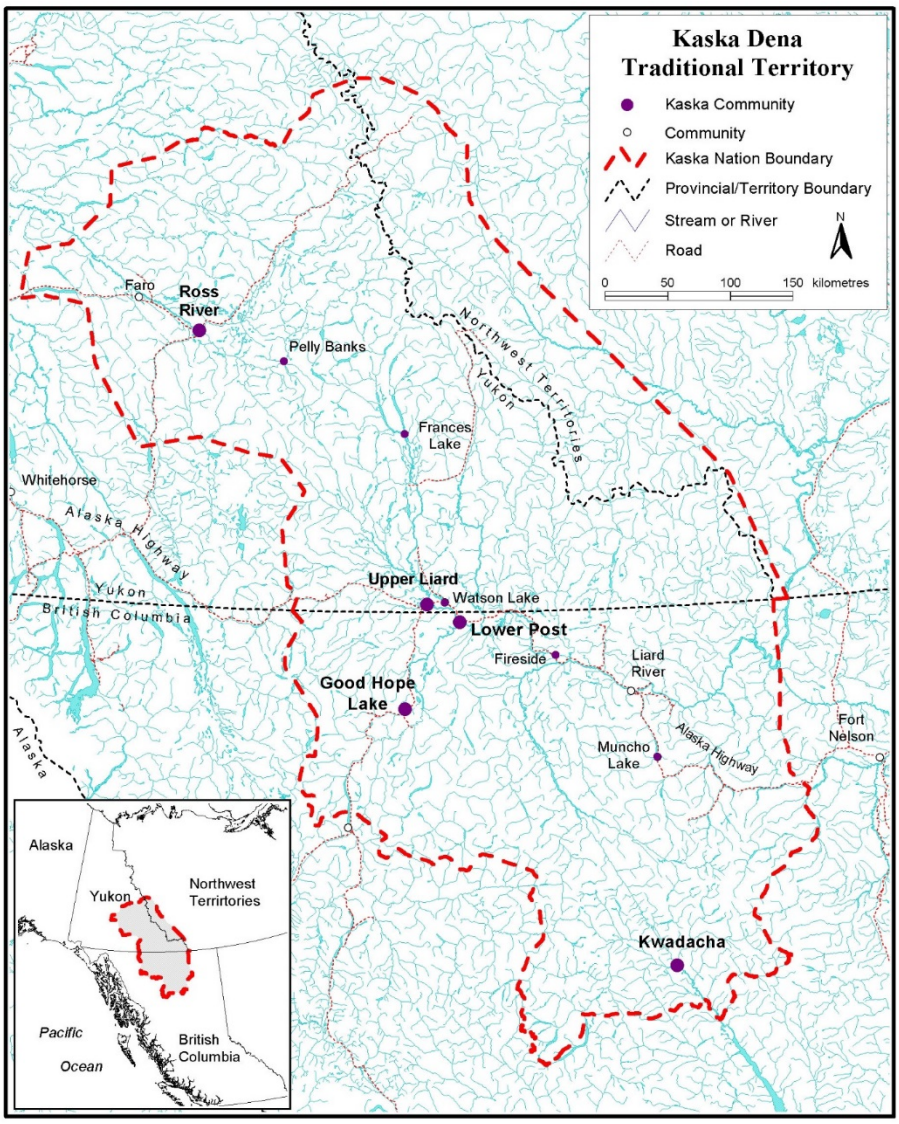
Victor Kisoun	Muncho
George Miller	Chair
Ruby Johnny	Vice-Chair, Finance and Administration
Danny Case	Vice-Chair, Lands and Resources

Source: KDC, 2014b



The following are objectives of the KDC are (KDC, 2013):

1. Promote and protect respect for the land and cultural heritage of the Kaska Dena people;
2. Promote unity and sharing amongst all Kaska;
3. Assist in the delivery of services including social, economic, cultural and educational programs to Kaska Dena communities;
4. Promote a community environment wherein all Kaska people can enjoy physical and spiritual health and live with dignity and pride;
5. Work toward the recognition and protection of the aboriginal rights of all Canadian Native people, and;
6. Do all things necessary to achieve the foregoing objectives

The traditional territory of the KDC encompasses over 240,000 square kilometres of land, from the MacMillan Pass on the Yukon/Northwest Territories border to the community of Kwadacha in British Columbia, and from Little Salmon Lake, Yukon in the west to Fort Nelson in the east (Figure 6L-57). Member nations in British Columbia are the Daylu Dena Council, Dease River First Nation, and the Kwadacha Nation. The RRDC and the LFN are the two Yukon members of the KDC. The FMC lies just within the northern boundary of the KDC traditional territory (KDC, 2013).

In October of 2011, the KDC signed an historic agreement amongst all its member nations. The “Kaska Collaboration Agreement” outlines the responsibilities and processes to facilitate the negotiation and implementation of agreements between project proponents looking to pursue projects within Kaska traditional territory. Of note, this agreement specifically addresses the on-going work of the FMC remediation, and acknowledges that the RRDC is the primarily impacted community of the Faro project and will be the lead community (KDC, 2011).

FIGURE 6L-57
Kaska Dena Traditional Territory

4.5 Selkirk First Nation

The SFN is based in Pelly Crossing, in a valley on the banks of the Pelly River. The SFN is part of the Northern Tutchone, who traditionally used the nearby sites of Fort Selkirk and Minto for camping while hunting, trapping and gathering in the area. In 1997, the SFN became the seventh Yukon First Nation to sign their land claim and self-government agreements. Unrelated to the FMC and the IW, but important to the SFN, is the Minto Mine. The Minto Mine, owned by Capstone Mining, is a copper-gold-silver mine located on SFN settlement land southwest of Pelly Crossing on the west side of the Yukon River. The mine commenced operations in 2007 (Capstone, 2014). The Minto Mine contributes to the local economy of Pelly Crossing by accessing its labour force and some local services as well as contributing to the Selkirk First Nation revenues due to its location on Type A settlement land (YG, 2010e). Economy and Employment

4.5.1 Economy and Employment

As Figure 6L-58 shows, in 2010 Pelly Crossing was home to eight businesses, which altogether employ 13 people (YG, 2011c). It should be noted that the figure below (6L-58) represents the number of businesses headquartered in Pelly Crossing and the number of people those businesses employ. The labour force accounts in later graphs represent the total labour force for Pelly Crossing, including businesses without local headquarters.

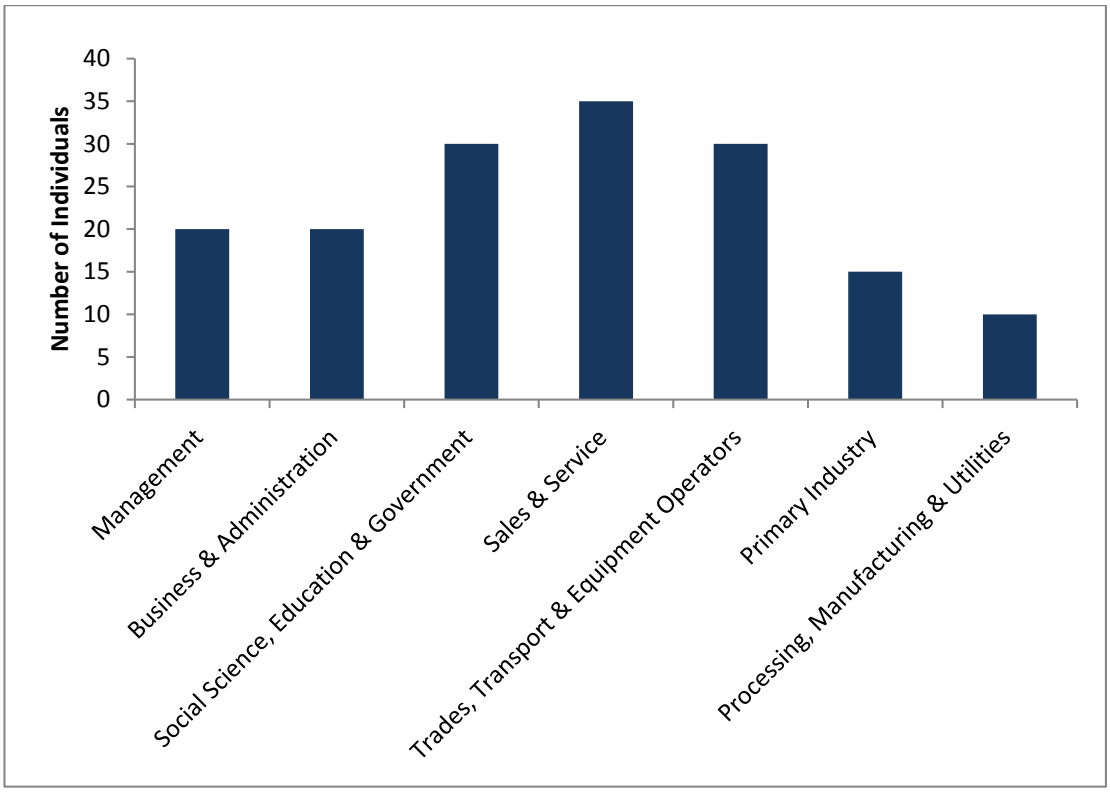

FIGURE 6L-58
Pelly Crossing: Businesses and Employees in 2009 and 2010
Faro Mine Interim Works

Source: YG, 2011c and 2010d.

Sales and service represents the greatest labour force in regards to occupation type (Figure 6L-59). The labour force includes employed and unemployed individuals who are those without work, are available for work, and are actively seeking work.

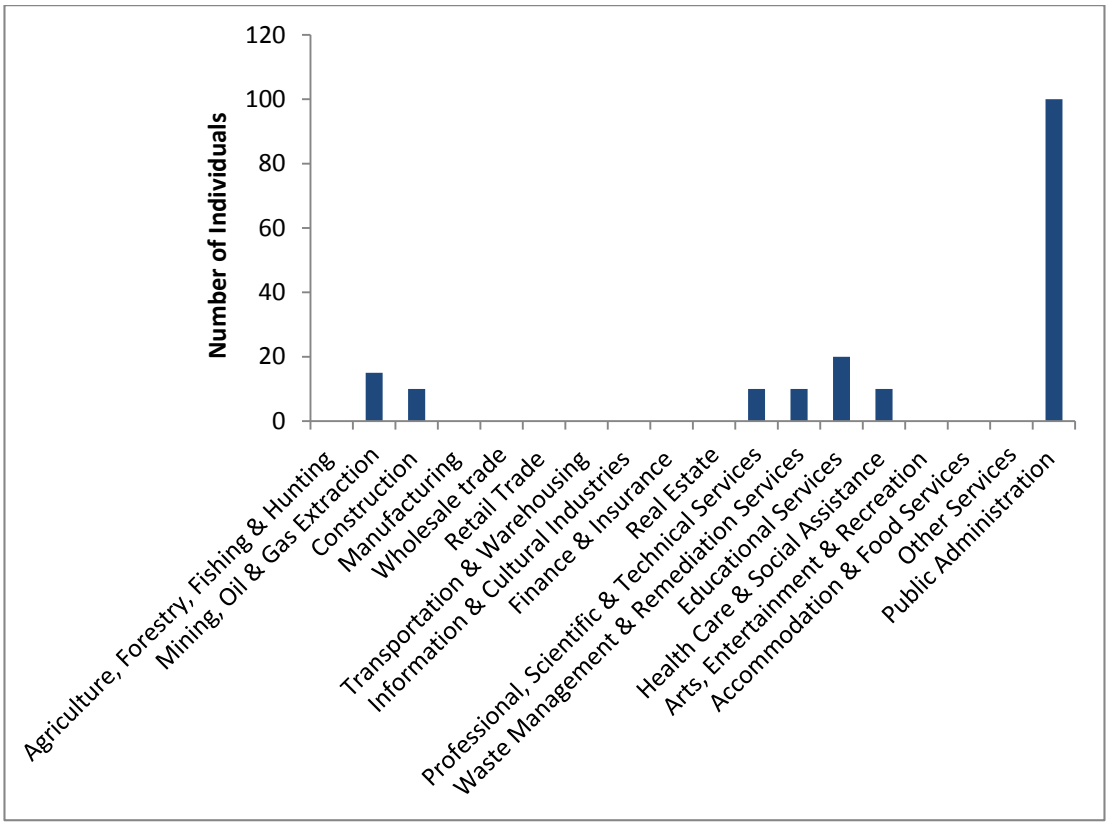

FIGURE 6L-59
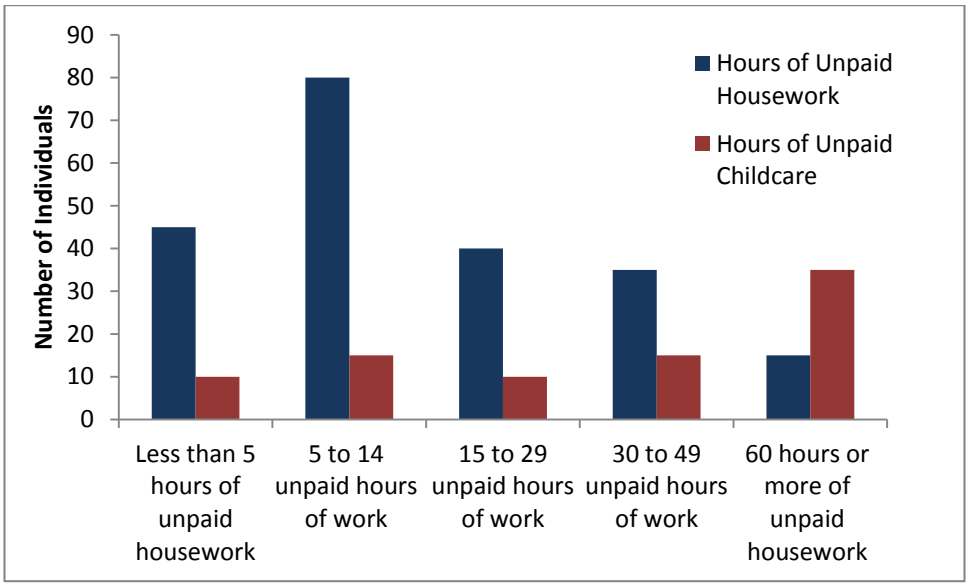
Pelly Crossing: Labour Force by Occupation from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

In 2005, the largest labour force industry in Pelly Crossing was public administration, accounting for 57 percent of the overall labour force (180 individuals) (Figure 6L-60). Educational services was the second largest labour force segment, accounting for 11 percent of the overall labour force. The labour force participation rate for Pelly Crossing was 77 percent in 2005 (Statistics Canada, 2008).

FIGURE 6L-60
Pelly Crossing: Labour Force by Industry from Census 2006
Faro Mine Interim Works



Source: Statistics Canada, 2008

The following figures show individuals by hours spent doing unpaid per week work including housework and childcare (Figure 6L-61) and senior care (Figure 6L-62). In regards to unpaid work, in 2005 34 percent of the Census population sample (235 individuals) reported spending 5 to 14 hours doing unpaid housework. The number of individuals indicating 15 to 29 hours and 30 to 49 hours of unpaid housework was relatively equal at approximately 17 and 15 percent, respectively. Six percent of respondents reported 60 or more hours of unpaid housework.

Number of weekly unpaid hours spent providing childcare was less than unpaid housework. Approximately 6 percent of respondents claimed performing 5 to 14 hours of unpaid childcare, while 4 percent of respondents indicated 15 to 29 unpaid hours. Six percent reported 30 to 49 hours and 15 percent stated doing 60 or more hours of unpaid childcare.

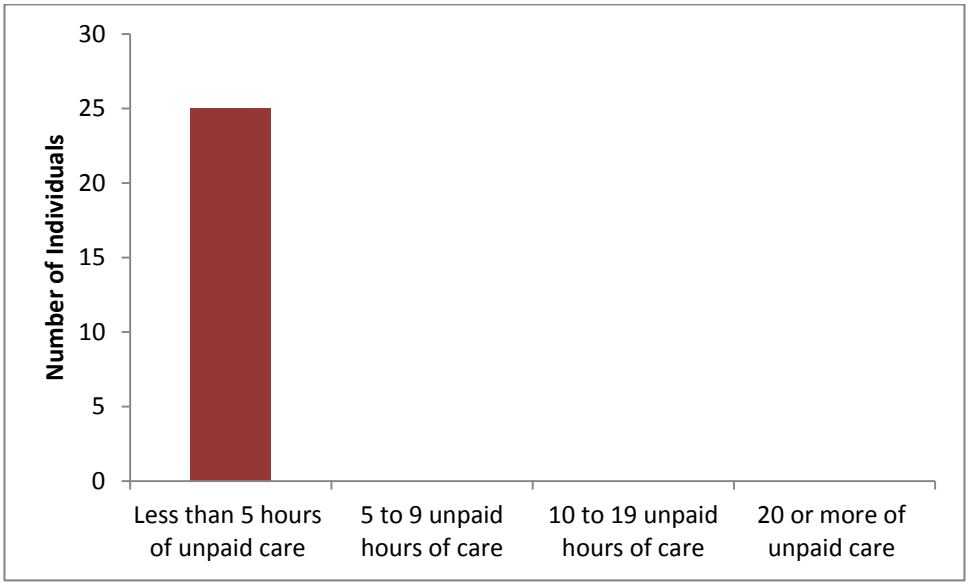


FIGURE 6L-61
Pelly Crossing: Population by Weekly Hours Spent Doing Unpaid Work (Housework and Childcare) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

As shown below (Figure 6L-62), of the total survey respondents (240 individuals), 10 percent reported less than 5 unpaid hours per week to providing assistance or care to seniors.

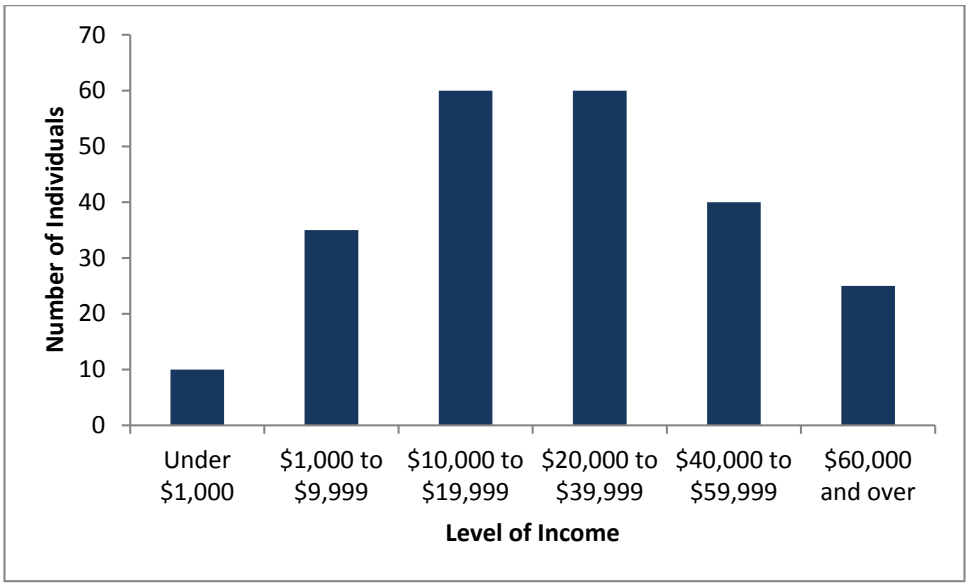

FIGURE 6L-62
Pelly Crossing: Population by Weekly Hours Spent Doing Unpaid Work (Senior Care) from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

In 2005, the average annual individual pre-tax income for residents of Pelly Crossing was $29,092; average annual household income was $56,331 for the same year (Figure 6L-63) (Statistics Canada 2008). According to the Canada Revenue Agency, a total of 250 tax returns were filed by Pelly Crossing residents for the 2009 tax year, 140 of which included taxable income. Total income reported on all returns was $7.9 million in 2009 (Canada Revenue Agency, 2011).

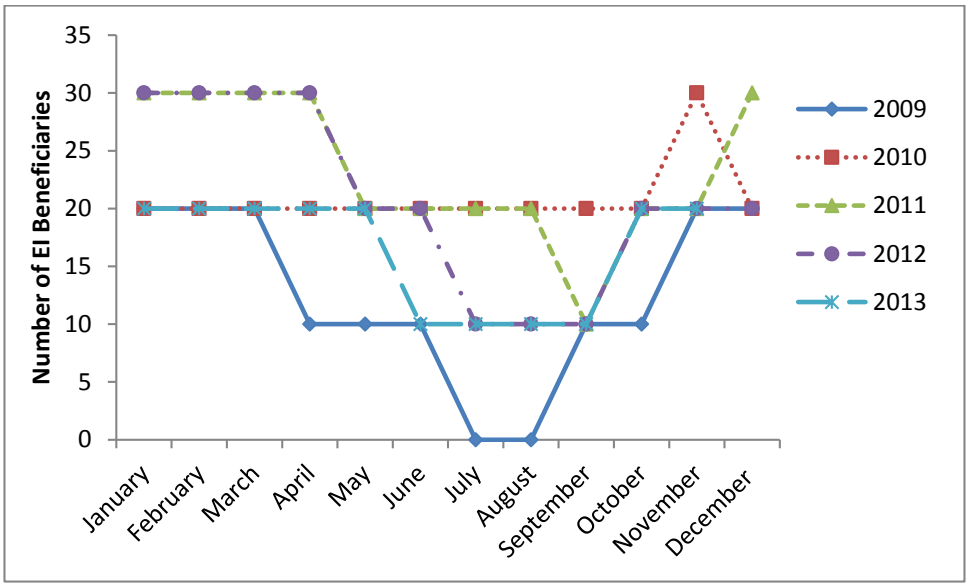

FIGURE 6L-63
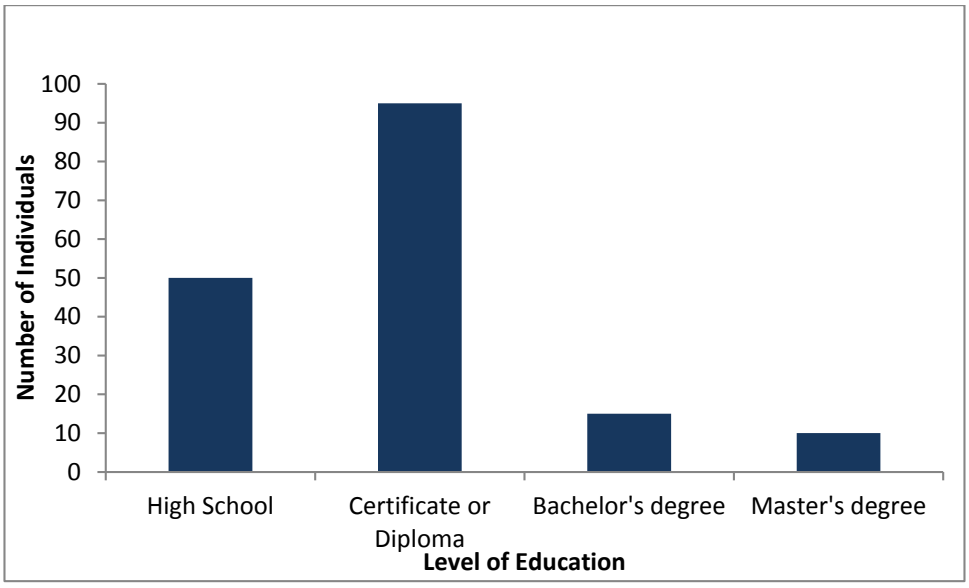
Pelly Crossing: Annual Individual Pre-tax Income from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

Figure 6L-64 shows the number of individuals receiving regular EI benefits, which excludes benefits associated with sickness, maternity, fishing, work sharing, adoption, parental, regular, training, job creation, and self-employment assistance. Between 2009 and 2013, EI insurance levels have maintained the trend of increased EI beneficiaries during the winter months with a decline in the summer. Once again, similar to the other communities, the lower EI levels during the summer months may be related to increased employment associated with the summer tourism industry, field research, and environmental work that typically occurs during the warmer months. The highest number of EI beneficiaries was observed in the winter of 2012. However, more recently in 2013 these numbers have decreased by approximately 30 percent.

FIGURE 6L-64
Pelly Crossing: Employment Insurance Beneficiaries from 2009 to 2013
Faro Mine Interim Works



Source: Statistics Canada, no date.

In terms of educational attainment, of the 240 individuals who were aged 15 years and older in 2006, 65 had completed a certificate or diploma in the trades or other non-university programs (Figure 6L-65). A total of

25 individuals reported having a Bachelor's or Master's degree as their highest level of schooling (Statistics Canada, 2008).

FIGURE 6L-65
Pelly Crossing: Education Levels from Census 2006
Faro Mine Interim Works

4.5.2 Community Stability and Well-being

The population of Pelly Crossing in June 2013 was 348 people representing a 189 males and 159 females (Figure 6L-66) (YG, 2013a).

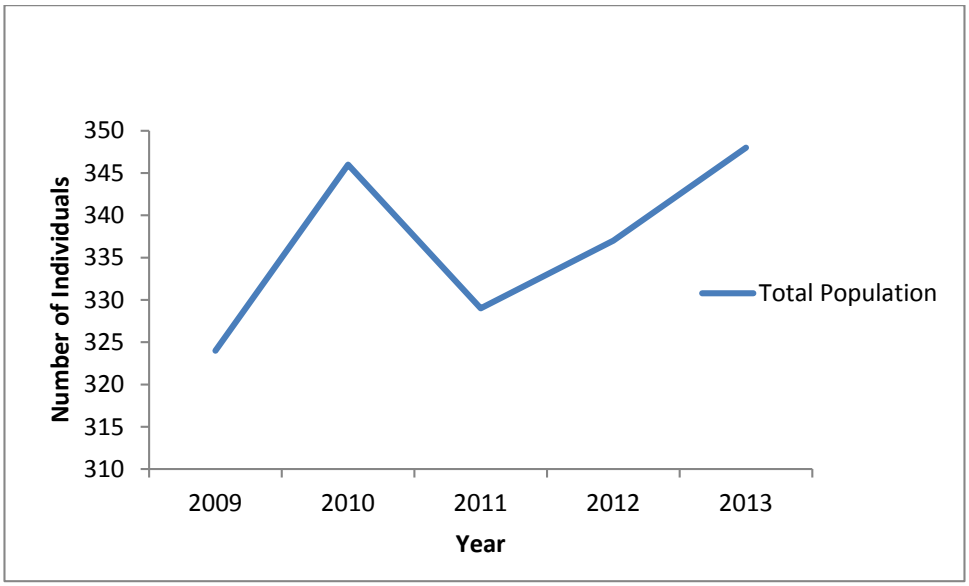

FIGURE 6L-66
Pelly Crossing: Population by Age and Sex in 2013

Figure 6L-67 indicates a trend of population growth since 2011.

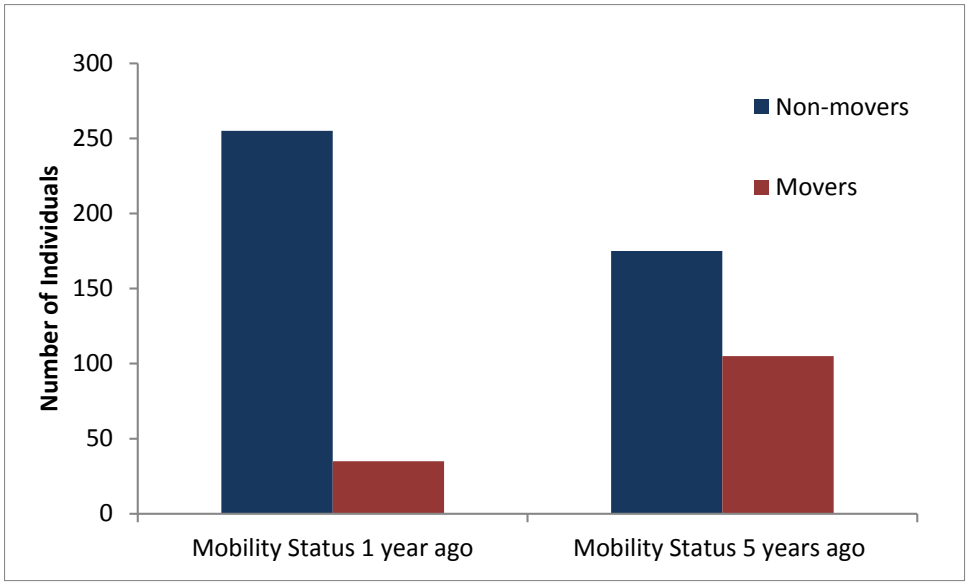

FIGURE 6L-67
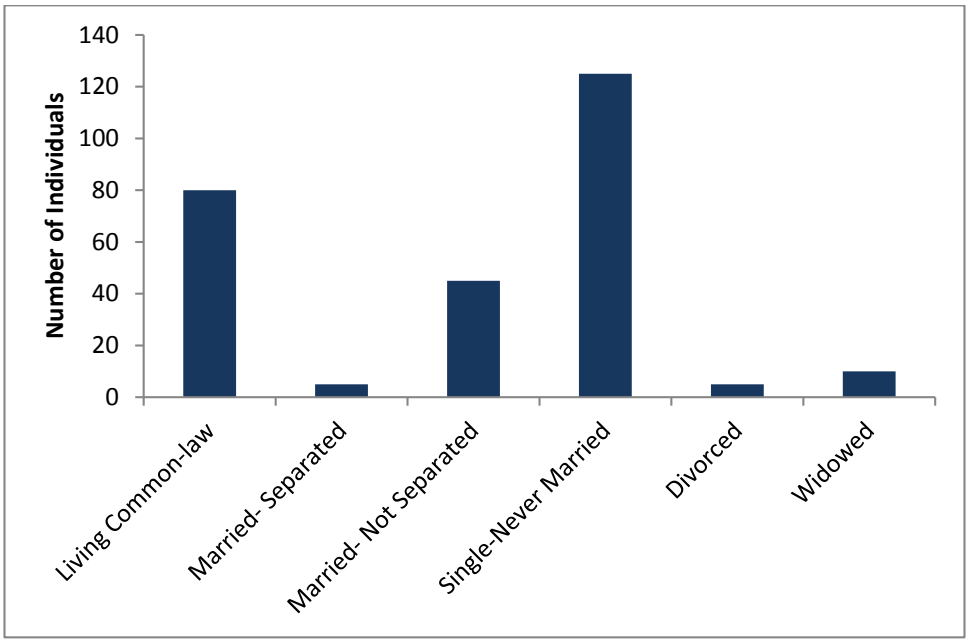
Pelly Crossing: Total Population 2009 to 2013
Faro Mine Interim Works

Source: YG2013a.

Figure 6L-68 shows the community is very stable. Of those Census respondents (290 individuals), only 12 percent of the community having indicated they moved during 2005 (Statistics Canada, 2008). The Mobility Status 5 years ago represents the number of people that moved within the last 5 years.

FIGURE 6L-68
Pelly Crossing: Mobility Status from Census 2006
Faro Mine Interim Works



Source: Statistics Canada, 2008.

Pelly Crossing has a high number of both individuals reporting single marital status (Figure 6L-69) and lone-parent households (Figure 6L-70).

FIGURE 6L-69

[5] Statistics Canada provides the following classifications of marital status: "Living common-law includes persons who are living with person of the opposite sex or of the same sex as a couple but who are not legally married to that person. Married-separated includes persons currently legally married, but who are no longer living with their spouse and have not obtained a divorce. Married includes persons whose opposite- or same-sex spouse is living, unless the couple is separated or a divorce has been obtained. Also included are persons in civil unions. Single includes persons who have never married (including all persons less than 15 years of age). It also includes persons whose marriage has been legally annulled who were single before the annulled marriage and who have not remarried. Widowed includes persons who have lost their legally-married spouse through death and who have not remarried" (Statistics Canada, 2012b).

Pelly Crossing suffers from high crime rates relative to other rural Yukon communities (Figure 6L-71). In 2012, there were 231 criminal code violations reported—a per capita rate of 0.69 (YG, 2012).

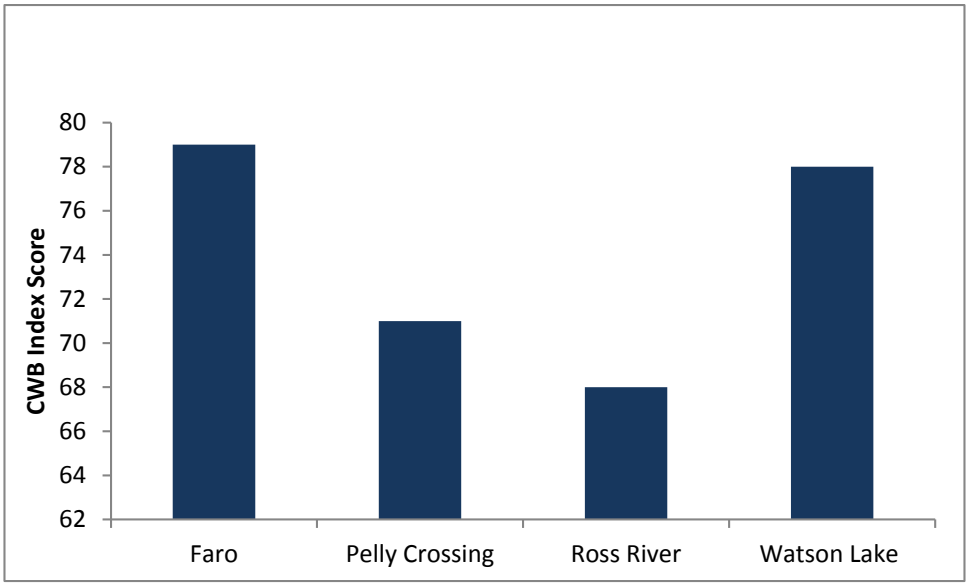

FIGURE 6L-71
Community Crime Rates: 2009-2012
Faro Mine Interim Works

Source: YG, 2012.

The Community Well-being score is a number generated by AANDC, which reflects data on income, education, housing conditions and labour force activity. It can range from a low of 0 to a high of 100. Figure 6L-72 identifies the Community Well-being score for all communities in the study area in 2006. Pelly Crossing's score is 71 (AANDC, 2006).

FIGURE 6L-72
Community Well-being Index Score in 2006
Faro Mine Interim Works

Source: AANDC Community Well-being Database, 2006.

4.5.3 Infrastructure and Services

Pelly Crossing is located along the Klondike Highway, 282 km northwest of Whitehorse and 254 km southeast of Dawson City.

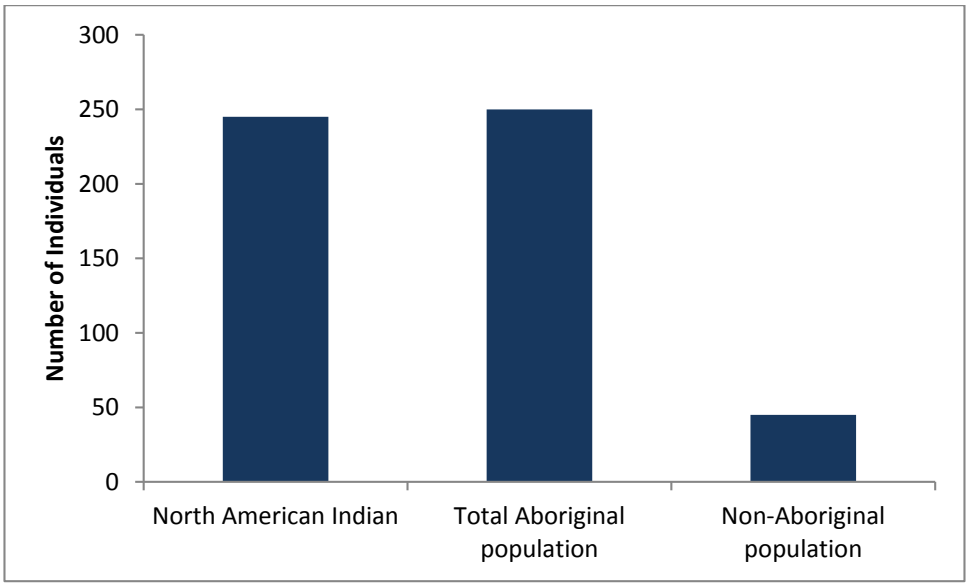
Like Ross River, Pelly Crossing is an unincorporated community where the YG is responsible for delivering services to property and residents. The SFN provides water, wastewater services, and municipal road maintenance services; landfill operation is managed by YG. Yukon Electric provides electrical power from the Yukon grid, with a backup diesel generator. Northwestel offers high-speed internet, cellular, and land line service. Yukon Highways and Public Works maintains the highways around Pelly Crossing. Pelly Crossing has a 3,305-foot gravel airstrip. YG's Department of Highways and Public Works provides limited maintenance of the airstrip (YG, 2013d).

The Eliza Van Bibber School had 48 students in 2012, which increased to 67 students enrolled in the 2013 school year. The school serves Kindergarten to Grade 12. Most students are members of SFN. Yukon College provides a local campus in Pelly Crossing with courses offered online or through teleconferencing facilities. The community library is co-located in the Eliza Van Bibber School (YG, 2013d).

The ambulance service for Pelly Crossing and area is provided by Yukon Emergency Medical Services based out of the fire hall in Pelly Crossing. The Emergency Medical First responders are all volunteers and are dispatched to calls by the Pelly Crossing nursing station. Pelly Crossing houses a Royal Canadian Mounted Police detachment. A nursing facility is staffed by one nurse on-call 24 hours per day (YG, 2013d). The SFN provides additional services and support to its citizens through their department of Health and Social Services. The Yukon Children's Dental Program provides diagnostic, preventative, and restorative dental services, scheduled through the school (YG, 2013d).

There are approximately 135 private dwellings in Pelly Crossing, predominately single-detached dwellings. Most housing is owned by the First Nation (Statistics Canada, 2012). Yukon Housing Corporation offers 11 staff units in Pelly Crossing and offers programs and services that enable home renovations, construction of additional rental suites, mortgages and financing (YG, 2013d).

Pelly Crossing has a recreation centre, youth centre, swimming pool and seasonal heritage centre. The natural environment around Pelly Crossing provides seasonal recreation, such as hiking, cross-country skiing, and snowmobiling.



4.5.4 Land Use and Access

The FMC is not within the traditional territory of the SFN, nor do they typically use the land near the FMC. However, the creeks and rivers that flow through the FMC feed into the Pelly River watershed, and the SFN traditional territory extends upriver on the Pelly River to a location a few kilometres downstream of the FMC. Traditional activities such as stick gambling, hunting, fishing, and trapping are all popular. Ta'Tla Mun, Ddhaw Ghro, Minto, and Fort Selkirk are important sites used for recreation and leisure activities by residents of Pelly Crossing (SFN, 2013).

4.5.5 Culture and Heritage

As Figure 6L-73 shows, Pelly Crossing is predominantly Aboriginal, with the non-Aboriginal population accounting for 15 percent of the total population.

FIGURE 6L-73
Pelly Crossing: Aboriginal and Non-Aboriginal Population from Census 2006
Faro Mine Interim Works

Source: Statistics Canada, 2008.

The current Chief and Council of SFN is identified in Table 6L-8. On February 14, 2014, a Call for General Election was announced, and the election will be held in April (SFN, 2014a).

TABLE 6L-8

The SFN people are part of the Northern Tutchone Tribal Council and part of the Northern Tutchone language and cultural grouping.

The Northern Tutchone inhabit the centre of the Yukon, often referred to as the 'heart.' There are three modern-day political organizations that make up the Northern Tutchone Tribal Council: The First Nation of Na-cho N'yak Dun, Selkirk First Nation, and the Little Salmon/Carmacks First Nation. All have signed their First Nation Final and Self-Government Agreements and are now self-governing.

SECTION 5

Conclusion

This report presents the baseline conditions for each of the identified VCs in the potentially affected communities for the FMIW, for the purpose of an environmental and socio-economic assessment under the *Yukon Environmental and Socio-economic Assessment Act*. Every effort has been made by the assessment team to reflect as much relevant and appropriate secondary data for the communities in the study area. A baseline conditions report simply provides a snapshot of community conditions at a certain point in time based on available secondary data for purposes of conducting a socio-economic effects assessment.

SECTION 1

1 Introduction

This appendix presents an assessment of the potential effects of Interim Works (IW) activities on ambient air of the area around the Faro Mine Complex (FMC), more specifically of particulate matter, and of metals within airborne particulate matter. Air quality is important to the health of humans, wildlife, and vegetation. IW construction and maintenance activities may cause dust and particulate matter to become airborne and thereby affect the air quality in the region.

The baseline air quality in the area surrounding the FMC was described in the *Air Quality Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2013a). The baseline climate and meteorological conditions were described in the *Climate Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2013b). The Baseline Climate Report summarized the meteorological data and stations from which the meteorological surface data used in air dispersion modelling in this Air Quality Effects Report were pulled.

An initial assessment was performed to identify which IW activities may have the potential for specific pathways between the activity and the air quality valued component. Based on the results of the initial assessment, this report considered emissions from haul roads and access roads, construction activities associated with the Down Valley Interim Hydraulic Upgrades (DVIHU), and wind erosion from the tailings area. The haul roads and construction activities were considered as an aggregate pathway and were explicitly considered in the effects assessment. In addition, dust resuspension from the tailing area was quantified, because it was deemed a possible source of emissions and pathway.

Air dispersion modelling was performed using the U.S. Environmental Protection Agency (USEPA) CALPUFF model. This model was used to quantify the dispersion of the estimated emissions from the identified emission sources and to estimate contaminant air concentrations resulting from those emissions. The dispersion modelling was conducted in accordance with the BC Ministry of the Environment's March 2008 Guidelines for Air Quality Dispersion Modelling Guidance, except where otherwise noted. The air quality effects of the interim work activities described above were assessed by comparing to Yukon ambient air quality standards. In the absence of Government of Yukon (YG) standards, British Columbia (BC) or Ontario ambient air quality standards and guidelines were used.

The overall significance of the IW construction and maintenance activities were assessed by quantifying changes in ambient air concentrations relative to those of the baseline concentrations for particulate matter and metals. This was accomplished by developing an inventory of emission sources, estimating the emissions for each source of emissions, and performing comprehensive air quality dispersion modelling for receptors located both on- and off-property of the FMC. Based on the modelled results, consideration was given to a number of indicators such as magnitude and likelihood of the expected change, geographic extent of the change, and reversibility of the change in order to assess the overall significance of effect on air quality. Following this introduction, the Air Quality Effect Report is organized as follows:

- Section 2 describes the method of assessment used.
- Section 3 discusses the ambient air quality criteria (AAQC) (that is, the government regulations and standards) for relevant pollutants evaluated in the assessment.
- Section 4 describes the modelling results.
- Section 5 presents an assessment of the air quality impacts.

SECTION 2

2 Methods and Data

This section summarizes the methodology used for estimating air quality effects that could occur as a result of IW activities.

The FMC has a footprint of over 25 square kilometres (km^2) and consists of three primary areas, as follows:

- The Faro Mine Area, incorporating the Faro Pit, an out-of-service mill, and associated buildings.
- The Rose Creek Tailings Area (RCTA) and its impoundment, which is located in Rose Creek Valley.
- The Vangorda/Grum Area, which is located on the Vangorda Plateau and includes the Grum and Vangorda Pits.

The study area was based on the anticipated extent of potential air quality effects that could be attributable to project-related emissions, and comprised a 100-kilometre (km) -by-100-km square area approximately centred on the project site. The effects assessment used dispersion modelling to evaluate the air quality effects of the project over the study area. The emissions associated with each of the activities considered were estimated based on published emission factors and estimated activity parameters for similar activities.

Because of the complexity of the terrain in the vicinity of the FMC, it was decided that USEPA's CALPUFF air dispersion model would be most suitable to analyze the effects of IW activities on ambient air in the study area. The input parameters and rationale are presented in Attachment 7A-2 for both the CALMET meteorology pre-processing and CALPUFF dispersion modelling. A discussion of the assumptions used in emissions estimates and modelling methodology is presented in the following subsections.

2.1 Emissions and Scenarios

Only emissions directly associated with ongoing IW-related activities were quantified for the effects determination. Further, only activities that were deemed to have a pathway that could potentially affect air quality were considered in this study. Emission mitigation activities that will be implemented during construction and maintenance activities were included in the emission estimating process; the specific sources of emissions are discussed in the following subsections.

2.1.1 Sources and Contaminants

Based on a review of potential sources of emissions at the FMC facility, three primary sources of emissions were identified, namely the tailings area, haul and access roads, and construction activities. The dispersion modelling analysis was conducted to assess the effects on ambient air quality of total suspended particulate matter (TSP), particulate matter with aerodynamic diameter less than 10 microns (PM_{10}), and particulate matter with aerodynamic diameter less than 2.5 microns ($PM_{2.5}$).

It is noted that "dust" is a more general term associated with particulate matter but it typically refers to any form of particulate matter that is considered to be visible and therefore includes larger particles that tend to settle to the ground relatively quickly. There is no ambient air quality standard for "dust." Ambient air quality standards exist for TSP, PM_{10}, and $PM_{2.5}$. Also, the *Air Quality Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2013a) characterized the content of metals within TSP and PM_{10} and concentration estimates of metals within ambient air are presented in this assessment as well.

The sources of emissions considered in this study are summarized in Table 7A-1.

TABLE 7A-1
Source Identification Table
Faro Mine Interim Works

Source Identifier	Source Type	Source Description	Contaminants
TA	Tailings Area	• Waste and Water Management – Storage of tailings material in the RCTA	TSP, PM_{10}, $PM_{2.5}$, metals
RD	Roads	• Supporting Activities: – Transport of fuel and materials – Transport of personnel and supplies – Sourcing and transport of borrow material – General Project-related traffic	TSP, PM_{10}, $PM_{2.5}$, metals
CN	Construction	• Intermediate Dam Spillway Upgrade – Excavation of Intermediate Dam Spillway – Sourcing and transport of borrow material – Construction of erosion protection in spillway • Intermediate Dam Raise • Geomembrane and concrete barrier installation	TSP, PM_{10}, $PM_{2.5}$, metals

There are expected to be only minor amounts of combustion-related emissions occurring on the site during the IW activities. These emissions will be associated with comfort heating, diesel generators, and tailpipe emissions from onsite traffic. Combustion related contaminant emissions from the IW have been assumed to be small and of a nature that will not result in a significant change in ambient air quality at any location; therefore, these emissions have not been estimated or modelled.

2.1.2 Emission Estimates

Emission estimates have been developed for IW activities in each of the three identified areas using generally accepted methods, such as emission factors, source activity levels, meteorological parameters, and material properties. A discussion of the emission calculations for each source type is listed in Table 7A-1. Detailed emission estimate calculations are provided in Attachment 7A-1 for each of the source types.

2.1.2.1 Tailings Area Emissions

When the FMC was operational, the milling of ores resulted in solid waste which left the mill as a slurry. The slurry was channelled to the Original, Secondary, and Intermediate Impoundments, where the solids were allowed to settle out of suspension and now form a large, exposed tailings surface. The tailings area can be subject to wind erosion during periods of dryness. Fugitive particulate matter emissions from wind erosion of these tailings were included in this assessment. The emission factors of the RCTA were calculated using an equation published by Evans and Cooper (1980) using onsite meteorological data obtained in 2010 from the Faro Dump meteorological station. The meteorological data used in the estimation of emissions from the RCTA included monthly precipitation totals and mean monthly temperatures.

This method was designed to estimate annual emissions; therefore, it was necessary to scale the estimated annual emission factors to 24-hour average emission factors. This scaling helps account for the variability that occurs in a source's emissions on a day-to-day basis and that modelling of 24-hour concentrations should be done using a maximum 24-hour emission instead of an annual average. This scaling was performed consistent with a the Ontario Ministry of the Environment guidance document "Procedure for Preparing An Emissions Summary and Dispersion Modelling Report", Version 3, Table 7-1 (Ontario Ministry of the Environment, 2009). A summary of particulate matter emissions for the Tailings Area is provided in Table 7A-2.

2.1.2.2 Construction Emissions

The construction activities associated with the DVIHU have the potential to result in particulate matter emissions in the immediate vicinity of the Intermediate Dam area. Fugitive particulate matter resulting from construction

activities will have a significant fraction of particles with large aerodynamic diameters that have a tendency to settle out of the atmosphere rapidly.

The contaminants that arise from diesel engine combustion will be small and localized and are not expected to result in a significant impact on ambient air quality beyond the FMC site. The air emissions associated with construction activities will be highly variable in that the exact number of machines and timing are very difficult to quantify. Consequently, predicting emission impacts from these sources and activities has a high degree of uncertainty. Construction emissions associated with material handling and movement were included in the estimates of emissions for particulate matter.

Emissions from construction have been estimated using the methodology from the current USEPA AP-42, Fifth Edition, Chapter 13.2.3 (1995). This emission methodology is an all-inclusive estimate of particulate matter emissions from construction areas where the emissions are proportional to the amount of land being worked and to the level of construction activities. Sources of emissions from construction-related activities will include land clearing and forming, drilling, ground excavation, cut and fill operations (earth moving), and construction-related activities of roads and facilities. In this report, construction areas were assumed to cover the DVIHU construction area, the Cross Valley Pond area and the Intermediate Pond area; thus the impacts of construction activities are considered conservative.

Construction was assumed to be year-round for the purposes of modelling, but much of the activity is done during the summer months only. Also, the construction activity was restricted to daytime only, from 7 a.m. to 7 p.m.

A summary of particulate matter emissions for the construction area is provided in Table 7A-2 and further details about the emission calculations are provided in Attachment 7A-1 of this report.

Fugitive Particulate Matter Emissions from Roads and Access Routes

Particulate matter emissions from onsite unpaved roads, trails and access routes were estimated using methods provided in Environment Canada's *National Pollution Release Inventory Tool Box – General NPRI Reporting Tools* (1986). It was assumed that snow cover would mitigate road dust during the winter months (October to April inclusive). Further, roads were only assumed travelled during the day (7 a.m. to 7 p.m.). The emission rates of identified contaminants for each identified sources used in the modelling are presented in Table 7A-2. The emissions from the roadways are dependent on the length of the roads, silt content, vehicle weight, and vehicle traffic counts on each road segment.

Since there are numerous smaller roads in both the Faro side and the Vangorda/Grum sides of the FMC, the total road distances were estimated and aggregated into a single area source for each side of the FMC. These sources were designated as RD_FS and RD_GS for Faro side and Vangorda/Grum side respectively in Table 7A-2. The haul road connecting the two sides of the FMC and the access road to the south were modelled as a series of elongated area sources of 15 metres (m) by 150 m.

Emission Controls

An average control efficiency of 60 percent was applied to the uncontrolled tailings area emissions, construction emissions, and road dust emissions. This is because of the expected addition of water and dust suppression substances on the roadways and the tailings area, and use of best management practices (BMPs) for fugitive reduction control during construction activities. This control efficiency is consistent with that provided in Cowherd et al. (1988), for similar activities and was applied to all emissions of TSP, PM_{10}, and $PM_{2.5}$ in this study.

All of the particulate matter emission sources were modelled as area sources. A summary of the total emissions, normalized to a square metre area from each of the modelled emission sources is shown in Table 7A-2, along with the percent contribution from each source with respect to total FMC-wide emissions. A summary of the total emissions by type (i.e. tailings, construction, and roads), as well as the percent contribution to total emissions are shown in Table 7A-3. A summary of the diurnal variation in emissions from the various sources are provided in Table 7A-4.

TABLE 7A-2
Source and Emission Summary
Faro Mine Interim Works

Source Identifier	Source Description	Contaminants	24-hour Emission Rate ($g/s/m^2$)	Method Reference	Percent of overall emissions (%)
TA-1	Tailings Area	TSP	1.14E-6	EF/EC	3.1
		PM10	5.70E-7	EF/EC	3.5
		PM2.5	5.70E-8	EF/EC	3.5
RD-HAUL	Haul Road	TSP	2.41E-5	EF	5.8
		PM10	6.38E-6	EF	3.5
		PM2.5	6.38E-7	EF	3.5
RD-ACCES	Access Road	TSP	1.59E-5	EF	4.3
		PM10	4.21E-6	EF	2.6
		PM2.5	4.21E-7	EF	2.6
RD-Faro	Faro Side Roads Area	TSP	9.78E-7	EF	9.1
		PM10	2.59E-7	EF	5.5
		PM2.5	2.59E-8	EF	5.5
RD-Grum	Vangorda/Grum Roads Area	TSP	6.33E-7	EF	6.6
		PM10	1.68E-7	EF	4.0
		PM2.5	1.68E-8	EF	4.0
CN-1	Intermediate Dam Construction Area	TSP	2.08E-5	EF	71.1
		PM10	1.04E-5	EF	80.9
		PM2.5	1.04E-5	EF	80.9

Notes:
The sum of all individual TSP sources is 100 percent, as are the sums of the individual PM_{10} and $PM_{2.5}$ sources
EF = Emission Factors
EC = Engineering Calculation
$g/s/m^2$ = grams per second per square metre

TABLE 7A-3
Summary of Total Emissions by Type
Faro Mine Interim Works

Temporal Period	TSP (g/s) and (%)	PM_{10} (g/s) and (%)	$PM_{2.5}$ (g/s) and (%)
Tailings Area	1.95 / 3.1	0.975 / 3.5	0.0975 / 3.5
Unpaved Roads	16.4 / 25.9	4.35 / 15.6	0.435 / 15.6
Construction	45.1 / 71.1	22.6 / 80.9	2.26 / 80.9

TABLE 7A-4
Summary of Diurnal and Monthly Activity
Faro Mine Interim Works

Temporal Period	Construction Area	Tailing Area	Roads
Daily	7 a.m. - 7 p.m. only	All hours	7 a.m. – 7 p.m.
Monthly	All months	All months	May-September Emissions Only

It was assumed that construction for the DVIHU would occur only within the daytime hours of 7 a.m. to 7 p.m., and construction-related emissions would not occur in the late evening and overnight hours. The haul roads and access roads were assumed to have traffic only during hours consistent with construction activities. Also, accumulated snow from October to April inclusive would mitigate fugitive emissions from the haul roads and access roads during these months. In general, the maximum 24-hour contaminant emissions estimates were used for the modelling consistent with the averaging period of most standards for particulate matter and metals.

Metals Emissions

In order to estimate the ambient air concentrations of metals within particulate matter as a result of IW activities, data from previous monitoring studies were used, specifically the data from the SENES Consultants Ltd. (SENES) 2008 field monitoring program that measured PM_{10} and metals concentrations at various locations in the FMC. A statistical analysis of the data was performed and a ratio was developed between the ambient PM_{10} concentration and the concentrations of various metals reported in that study. The metals concentrations in this assessment were then estimated by using the modelled PM_{10} concentration times the observed ratio of metals to PM_{10}, and adding the metals concentrations that are expected to constitute background concentrations.

The SENES 2008 ambient air monitoring program and results are discussed in the *Air Quality Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2013a).

A summary of the ratio of metals to PM_{10} derived from the SENES study are listed in Table 7A-5. Metals designated with an “MDL” indicates that the metals were below method detection limits (MDL) during the SENES 2008 monitoring program.

TABLE 7A-5
Summary of Observed Ratios of Metals to PM_{10} Concentrations
Faro Mine Interim Works

Metals	Metal/PM_{10} Ratio
Antimony	MDL
Arsenic	0.027%
Barium	0.063%
Beryllium	MDL
Boron	MDL
Cadmium	0.0036%
Chromium	1.09%
Cobalt	MDL
Copper	0.16%
Iron	2.28%

Notes:
MDL = metals were below method detection limit

2.2 Modelling Methods

2.2.1 CALPUFF Dispersion Model

CALPUFF is a multi-layer, multi-species, non-steady-state puff dispersion model. Because of the complexity of the terrain, it was decided that the most recent version of the USEPA air dispersion model CALPUFF (Version 6.42) and the meteorological preprocessor for the CALPUFF modelling system (CALMET) would be most suitable to analyze the nearby and possible far-field dispersion of particulate matter emissions originating from the IW activities at the FMC.

CALPUFF is a non-steady-state Gaussian puff dispersion model with algorithms for chemical transformations and deposition. The model uses three-dimensional wind fields that can vary on an hourly basis. The model is capable of integrating surface meteorological observations from multiple sources/stations.

2.2.2 CALPUFF Methodology

The CALPUFF input files require a number of switches that must be defined by the modeller. These switches control factors such as transitional plume rise adjustments, stack-tip downwash, puff splitting, aqueous phase transformations, and wet and dry deposition to name a few. The model inputs used for the modelling were consistent with those recommended by the BC Ministry of the Environment unless otherwise noted and are shown in Attachment 7A-2.

2.2.3 Stack and Source Parameters

A summary of the area source parameters used in the modelling analyses are presented in Table 7A-6 for the FMC. All activities were modelled as area sources, including the haul and access roads. There are a number of roads in both the Faro and Vangorda/Grum sides of the FMC. The total length of roadway within the Faro and Vangorda/Grum sides of the FMC were estimated based on recent site maps. The total particulate matter emissions were allocated within the area sources provided in Table 7A-6 for the RD-FARO and RD-GRUM sources. The access roads leading to the FMC, as well as the haul road connecting the two sides of the FMC were modelled using a connected series of area sources each 15 m wide and 150 m long for both sources. The total number of vehicles estimated to be travelling on these roads were supplied by onsite personnel and people familiar with the site operations. A total of 10.24 km and 11.50 km of roadway were modelled for the haul road and access roads, respectively.

In Table 7A-6, the total area associated with each of the modelled sources is shown. Release height is the height aboveground at which emissions are assumed released to the atmosphere within the area source, and initial sigma is the initial vertical spread of the fugitive dust associated with the emission source. These values are typical for these emission types and are based on the professional judgement of the modeller.

A representation of the source layout as modelled in this study is shown in Figure 7A-1. Details of the emission estimates are shown in Attachment 7A-1.

TABLE 7A-6
Source Parameter Summary Table
Faro Mine Interim Works

Source Identifier	Point Source Description	Area (hectares)	Release Height (m)	Initial Sigma (m)
TA-1	Tailings Area	171.05	0.5	1.0
CN-1	Intermediate Dam Construction Area	217.61	2.5	5.0
RD-Faro	Faro Side Roads	588.86	1.5	3.0
RD-Grum	Grum Side Roads	666.72	1.5	3.0
HR	Haul Road	15.36	1.5	3.0
AR	Access Road	17.25	1.5	3.0

2.2.4 Receptor Grid

Ground level contaminant concentrations for the modelling domains were calculated over a uniform receptor grid with 500-m spacing as well as at discrete receptors situated along the perimeter of the FMC. Since the emissions are from near-ground level fugitive emission sources, it is expected that the highest off-property ambient air concentrations will be at the property line where the receptor spacing is 100 m. Onsite receptors were spaced at 500 m. The additional receptors were used with the following resolution:

- 100 m at the property line (defined by the boundary of the staking withdrawal area)
- 500 m out to 12,000 m from the approximate centre of the project site (i.e., 586.257 Universal Transverse Mercator [UTM] Easting, 6909.677 km UTM North Zone 8N)
- 1000 m spacing out to 50 km from approximate centre of the FMC

A total of 3409 receptors were used to calculate concentrations within the entire modelling domain.

The boundaries of the staking withdrawal area and locations of the area sources used for the effects assessment are shown in Figure 7A-1. Figure 7A-2 shows the terrain contours in the area of the FMC. A close up view of the perimeter receptors and gridded receptors in the vicinity of the FMC is shown in Figure 7A-3.

Air quality standards are generally compared to off-property air concentrations from any particular facility or site. However, maximum concentrations for both on-property and off-property receptors are shown in the summary tables. The Faro Mine staking withdrawal area was used as the property boundary.

2.2.5 CALMET Methodology

The air pollution potential is defined as the meteorological conditions which, given the existence of emissions, would be conducive to poor air quality. Conditions that allow for the accumulation of pollutants denote high air pollution potential. The dispersion of pollutants may be evaluated from the duration of light wind speeds, atmospheric stability, and mixing layer depths.

Meteorological data was processed using the most recent release of USEPA's CALMET meteorological pre-processor (Version 6.334, Level 110421). The major purpose of CALMET is to calculate atmospheric boundary layer parameters for use by CALPUFF. The CALMET meteorological model consists of a diagnostic wind field

module and micrometeorological modules for overwater and overland boundary layers. The final output for the CALMET meteorological preprocessor is a three-dimensional wind field and associated parameters required by CALPUFF to estimate dispersion and downwind concentrations of emitting sources and contaminants.

2.2.5.1 Meteorological Data Used for Effects Assessment

The local meteorology of the region must be characterized to evaluate the short-term atmospheric dispersion and transport of emissions released by the sources considered at the FMC. The data necessary to predict dispersion and transport include: wind velocities and direction, temperature, atmospheric stability, and mixing layer depth. Wind and temperature data are available from Environment Canada meteorological stations or onsite stations where available. Atmospheric stability and mixing layer depth are calculated from additional raw meteorological data such as cloud cover and solar radiation.

The surface meteorological data used in this study were presented in detail in the *Climate Baseline Report, Faro Mine Interim Works* (CH2M HILL, January 2013b). The data used in the study were taken from the Faro Dump monitoring station, the Grum Dump monitoring station, and the Faro Automated (AUT) Environment Canada station, all from the year 2010. As indicated in the *Air Quality Baseline Report, Faro Mine Interim Works* (CH2M HILL, January 2013a), the location of the Grum side monitoring station was moved in June of 2010, to a location about 1 km northeast of the old site. However, a correction factor was applied to the wind directions at the new site by the contractor responsible for those stations to keep the two data sets consistent (Denison Environmental Services, 2011). The old station location was used in the CALMET processing.

Additionally, prognostic meteorological data from the MM5 model (abbreviation for Fifth-Generation Penn State/NCAR Mesoscale Model) was used to supplement the surface data listed on Table 7A-7. These data are typically used for air dispersion modelling purposes when the study area is large and surface meteorological data may not be available for the entire domain, and when the available data may have gaps in either the parameters measured or in temporal completeness (BC Ministry of the Environment, 2008). The MM5 data were obtained through Lakes Environmental in Waterloo, Ontario, and were used as the initial wind field in the CALMET processing. No upper air radiosonde data were used in this study. Information on upper air winds and temperature structure of the atmosphere was taken from the multi-layer MM5 data. MM5 data is particularly useful in this modelling study due to the lack of upper air data in close proximity to the FMC.

A summary of CALMET switches used in the study are listed in Attachment 7A-2.

SECTION 3

3 Regulations and Standards

3.1 Background

The AAQC for relevant pollutants are discussed in this section. An AAQC is a desirable concentration of a contaminant in air, based on protection against adverse effects on health or the environment. The term "ambient" is used to reflect general air quality independent of location or source of a contaminant. AAQCs are most commonly used in environmental assessments, special studies using ambient air monitoring data, assessment of general air quality in a community and annual reporting on air quality across the territory. AAQCs are set with different averaging times (e.g., annual, 24 hours, 1 hour, and 10 minutes) that are appropriate for the effect that they are intended to protect against. Health, odour, vegetation, soiling, visibility, corrosion or other effects are considered.

Existing air quality in the vicinity of the FMC was previously discussed in terms of baseline air quality emissions and was presented in the *Air Quality Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2013a).

Governments have promulgated a number of air quality criteria for several pollutants considered to be harmful to either the ecosystem or humans. Since there are numerous air contaminants that could exist in the air, it is not possible to promulgate criteria for all contaminants. However, most jurisdictions have standards associated with the criteria contaminants, including particulate matter, sulphur dioxide (SO_2), nitrogen oxides (NO_x), carbon monoxide (CO), and ozone (O_3).

YG has established ambient air standard for TSP and $PM_{2.5}$, as well as other criteria contaminants. In BC, up to three objective values have been recommended using the categories "desirable", "acceptable", and "tolerable" (Levels A, B, and C, respectively); "desirable" being the most stringent. Ontario has a number of ambient air quality criteria introduced as part of Ontario Regulation 419. With that regulation, Ontario developed standards for a number of pollutants that previously had no standard, and reduced many existing standards to reflect a greater understanding of the health and vegetative effects of some pollutants.

Typically, an air quality standard is meant to connote a legal limit for a pollutant numerical concentration (i.e. part of a provincial or territorial regulation), while objectives and guidelines are meant to connote a desirable concentration of a pollutant but not necessarily legally binding with respect to air permitting or environmental assessment purposes.

3.2 Air Quality Standards and Guidelines

Predictions of the maximum ground level concentrations for each averaging period are compared to the corresponding air quality standards or guidelines from Yukon, BC, or Ontario, as shown in Table 7A-8. Preferentially, Yukon standards were used for the contaminants when available, in this case TSP for 24-hour and annual averages, and 24-hour average $PM_{2.5}$ concentrations. If Yukon standards were not available and more than one provincial standard exists for a particular contaminant or averaging period, the most stringent of them was used for comparison. For 24-hour PM_{10}, the "desirable" objective from BC was used, while for the metals, Ontario 24-hour average standards and guidelines were used. Governments use ambient air quality criteria to make decisions about acute exposure to air contaminants. Although some criteria were from other jurisdictions outside of the Yukon, the use of criteria from other provinces helps to put the concentrations determined in this assessment into context and gauge acceptability and significance.

Standards and guideline concentration units are in micrometres per cubic metre ($\mu g/m^3$) unless otherwise noted.

SECTION 4

4 Modelling Results

4.1 Introduction

The FMC was assessed quantitatively by modelling the estimated emissions that will result from construction and maintenance activities that are or will occur at the site over the next 10 years. The individual activities constituting the IW were initially qualitatively assessed to determine whether there existed a feasible pathway whereby air quality in the study region could potentially be affected. The activities that were deemed to likely affect air quality were quantified in terms of emissions and were then modelled to conservatively estimate the extent of the effects of those emissions.

The air quality effects from the identified emissions sources at the FMC are presented in this section. The activities chosen for quantitative assessment were previously summarized in Section 2 of this Appendix.

Ambient air standards are generally compared against a total pollutant concentration in air. Therefore, the assessment of effects was performed by adding existing background concentrations of particulate matter and metals with those estimated by the air dispersion modelling of construction and maintenance activity emissions. The background concentrations for particulate matter and metals were presented in *Air Quality Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2013a), and were measured at the FMC during 2008 when care and maintenance activities and road traffic associated with those activities occurred. It is likely that this will result in a "double counting" of emissions associated with road dust resuspension and tailings area wind erosion. Therefore, concentrations predicted in this assessment are likely to be conservatively high. The cumulative total of the modelled plus background were then compared to the applicable ambient air quality criteria as listed in Table 7A-8 to determine magnitude, extent, and frequency and overall significance of predicted effects, if any.

Effects of various components of the IW on air quality are summarized in the following sections.

4.2 Results

The maximum predicted 24-hour and annual average ground level concentrations were calculated using the CALPUFF dispersion model for each contaminant and applicable averaging period. Table 7A-2 in Section 2, provides a complete emissions summary.

4.2.1 Particulate Matter

A summary of the predicted maximum off-property ground level concentrations for each particulate contaminant and the applicable Air Quality Objective (AQO)/Point of Impingement (POI) are presented in Table 7A-9. Also presented in this table are the coordinates of the location where the maximum concentration occurs and the comparison of the predicted concentration with the applicable AQO or POI. Background concentrations for the contaminants have been listed and added to the modelled results to show an estimated total concentration for each contaminant and averaging period, as applicable.

A summary of the predicted maximum ground level concentrations for all receptors for each contaminant and the applicable AQO/POI are presented in Table 7A-10. These predictions include receptors that are very close to proposed construction activities, resulting in higher maximum concentrations.

TSP	102	582.257	6913.177	11.7	114	60

[a]75th Percentile
[b] Location of Maximum Impacts

Maximum 24-hour, and annual average Ground Level Concentrations (GLCs) for each modelled contaminant during the IW activities are below the applicable air quality standards when considering off-property receptors. Maximum off-property concentrations for particulate matter are occurring in the northwest part of the mining tenure border, west of the area where DVIHU construction is to take place.

Concentration isopleths showing the maximum 24-hour concentrations of TSP for off-property receptors are shown in Figure 7A-4. The same isopleths for PM_{10} and $PM_{2.5}$ are shown in Figures 7A-5 and 7A-6.

Concentration isopleths showing the maximum 24-hour concentrations of TSP for all receptors including on-property are shown in Figure 7A-7. The same isopleths for PM_{10} and $PM_{2.5}$ are shown in Figures 7A-8 and 7A-9. These figures show the modelled concentrations at each receptor predicted over the modelling period (2010). Figures 7A-10 through 7A-12 shows the number of days that an ambient air standard was exceeded as determined through dispersion modelling for TSP, PM_{10}, and $PM_{2.5}$, respectively. These figures show that exceedances of ambient air standards and guidelines are highly localized to the immediate construction area and to a lesser extent the tailings area.

Considering only off-property receptors, the maximum 24-hour and annual average concentrations for TSP, PM_{10}, and $PM_{2.5}$ are all predicted to be below the applicable standards at all times.

4.2.2 Metals

A summary of the predicted maximum off-property ground level concentration for each metal contaminant (contained within particulate matter) and the applicable standards or guidelines is presented in Table 7A-11. It should be noted that the metals standards and guidelines are from Ontario since no applicable Yukon standards exist for these contaminants. The comparison against Ontario standards is made to help assess the significance of the modelled concentrations.

TABLE 7A-11

Zinc	0.0569	0.1000	0.1569	120	0.1%

Notes:
MDL = less than Method Detection Limit (not detectable during monitoring program)
µg/m³ = micrograms of contaminant per cubic metre
n/a = Not applicable or Not Available

Table 7A-12 shows a summary of the predicted maximum ground level concentration for each metal contaminant (contained within particulate matter) and the applicable standards or guidelines from all receptors including onsite receptors.

Maximum 24-hour average GLCs of metals during the IW are well below the applicable objectives/standards for all off-property receptors. All metal concentrations are predicted to be less than their applicable standard and most are less than 1 percent of the standard or were not detectable during the SENES 2008 monitoring program. The maximum predicted concentration of metals is only 54 percent of the applicable standard. No off-property exceedances are predicted.

For all receptors, only two metals (chromium and iron) show highly localized exceedances in and near the construction area. It should be noted that metals concentrations were estimated by using a ratio of metal to PM_{10} concentrations developed from data supplied by SENES (2009). Emission estimates of fugitive particulate matter are difficult to develop and are subject to considerable uncertainty, and therefore the metals estimated are subject to the same uncertainty. The modelling shows that particulate matter decreases to below applicable standards beyond the property line and the modelled effects are highly localized.

4.3 Assessment Limitations

The assessment of the air quality effects of the FMC during construction and maintenance are subject to some limitations. The fugitive dust analysis is subject to significant uncertainties because of the inherent challenge in accurately estimating emissions inventories and in properly modelling their concentrations. The dust estimates were based on 2010 meteorological observations from the Faro Dump meteorological monitoring station. Estimates of PM_{10} and $PM_{2.5}$ were based on general particle size distributions consistent for that type of emission as per USEPA AP-42 guidance (USEPA, 1995).

Deposition loss from the suspended particulate matter would be expected in the near field but because of the lack of information regarding particle sizes within the dust. Because the model does not account for depositional loss of crustal dust which was not included in the modelling, the model will likely predict higher ambient concentrations of particulate matter and metals than what would actually be predicted if deposition were included.

The IW activities did not include an analysis of criteria contaminants, other than particulate matter, for two reasons:

- The emissions of other criteria contaminants are expected to be very small and no significant effect on ambient concentrations of those pollutants is expected. Also, there would be significant uncertainties associated with modelling of mobile equipment such as work schedule, number of vehicles, location of vehicles, as well as uncertainties in the emissions factors and estimates themselves.
- The property line for the IW activities analysis was based on the boundary of the existing mineral staking withdrawal and is therefore a large area. The concentrations at the edges of the mining tenure are expected to be very small and localized to near the edge of the property. Modelled concentrations because of IW activities at these locations are expected to be indistinguishable from the natural variability of contaminant background concentrations.

Emissions from roadways were determined from estimates of daily traffic as supplied by onsite personnel, including security guards and managers familiar with traffic flow into and out of the site. Since traffic patterns were not known with certainty, it was assumed that vehicle traffic on the haul roads would travel on all FMC and Vangorda/Grum mine site roads as well. This is an inherently conservative assumption.

All of the expected particulate matter sources were modelled simultaneously for each of the identified activities in order to determine a worst case scenario. In reality, only infrequent occurrences of simultaneous tailing emissions, construction emissions, and roadway emissions are likely to occur on a consistent basis.

A 60-percent reduction in fugitive dust emissions was assumed to account for dust mitigation because of the anticipated application of tackifiers, water, and dust mitigation BMPs throughout the site. In reality, these activities will likely be more effective and reductions larger than the 60 percent (Hayden, 2005) are likely for both unpaved roads and the tailings area.

The modelling also assumed year-round emissions from the tailings area, which would likely not occur when there is snow cover. However, winter emissions were included in the study since dusting from the tailings area is known to occur when temperatures are cold but when there is not yet snow cover.

SECTION 5

5 Assessment of Air Quality Effects

5.1 Introduction

The IW activities have the potential to emit particulate matter and metals within particulate matter because of material handling, wind erosion, and resuspension of road dust because of onsite traffic. The overall assessment of significance of the air quality effects was determined by the direction of the effect, the magnitude and probability of the effect, the reversibility of the effect with consideration of timing and requirement of mitigation, and the geographic extent of the change. These will be discussed in more detail in the following sections.

Section 5.2 discusses the significance of possible cumulative effects that may occur in the study region as a result of IW emissions.

An assessment of the overall significance of the air quality effects are presented in Section 5.3 and includes the considerations and rationale used for determining significance and definitions of the ratings scale for each.

5.2 Cumulative Effects Assessment

A cumulative effects assessment extends what is normally in an environmental impact assessment to include effects over a larger area and a longer time period. Cumulative impacts can occur when more than one disturbance affects a resource, when one action results in multiple effects on a resource, or when similar small-scale events occur repeatedly in time or space, thereby causing a magnified impact (Hegmann, 1999).

This section considers the cumulative effects of the IW activities in the study area.

5.2.1 Interim Works Emissions with Existing Emission Sources

The modelling impact analyses presented previously include existing background concentrations for particulate matter. It is expected that these background levels are representative of the impacts from existing contaminant sources in the area surrounding the FMC.

The area surrounding the FMC is isolated and, therefore, the background levels of each of the contaminants are expected to be relatively small. The Town of Faro is located about 12 km south of the FMC and 6 km southwest of the Vangorda/Grum side of the complex. There is also an access road leading from the Robert Campbell Highway, through the Town of Faro and up to the FMC. Therefore, some contribution to background levels would be expected from mobile source combustion products such as nitrogen oxides, particulate matter, and carbon monoxide as well as contributions to particulate from residential heating and wood burning. The model predictions are conservative, especially with respect to particulate matter from construction activities at the site. The actual incremental impact from the FMC emissions are expected to be less than those presented in the modelling analyses provided, especially when a dust/particulate matter BMP plan is implemented.

The cumulative effects of criteria contaminants from the FMC with other emissions from nearby access road, highways, and the Town of Faro are expected to be minimal.

5.2.2 Secondary Particulate from Interim Works Emissions

A long-range assessment of secondary formation of ammonium sulphate and ammonium nitrate from the precursor gases of sulphur dioxide and nitrogen oxides was not performed in this study. This is because of the minimal amount of SO_2 and NO_x that is expected to be generated at the FMC because of the IW. Further, it is expected that in the field where the highest concentrations are expected to be found, secondary particulate formation will be insignificant compared to primary particulate matter from the various fugitive sources.

No significant cumulative effects from the IW with respect to secondary particulate formation from precursor emissions are expected to occur.

5.2.3 Long Range Transport of Interim Works Emissions

Based on the modelling results for particulate matter, and the likely insignificance of secondary particulate formation from SO_2 and NO_x precursor emissions, the IW emissions are not expected to have a measurable effect on air quality in the Town of Faro. The effects are therefore expected to be indistinguishable from background levels.

5.3 Residual Effects and Effects Assessment

This section describes the results of the detailed analysis of the potential effects on air quality from the IW. The air quality assessment considers the effect of all activities that may adversely affect the air quality of the region.

The model predictions presented in Section 4 are conservative and the incremental contribution to ambient contaminant levels is expected to be moderate to high within the construction and tailings area but low or no effect outside of the area withdrawn from mineral staking.

5.3.1 Air Quality Pathways of Effects

The pathways of effects are the activities that were identified as having the ability to affect air quality. These pathways include dust resuspension from the tailing area, general construction activities, and dust resuspension from vehicle traffic on unpaved roadways within the FMC. All of these activities have the potential to affect air quality and are assessed together through emission estimates and air dispersion modelling to quantify their potential effects.

5.3.2 Air Quality Indicators

The indicators used to assess air quality included the change in concentration of particulate matter in air, specifically TSP, PM_{10}, $PM_{2.5}$, and metals. The changes in air concentrations for these contaminants were estimated using emission estimates and air dispersion modelling for each of the potential pathways. Also, previous monitoring programs at the site (SENES, 2009) measured ambient air concentrations of a number of metals as shown in Table 7A-5. The concentrations of these metals were estimated based on the correlation of the observed ratio of metals to PM_{10} during the monitoring program and the model estimates for PM_{10} from this study. These indicators were chosen because of the IW activities being assessed as pathways; particulate matter and the (possible) metals within them were expected to show the greatest change in ambient air compared to background.

The possible interactions of each of the main sources that could potentially affect air quality were assessed individually in Table 7A-14.

5.3.3 Air Quality Ecological Objectives

A description of the standards and guidelines used to assess effects was presented in Section 3, specifically Table 7A-8. The ambient air standards and guidelines used were taken preferentially from Yukon, but were supplemented with objectives and standards from BC and Ontario, as necessary. These standards are generally used within each jurisdiction to provide regulators with a sense of the magnitude of the effect that an emitting source or group of sources has on the surrounding ambient air. It should be noted that usually concentrations at off-property receptors are compared against the ambient air standards and guidelines. In this study these standards were used to compare both on-property and off-property concentrations. As a result, they are an inherently conservative comparison metric.

5.3.4 Analysis of Potential Effects

The maximum 24-hour and annual averages (for TSP only) of ambient air concentrations predicted by the air dispersion modelling assessment was compared to ambient air standards in order to determine the magnitude of the total ambient air concentration for each contaminant. For all of the effects considerations, magnitude ratings were assigned “low”, “medium” or “high” where “low” means that there is minimal effect, and “high” means the effect was substantial. Table 7A-13 summarizes the significance criteria used in this air quality effects assessment.

The assessment of the magnitude and likelihood of the changes to ambient air concentrations were based on a comparison to standards and the frequency of occurrence or duration of predicted exceedances of standards at any of the modelled receptors. There was no consideration of whether the predicted exceedances were on-property or off-property, as this was considered in the geographic extent consideration discussed in the following section. A designation of "high" in this category was defined as having any one model receptor showing an exceedance of a contaminant air standard for more than 25 percent of the modelled days. It should be noted that there were several receptors in the immediate vicinity of the construction zone and the tailings area where predicted exceedances were expected.

The geographic extent effects assessment was defined by considering whether the exceedance areas occurred on or in close proximity to the emission sources, whether there were any exceedances off-property of the mineral staking withdrawal area, or whether there was a wide-spread area of exceedance off-property. For this category, a "low" designation was assigned when there was no off-property exceedance of ambient air standards for any of the contaminants and averaging periods.

The reversibility effects assessment was defined by considering whether the ambient air concentrations affected by the various sources were reversible or irreversible. A "low" designation for this attribute means that the effect was reversible without mitigation, medium means reversible with mitigation and time, while high means irreversible even with mitigation.

5.3.5 Air Quality Mitigation

A summary of the proposed mitigation is provided in Table 7A-14 but more details of the anticipated best management practices for the construction area and other aspects of the dust mitigation measures to be employed are presented in Section 4.3 of the *Faro Mine Interim Works Project Proposal* (CH2M HILL, 2014a).

5.3.6 Air Quality Significance of Effects

The effects classifications are presented in Table 7A-13. The assessment includes a level of concern with each Project potential interaction on the air quality component. Also, if a residual effect is noted, an evaluation of the residual effect will include an assessment of magnitude and frequency, geographic extent of effect, and overall significance of effect.

For the effects assessment, it was assumed that all potential pathways affected air quality in a negative sense, and therefore direction of effects was not explicitly included in the summary tables. The magnitude and frequency of effect was based on whether the total ambient air concentrations were less than or greater than applicable standards or guidelines, and if so, what percentage of the days were the concentrations greater than the applicable standards. The geographic extent of the effect differentiated between the on-property receptors and the off-property receptors, and whether receptors in those areas showed exceedances. Finally, reversibility considered whether the air quality effect was reversible, was reversible with time and mitigation, or was irreversible.

It should be noted that under the magnitude and frequency columns, these considerations are based on concentrations relative to a standard or guideline. There were several modelled contaminants for this assessment and these considerations were allocated based on the worst-case pollutant concentrations relative to their applicable standards or guidelines.

Table 7A-14 summarizes the air quality effects assessment for the IW activities after the proposed mitigation. A summary of the proposed mitigation is also shown in Table 7A-14 for each of the three areas.

5.3.7 Air Quality Monitoring

The dispersion modelling analysis has shown that on-property effects are moderate when using conservative emission estimates and dust mitigation methods for the three emission source areas. Overall significance is considered none to low off-property; therefore, no monitoring is proposed for air quality.

A brief discussion and context of the ambient air quality effects on particulate matter, metals, and dust is provided in the following sections.

Table 7A-13

Definitions for Evaluating Significance

Faro Mine Interim Works

VC	Indicator	Rationale for Selection	Measurements	Effects Attributes	Significance Ranking	Ranking Criteria
Air Quality	Contaminant Air Concentrations affected by Tailings Area, Construction, and Unpaved road traffic	Elevated pollutant concentrations can be harmful to humans, wildlife and vegetation. Ambient air quality standards will be used to assess significance of effects and these standards and guidelines are measured in terms of contaminant concentrations in air.	Modelled changes in Air concentrations for TSP, PM10, PM2.5, and metals	**Magnitude and Likelihood**	Low	Air concentrations less than applicable standards on-property, throughout the modelled year
					Medium	Air concentrations less than applicable standards off-property, throughout the year, but above on-property < 25% of modelled days at any receptor
					High	Air concentrations more than standards on-property, more than 25% of days in modelled year at any receptor
				Geographic Extent	Low	Air concentrations greater than standards only on-property
					Medium	Air concentrations greater than standards off-property
					High	Air concentrations greater than standards on a regional basis (greater than 1 km from site boundary)
				Reversibility	Low	Effects are completely reversible
					Medium	Effects are reversible but with mitigation and it may takes months or years for reversal to occur
					High	Effect is non-reversible despite mitigation.

Table 7A-14

Projected Air Quality Effects From IW Activities After Mitigation

Faro Mine Interim Works

IW Activity	Potential Interaction	Reversibility	Magnitude	Frequency/ Probability	Extent	Overall Level of Significance	Mitigation Plan Summary
Tailing area	Wind erosion from dried tailings material	Medium	Low	Medium	Low	Medium	Application of a chemical dust suppression compound on an annual basis or more frequently as required.
Intermediate Dam Construction	Emissions from various activities associated with vehicles, material handling, blasting etc.	Low	Medium	High	Low	Medium	Apply water spray during dry periods to disturbed areas, control of vehicle access and speeds, work stoppage under high wind events, minimize material drop distance, periodic washing of vehicles to reduce load out of dust.
FMC Access and Hauls Roads	Emissions from road dust resuspension caused by traffic	Low	Low	Low	Low	Low	Fuel efficient vehicles, environmental awareness, proactive identification of emission sources, maintenance programs, reduced idling times, water application to roads during dry periods, snow grading on top of roads, posting and enforcement of speed limits.

Particulate matter emissions from the FMC are expected to result in no offsite exceedances of applicable TSP, PM_{10}, $PM_{2.5}$ or metal standards. It should be noted that because of the low release height of the fugitive emission sources resulting from IW activities, all of the highest off-property concentrations are located at the mining boundary limits west of the DVIHU construction area. Also, the model predictions are conservative in that all emission sources were modelled simultaneously and it is unlikely that this will occur in practice. Dust suppression BMPs will be used wherever feasible to reduce on-property and off-property effects. Dust control techniques and their effectiveness are difficult to accurately quantify, but a conservative estimate of 60 percent was used in the modelling consistent with water spray control of fugitive emissions sources. This is consistent with what was shown by other investigators (Cowherd, 1988).

It is expected that after the appropriate dust control techniques are employed at the tailings area, construction area, and unpaved roadways, the residual effects of particulate matter emissions (including metals) at off-property locations will be negligible and concentrations will be indistinguishable from those measured during the previous monitoring campaigns. The geographic extent and reversibility of air quality effects are low, and although the magnitude and likelihood of effects can be high within and close to the emission sources, a negligible effect is expected at the property line and in the neighbouring Town of Faro.

It is noted that “dust” is a more general term associated with particulate matter but it typically refers to any form of particulate matter that is considered to be visible and therefore includes larger particles that settle relatively quickly to the ground. There is no ambient air quality standard for “dust.” The primary air pollutant from the FMC will be dust generated from construction activities. The main potential sources of dust will be tailings dust, haul truck operations including loading, vehicle traffic, grading, and other types of material handling.

A dust management plan has been developed and can be found in the *Environmental Management Plan, Faro Mine Interim Works* (CH2M HILL, 2014b). The influence of the dust management plan on the residual impacts of dust and particulate matter will be to lower the amount of particulate being generated, such that the significance of the residual impacts is low.

SECTION 6

6 Summary of Air Quality Assessment and Effects

A comprehensive modelling assessment was completed for several contaminants that are expected to be emitted as a result of IW activities. The contaminants assessed included particulate matter, as well as metals within particulate matter. All modelled contaminants have an applicable Yukon, BC, or Ontario air quality criterion.

The dispersion model used to evaluate the effects of particulate matter emissions resulting from IW activities was the USEPA CALPUFF dispersion model, which is ideal for long-range transport of contaminants and particularly suited for complex terrain, as is the case of the FMC. Meteorological data from two meteorological surface stations located at the FMC and one Environment Canada station located in the Town of Faro were used in the dispersion model. Additional MM5 prognostic meteorological data for the year 2010 was used. The effects were calculated with a higher resolution of receptors within 12 km from a point central to the FMC, as well as a less dense resolution of receptors for a larger 100 km by 100 km area centered on the site. The emission rates used for 24-hour and annual averaging periods for the modelling were maximum 24-hour emissions from the tailing area, the unpaved onsite roads, and the Intermediate Dam construction work.

The results show modest off-property concentrations for the particulate matter, but all off-property concentrations were predicted to be less than all applicable ambient air quality standards. Modelling of metals and particulate matter (TSP, PM_{10}, and $PM_{2.5}$) for IW showed the highest offsite concentrations were downwind of the construction area along the northwestern part of the mineral staking withdrawal area. All property line concentrations were less than applicable criteria. Emission control factors were used consistent with water spraying and other dust management practices to reduce predicted fugitive dust emissions for the sources considered in this assessment.

There were highly localized onsite areas where particulate matter is expected to be higher than applicable ambient air standards. These areas were restricted to the immediate vicinity of the DVIHU construction zone and to a lesser extent the tailings area. The air quality effect from these activities will be mitigated by the proposed BMPs and dust suppression compound application. The overall significance of the activities is expected to be low to medium during the construction period, and then will become low to none afterwards. Any short-term effects on ambient air quality are expected to be reversible. Off-property the overall significance of effect to air quality is estimated to be low to none.

Because of modest concentrations and the limited geographic extent of particulate matter effects, no particulate monitoring is proposed. Regular visual checks for dusting and fugitive dust emissions will occur subsequent to dust suppression applications to confirm the effectiveness of the measures and to help guide the frequency of the applications. For more details of the dust management plan, a comprehensive dust and particulate matter mitigation plan is included in Section 4.3 of the *Faro Mine Interim Works Project Proposal* (CH2M HILL, 2014a).

Attachment 7A-1
Emission Estimates Calculations

7A-1-1
Emissions from Construction

Fugitive Emission Estimates for Heavy Construction Operations
Reference:

1) US EPA AP-42 Section 13.2.3 - Heavy Construction Operations
2) Industrial Wind Erosion, US EPA AP-42 Section 13.2.5

1. Emission Factor Source: US EPA AP-42 Section 13.2.3 - Heavy Construction Operations

1.1 TSP Emission Estimates

E_{TSP} = 2.69 megagrams (Mg) / hectare/ month of activity

Since the AP-42 emission factor was based on the month-round construction activities, a scaling factor is applied to reflect the day-time construction nature in Faro.

scaling 12 hours / 24 hours = 0.5

E_{TSP} = Scaling factor x 2.69
= 0.5 x 2.69
= 1.345 (megagrams (Mg) / hectare/ month of activity)

Convert to grams per square meter per day
= 1.345*1000,000 g/10,000 m^2/30 day =
= 4.48 (g/m^2/day)

Convert to grams per square meter per second (24 hour average emissions)
= 4.48 / 24 / 3600
= 5.19E-05 $g/m^2/s$

1.2 PM_{10} Emission Estimates

Using a PM_{10}/TSP ratio of 0.5 to calculate PM_{10} emission ra (AP-42 Section 13.2.5)

E_{PM10} = 5.19E-05 x 0.5
= 2.59E-05 ($g/m^2/s$)

1.3 $PM_{2.5}$ Emission Estimates

Due to a limited amount of information available for $PM_{2.5}$ ratio over PM_{10} for construction, a ratio of 0.1, calculated from onsite unpaved roads $PM_{2.5}$ and PM_{10} emissions was used.

$E_{PM2.5}$ = 2.59E-05 x 0.1
= 2.59E-06 ($g/m^2/s$)

1.4 Dust Control Efficiency

Dust control is required for construction operations, conservatively assume a basic control efficiency of 60% for using watering applications.

Details will be discussed in Environmental Management Plan.
Sample calculation for TSP emissions after control:

$E_{TSP\ w\ control}$ = 5.19E-05 x (1-60%) = 2.08E-05 ($g/m^2/s$)

2. Total Construction Emission Summary

Construction Area ID	Construction Area Description	Area (m^2)	Emission Rate ($g/s.m^2$)			Control Efficiency	Emission Rate after control ($g/s.m^2$)		
			TSP	PM_{10}	$PM_{2.5}$	(%)	TSP	PM_{10}	$PM_{2.5}$
CN_1	Constructio	2175059	5.189E-05	2.595E-05	2.595E-06	60%	2.08E-05	1.04E-05	1.04E-06

7A-1-2
Emissions from Tailings

Fugitive Emission Estimates for Tailing Areas
Reference:

1) An Inventory of Particulate Emissions from Open Sources, John S. Evans and Douglas W. Cooper, 1980
2) Industrial Wind Erosion, US EPA AP-42 Section 13.2.5

1. Method Description: The milling of ores results in solid waste which leaves the mill as a slurry. This slurry is channeled to a tailings pond, where solids are allowed to settle out of suspension. After the separation of water and solids, a dried pile of mill tailings remains. These piles are subject to wind erosion.

The emission factor were calculated using a equation suggested by Reference 1 and 2010 climate factors at on-site Faro Dump Station.

EF_{PM} *(ton/year.acre)* = *0.133 C*

where:

C = climate factors

$$C = 0.345(\bar{\upsilon}_{30})^3 / (PE)^2$$

where:

$\bar{u}_{30}$ = average annual wind speed (mph) at 30 ft above the ground,

PE = Thornwaite's PE index

$$PE = 10 \times \sum_{i=1}^{12} \left[11.5 \times (P_i / (T_i - 10))^{10/9} \right]$$

where:

P_i = monthly precipitation (inches of rain)

T_i = mean monthly temperature (°F) or 28.4 °F, whichever is less.

Total emissions (ton/year) = E_{PM} x A

where:

A = acres of tailing areas

2. Calculations:

2010 monthly precipitation and mean temperature at on-site Faro Station

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Pi (mm)	20	4.1	8.9	25.6	41.3	36.7	21.2	30.2	38.8	17.7	22.1	21	
Pi (in)	0.79	0.16	0.35	1.01	1.63	1.44	0.83	1.19	1.53	0.70	0.87	0.83	
Ti (°C)	-12.41	-7.28	-6.64	0.27	6.76	9.68	12.32	11.41	4.51	-1.73	-9.13	-18.52	
Ti (°F)	9.66	18.89	20.05	32.49	44.16	49.42	54.17	52.54	40.12	28.89	15.57	-1.34	
$(Pi/(Ti-10))^{(10/9)}$	0.03	0.01	0.01	0.03	0.03	0.03	0.01	0.02	0.04	0.03	0.03	0.03	
$11.5*(Pi/(Ti-10))^{(10/9)}$	0.35	0.06	0.14	0.37	0.39	0.29	0.14	0.22	0.42	0.29	0.39	0.37	
$\bar{u}_{30}$ *(m/s)*													5.59
$\bar{u}_{30}$ *(mph)*													12.50

PE = 34.17

C = 0.345 x 12.5/34.17^2 = 0.577

2.1 Calculation of annual emissions:

Annual EF_{PM} = 0.133 X 0.577

= 7.68E-02 (ton/year. acre)

= 4.21E-01 (lb/day.acre)

= 1.75E-02 (lb/hr.acre)

Convert to grams per second per square meter:

$$= \frac{7.68\text{E-}02 \text{ ton} * 2000 \text{ lb} * 454 \text{ g} * \text{year} * \text{day} * \text{hour} * \text{acre}}{\text{year.acre} \quad \text{ton} \quad \text{lb} \quad 365 \text{ day} \quad 24 \text{ hour} \quad 3600 \text{ sec} \quad m^2}$$

= **5.46E-07** **g/s/m^2**

Annual EF_{PM10} = **2.73E-07** **g/s/m^2** [using PM_{-10} to PM ratio of 0.5 from AP-42 Section 13.2.5]

2.2 Calculation of 24-hr average emissions.

As the method used above is for the estimate of annual emission from tailings, to obtain a 24-hour average emission, a conversion factor recommended by the Ontario MOE for conversion of annual POI concentration to 24-hr POI concentration was used to obtain the 24-hr average emission

$EF_{24\text{-hr}} = EF_{annual} \times (8760/24)^{0.28} = EF_{annual} \times 5.217$

24-hr EF_{PM} = 5.46E-07 x 5.217

= **2.851E-06** **g/s/m^2**

2.3 PM_{10} Emission Estimates

Using a PM_{10}/TSP ratio of 0.5 to calculate PM10 e (AP-42 Section 13.2.5)

E_{PM10} = 2.85E-06 x 0.5

= 1.43E-06 ($g/m^2/s$)

2.4 $PM_{2.5}$ Emission Estimates

Due to a limited amount of information available for PM2.5 ratio over PM10 for construction, a ratio of 0.1, calculated from onsite unpaved roads PM2.5 and PM10 emissions was used.

$E_{PM2.5}$ = 1.43E-06 x 0.1

= 1.43E-07 ($g/m^2/s$)

2.5 Dust Control Efficiency

Dust control is required for construction operations, conservatively assume a basic control efficiency of 60% for using watering applications. Details will be discussed in Environmental Management Plan.
Sample calculation for PM emissions after control:

$E_{PM\ w\ control}$ = 2.85E-06 x (1-60%) 1.14E-06 ($g/m^2/s$)

$E_{PM10\ w\ control}$ = 1.43E-06 x (1-60%) 5.70E-07 ($g/m^2/s$)

$E_{PM2.5\ w\ control}$ = 1.43E-07 x (1-60%) 5.70E-08 ($g/m^2/s$)

Emission rate after control = 1.14E-06 **$g/s/m^3$**

24-hr EF_{PM10} = **1.425E-06** **$g/s/m^2$** [using PM_{-10} to PM ratio of 0.5 from AP-42 Section 13.2.5]

Emission rate after control = 5.702E-07 **$g/s/m^3$**

3. Emission Summary for Tailings

Source ID	Source Name	Tailing Area size (m^2)	Uncontrolled Emissions ($g/m^2/s$)			Control Efficiency (%)	Controlled Emissions ($g/m^2/s$)		
			PM	PM10	PM2.5		PM	PM10	PM2.5
TA-1	Tailings Area	1710520	2.85E-06	1.43E-06	1.43E-07	60%	1.14E-06	5.70E-07	5.70E-08

Notes:
Area for Tailing Area calculated from CALPUFF view

7A-1-3
Emissions from Onsite Unpaved Roads

Calculation of Road Dust Emissions from Unpaved Roadways:

1. Environment Canada's "Unpaved Industrial Road Dust Calculator" spreadsheets were used for road dust estimate.

Emission Summary for Road Segments Calculation using EC Spreadsheets.

Source ID	Description	Modelled Source Type	Area (m^2)	Emission Rate (g/s)					
				24-hr average			Annual		
				TSP	PM_{10}	$PM_{2.5}$	TSP	PM_{10}	$PM_{2.5}$
RD_HAUL	Haul Road	Area Line Source	153600	9.256	2.450	0.245	2.612	0.691	0.069
RD_ACCES	Access Road	Area Line Source	172530	6.863	1.816	0.182	1.937	0.513	0.051
RD_Faro	Roads in Faro Site	Area source	5888607	14.391	3.809	0.381	4.061	1.075	0.107
RD_Grum	Roads in Grum Site	Area source	6667147	10.558	2.795	0.279	2.980	0.789	0.079

2. Calculate emission rate in per square meter basis by dividing the total emissions by the total area of the applicable road segments.
Sample calculations:

RD_Haul 24-hr TSP emission = 9.256 (g/s) / 153600 (m^2)
= 6.03E-05 ($g/m^2/s$)

Emission Summary:

Source ID	Description	Modelled Source Type	Area (m^2)	Emission Rate ($g/s.m^2$)					
				24-hr average			Annual		
				TSP	PM_{10}	$PM_{2.5}$	TSP	PM_{10}	$PM_{2.5}$

UNPAVED INDUSTRIAL ROAD DUST CALCULATOR

Purpose

This spreadsheet was designed to assist with estimating the releases of NPRI substances from unpaved road dust. The substances of concern in this activity are TPM (Total Particulate Matter), PM10 (Particulate matter with aerodynamic diameter less than 10 µm) and PM2.5 (Particulate matter with aerodynamic diameter less than 2.5 µm).

Considerations on preparing unpaved road dust estimates

Due to the high degree of variability in the silt content measurements, applicability of weather observations to the site and many other similar influencing factors, it is generally accepted that these methodologies give orders of magnitude results for indicative purposes. In consideration of these factors it is expected that facilities estimating their releases will use average type information, not highly detailed daily traffic monitoring or other means to try and arrive at a theoretically precise emissions estimate.

How to Use the Estimation Tool

The reporting threshold for including TPM, PM10 and PM2.5 emissions from road dust is 10 000 Vehicles Kilometres Traveled (VKT) on unpaved surfaces within the facility in a given year. Before estimating emissions, check if you meet first the requirement of 10 000 VKT on unpaved surfaces within a facility per year.

This spreadsheet is used for the estimation of road dust emission from a given unpaved surface road within the facility. The calculation should be repeated for the other unpaved surface roads within the facility and the total emission should be obtained by summing the emissions from each unpaved segment road.

Cells highlighted in yellow are required values. Once you have entered all the required values you can view the generated adjusted emission factors and release estimates, which will appear in red bold font.

Since the NPRI reporting thresholds are for the facility as a whole, the air releases calculated from the unpaved road surfaces must be added to the NPRI releases from other sources (air releases) and activities at the facility.

Sources of Information

Emission factors are from the US EPA's AP-42 Chapter 13.2.2- Unpaved Roads (Industrial Roads). Last update November 2006. http://www.epa.gov/ttn/chief/ap42/ch13/index.html

Environment Canada Weather information website: http://www.climate.weatheroffice.ec.gc.ca/Welcome_e.html

Additional Information

Read the instructions under the tab "Instructions" for more information about the technical terms and simplifications about the reduction of dust emissions due to precipitation and other weather conditions.

The tab "Dust Control Methods" in the calculator includes corrections for a number of dust suppression methods.

The following instructions (and guidance) describe the data that is required on the "Facility Information" sheet

(There are additional instructions and guidance for use on other sheets. Please refer to each sheet for specific instructions)

Definition - Unpaved road

The common types of unpaved road surfaces include:

gravel road surfaces, thin membrane bituminous, surface treatments and bituminous cold mix surfaces.

If a dust suppressant is applied to an unpaved road, this segment of road is still considered unpaved road surface.

Note that winter roads, though classed as unpaved roads are made on frozen ground, snow and ice and typically have negligible dust emissions. Therefore winter roads will not be considered when reporting road dust to the NPRI.

Facility Information

Segment Road Length

It is the length in **km** of the segment road

Number of operating Days per Year

Enter the number of days (in the calendar year) that the traffic volume uses the road segment. If the volume is entirely different on the weekends, consider a second calculation for weekend traffic or add in the number of days which would be the equivalent number of days (eg. weekend traffic is generally 1/3 that of weekday traffic, there are 110 weekend days, equivalent days would be 110/3 or about 36 days)

Silt content

Use facility test data or representative test data from other sites. If this information is unavailable, please refer to the *Typical Silt Content AP-42* sheet reproduced from the US EPA. If roads are graded frequently this will generally change silt content on the running surface so a representative value must be chosen which will yield an average for the year. Do not use the silt content of the aggregate used in the construction of the road as due to compaction of the running surface - a significant proportion of this may not be available to generate dust.

Vehicle Class

Utilize general vehicle classes of similar Gross Vehicle Weight (GVW) ranges. The equations were developed for such and using specific weights will increase the reporting burden for little increase in accuracy.

If more than 20 classes of vehicles are being entered please contact the NPRI regional office.

Average daily traffic

The average daily traffic is the total count of vehicle passes over the segment roads per day. This value is used in the calculation of the fleet average weight and VKT calculation

Empty weight

The equations are based on the fleet average weight for all traffic. Estimate the typical unloaded weight for each class of vehicles which would include the fuel, equipment, operator, etc.

Full weight

The equations are based on the fleet average weight for all traffic. Estimate the typical loaded weight for each class of vehicles which would include the fuel, equipment, operator, etc. as well as the payload.

Mean weight
This is the calculated average weight of each vehicle class, considering the empty and full weights. This value will be used in the calculation of the fleet average weight.

Calculated VKT
Based on the road length, number of vehicles, the days of operation, the kilometres travelled by each class of vehicle. This calculation is used when the actual VKT is unknown.

Annual VKT from other methods
This section is used when the actual VKT value is known for each vehicle class, or estimated using an alternative method. This value can be obtained from odometer readings of the vehicles, actual annual vehicle counts or alternative methods. This value will be used preferentially over the Calculated VKT (it must be left empty if the Calculated VKT is used) in the calculation of the Fleet average weight and the Total VKT

Percentage of traffic on the segment road
This is the calculated percentage of traffic on the road based on the entered VKT information. This value will be used in the calculated of the weighted Fleet Average Weight.

W * P
This is the calculated Mean weight multiplied by the Percentage of Traffic on the road segment for use in the calculation of the Weighted Fleet Average Weight.

Annual Total Vehicle Kilometres Travelled on the segment road (VKT)
This is the sum of the Calculated and Actual VKT. If all of the formulas are properly in place there will be no duplication of information, please verify after entering information that everything is in place properly. This value will be used in the emissions calculation.

Wfleet: Fleet average weight for vehicle classes on the segment road (metric tonnes)
This is the calculated, weighted Fleet Average Weight considering the average vehicle weights and the VKT. This value will be used in the emissions calculation.

Precipitation

Means the sum of the rainfalls and snow falls.

Estimated working days when roads were frozen or snow covered and wet for Winter+Estimated working days with precipitation exceeding 0.2 mm

	2009		total	2010		total
Station	Days < 0 ℃	Precipitation>2mm (May to Sep)	days	Days < 0 ℃	Precipitation>2mm (May to Sep)	days

Vehicle Summary

Type of Vehicle	# of vehicle	Description	Using frequency
class 2 light duty	20	employee used vehicles	daily
class 2 light duty	7	management vehicles	daily
class 2 light duty	2 - 4	visitor's vehicles	daily in summer months
class 7 heavy duty	10 - 15	heavy equipment	daily
class 2 light duty	6	CH2M vehicles/truck	daily, Each vehicle made trip up and back to Town each day and made 2 to 4 trips on site.
class 2 light duty	2	CH2M sub vehicles	daily, Each vehicle made trip up and back to Town each day and made 2 to 4 trips on site.

TYPICAL SILT CONTENT VALUES OF SURFACE MATERIAL ON INDUSTRIAL UNPAVED ROADS

Industry	Road Use Or Surface Material	Silt Content (%)
Copper smelting	Plant road	17
Iron and steel production	Plant road	6
Sand and gravel processing	Plant road	4.8
	Material storage area	7.1
Stone quarrying and processing	Plant road	10
	Haul road to/from pit	8.3
Taconite mining and processing	Service road	4.3
	Haul road to/from pit	5.8
Western surface coal mining	Haul road to/from pit	8.4
	Plant road	5.1
	Scraper route	17
	Haul road (freshly graded)	24
Construction sites	Scraper routes	8.5
Lumber sawmills	Log yards	8.4
Municipal solid waste landfills	Disposal routes	6.4

Source:
http://www.epa.gov/ttn/chief/ap42/ch13/final/c13s0202.pdf

This information is provided for entry on the **Facility Information** sheet in the **Silt Content section**.

Site specific testing information should be used preferentially over these values if available.

This is the silt content of the loose material on top of the packed running surface of the road in the vehicle tracks., Generally no direct correlation to the silt content of the unpaved road strata.

RD_HAUL

ROAD SEGMENT TRAFFIC DETAILS

This calculation is done for a given unpaved segment road in the facility. If the facility has other segment roads, save the calculation for this given segment road and do the other calculations segment by segment. The meteorological data will remain unchanged.

Attachment 7A-2
CALMET and CALPUFF Parameters and Switches

TABLE 7A-2-1
Input Parameters for CALMET
Faro Mine Interim Works

Option	Parameter	Value	Explanation and Justification
Wind field model selection variable	IWFCOD	1	Use diagnostic wind module (allows 2-step approach)
Compute Froude number adjustment effects?	IFRADJ	1	Used to evaluate thermodynamic blocking effects of the terrain on the wind flow and are described using the critical Froude number
Compute kinematic effects?	IKINE	0	No, do not calculate a terrain-forced vertical velocity in the initial guess wind field DIVLIM, NITER and ALPHA do not need to be specified
Use O'Brien procedure for adjustment of the vertical velocity?	IOBR	0	No adjustment to the vertical velocity profile at top of model domain
Compute slope flows?	ISLOPE	1	Slope flow calculated as a function of sensible heat flux, distance to the crest or valley bottom, and slope angle
Extrapolate surface wind observations to upper layers?	IEXTRP	1	No surface wind extrapolations to upper layers
Extrapolate calm winds aloft?	ICALM	0	No surface wind calm extrapolation
Layer-dependent biases	BIAS	0	No bias of MM5 and surface winds
Minimum distance between upper air station and surface station for which extrap of surface winds will be allowed	RMIN2	4	
Gridded prognostic wind field model output fields	IPROG	14	MM5 Prognostic data introduced as initial guess field
Use varying radius of influence?	LVARY	F	No. Sparse surface data available.
Maximum radius of influence over land of the surface layer	RMAX1	10	
Maximum radius of influence over land aloft	RMAX2	50	
Maximum radius of influence over water	RMAX3	50	NA
Minimum radius of influence used in the wind field interpolation	RMIN	0.1	NA
Radius of influence of terrain features	TERRAD	5	
Distance from a surface station at which the station observations and first guess field are equally weighted	R1	1	
Distance from an upper air station at which the observation and first guess field are equally weighted	R2	5	
Relative weighting of the prognostic wind field data	RPROG	N/A	Not used
Maximum acceptable divergence in the divergence minimum procedure	DIVLIM	$5x10^{-6}$	Not used since IKINE = 0
Maximum number of iterations in the divergence min. procedure	NITER	50	Not used since IKINE = 0

TABLE 7A-2-1
Input Parameters for CALMET
Faro Mine Interim Works

Option	Parameter	Value	Explanation and Justification
Number of passes in the smoothing procedure	NSMTH	2	2 in lowest layer, 4 in higher layers
Maximum number of stations used in each layer for the interpolation of data to a grid point	NINTR2	99	Default
Critical Froude number	CRITFN	1	If Froude number is less than CRITFN, wind has an uphill component and direction is changed to be tangent to the terrain; If Froude number is greater than CRITFN, no adjustment is made
Empirical factor controlling the influence of kinematic effects	ALPHA	0.1	Not used since IKINE = 0
Multiplicative scaling factor for extrapolation of surface observations to upper layers	FEXTR2	N/A	Not Used
Number of barriers to interpolation of the wind fields	NBAR	0	Not Used
X and Y coordinates of barriers	XBBAR, YBBAR, XEBAR, YEBAR	N/A	Not Used
Diagnostic module surface temperature option	IDIOPT1	0	Usually surface temperatures are computed internally
Diagnostic module sfc. met station to use	ISURFT	-1	Default
Diagnostic module domain-averaged lapse rate option	IDIOPT2	0	Usually lapse rate computed internally.
Diagnostic module upper air station to use for lapse rate	IUPT	N/A	Not Used
Depth through which the domain-scale lapse rate is computed	ZUPT	N/A	Not Used
Initial guess field wind components	IDIOPT3	0	Usually computed internally from upper air observations
Upper air station to use for domain-scale winds	IUPWND	N/A	Not Used
Bottom and top of layer though which the initial guess winds are computed	ZUPWND	N/A	Not Used

TABLE 7A-2-2
Input Parameters for CALPUFF
Faro Mine Interim Works

Option	Parameter	Value	Explanation & Justification
Vertical distribution used in the near field	MGAUSS	1	Gaussian
Terrain adjustment method	MCTADJ	3	Partial plume path adjustment (allows plume penetration into elevated inversions)
Sub grid-Scale complex terrain flag	MCTSG	0	Usually 0, but allows for CTDM-like treatment of sub grid-scale hills
Near-field puffs modelled as elongated?	MSLUG	0	Slug model not used
Transitional Plume Rise modelled?	MTRANS	1	Yes, transitional rise computed
Method used to simulate building downwash?	MBDW	1	No downwash used, area sources only
Stack-tip downwash?	MTIP	1	Not used
Vertical wind shear modelled above stack top?	MSHEAR	0	No, vertical wind shear above stack top not modelled; if this option is chosen, a power law wind speed extrapolation is done above stack top
Puff splitting allowed?	MSPLIT	0	No, splitting not allowed
Chemical Transformation Scheme	MCHEM	0	Chemical transformations not modelled
Aqueous phase transformation flag (only used if MCHEM = 1 or 3)	MAQCHEM	0	Aqueous phase not modelled
Wet removal modelled?	MWET	0	Deposition was not modelled
Dry deposition modelled?	MDRY	0	Deposition was not modelled
Methods used to compute dispersion coefficients	MDISP	3	PG dispersion coefficients; default
Sigma measurements used?	MTURBVW	N/A	Used only if MDISP = 1 or 5
Back-up method used to compute dispersion when measured turbulence data are missing	MDISP2	N/A	Used only if MDISP = 1 or 5
PG sigma y,z adjusted for roughness	MROUGH	0	Default
Partial plume penetration of elevated inversion?	MPARTL	1	Yes, partial plume penetration; default
Strength of temp inversion provided in PROFILE.DAT extended records?	MTINV	0	Typically computed from measured/default gradients; depends on whether PROFILE.DAT contains extended records
Probability Distribution Function used for dispersion under convective conditions?	MPDF	0	No, default
Sub-grid TIBL module used for shore line?	MSGTIBL	0	Not used
Boundary conditions (concentration) modelled?	MBCON	0	Boundary concentrations not modelled
Configure for FOG Model output?	MFOG	0	FOG model usually not run unless condensed plume assessment is required
Test options specified to see if they conform to regulatory values?	MREG	0	No checks made regarding conformity to USEPA values

SECTION 1

Introduction

This appendix presents the methodology and results for the near-term (January 2014 through December 2023) prediction of water quality discharged from the Faro Mine Complex (FMC). The following water quality parameters relevant to the aquatics effects assessment were chosen for this evaluation (Minnow, 2014a):

- Hardness (calculated using calcium [Ca] and magnesium [Mg])
- Cadmium (Cd)
- Cobalt (Co)
- Lead (Pb)
- Manganese (Mn)
- Sulphate (SO_4)
- Zinc (Zn)

Results are presented in terms of percentiles from a range of stochastic simulations, and show the likelihood of having concentrations exceeding guideline values at the following key locations (presented in Figure 7B-1):

- North Fork Rose Creek (NFRC) upstream from North Fork Rock Drain (NFRD) at NF1
- North Fork Rose Creek upstream from mine access road at X2
- Rose Creek below confluence of South and North Fork Rose Creek at X3A
- Rose Creek downstream from mine site discharges at X14
- Rose Creek upstream from confluence with Anvil Creek at R4
- Anvil Creek downstream from confluence with Rose Creek at R5
- Anvil Creek near confluence with Pelly River at A1
- Pelly River downstream from Anvil Creek at P4
- Vangorda Creek upstream from confluence with Pelly River at V8

The near-term water quality predictions presented in this appendix assume that the recent concentration trends will remain the same for the next 10 years; therefore, whenever a trend in water quality was verified, it was extrapolated for 10 years. The assumptions presented in this document were conservative. More accurate predictions of water quality will be possible when results from ongoing modelling efforts (geochemistry, groundwater and surface water) are concluded to support the development of the Faro Mine Remediation Plan (FMRP), yielding a better understanding of the generation of loads from waste rock dumps and the processes that might attenuate those loads before they reach streams.

Recent surface water quality data for the NFRC and Rose Creek indicate an increase in zinc concentration in late 2013, likely originating in the area of NFRD. This deterioration may be due to a change in seepage water geochemistry from a nearby waste rock dump. The modelling work described in this appendix does not include this recent change in water quality as it is assumed that this development will be addressed through Adaptive Management processes and the new source will be managed to remove its impact on NFRC. Hence, the trends in water quality for the NFRC predicted by this model will include only longer-term trends observed for this reach of the creek and not the shorter-term influx of contamination observed starting the winter of 2013.

As presented in *Assessment of Effects of the Faro Mine Interim Works on Surface Water Quality and Resulting Effects on Fish and Fish Habitat* (Minnow, 2014a), none of the above water quality parameters are likely to be above guideline thresholds at the most downstream location (P4). However, consistent with past results, predictions indicate that certain parameters at some locations upstream of P4 in the Rose Creek, Anvil Creek, and Vangorda Creek drainages may exceed the determined guidelines.

SECTION 2

Background

The overall water modelling objective is the prediction of the effects of the Interim Works on water quality in the receiving environment; these predictions will be used in the environmental assessment for the project.

The model predicts water quality at key locations in the aquatic receiving environment as a result of the contaminant loads from the FMC, specifically seepage from the waste dumps and the Rose Creek Tailings Area (RCTA), and the discharge of treated water from the Interim Works Treatment System and Vangorda Water Treatment Plant (WTP). This model was developed using a similar framework to that being used for the long-term model currently under development to support the ongoing closure planning process (CH2MHILL, 2013a), with differences in the approach used for waste rock source terms: the Interim Works version of the model fixes source load concentrations at key mine locations based on actual site conditions and current trends in seepage water quality. A detailed description of this adapted model version is presented in Section 5, Model Assumptions.

A key challenge in predicting water quality at the FMC stems from the high level of uncertainty about the waste dump seepage water quality over time and hydrological variability. The uncertainties are addressed in the model with the use of stochastic elements in GoldSim, which are described in detail in Section 5.

The long-term model was refined as follows for the Interim Works modelling effort:

- Refined the water balance components on the Vangorda/Grum Area, a task not yet completed for the long-term model
- Compared historical model results against measured data (pit elevations, flows and water quality for key chemical constituents)

Fixed key water quality parameters at model boundaries based on recent measured water quality values. In this Report, Section 3, Methodology, describes in detail how water quality concentrations for the next 10 years were estimated. Section 4, Input Data, describes the available data used to calibrate the model water balance and to support the development of the water quality trends and estimates of uncertainty. Section 5, Model Assumptions, describes the flow and water quality assumptions. Section 6, Calibration, describes the calibration process for various model components. Finally, Section 7, Results, summarizes the model results; additional analysis and interpretation of these results is presented in Prediction of Water Quality Effects, Faro Mine Interim Works Minnow (2014a).

SECTION 3

Methodology

The study methodology is divided into three separate but connected elements: system representation, system flows, and system water quality. Section 3.1, System Representation, illustrates how the model elements are connected, including how catchments and waste dumps are connected and how and where they drain through the system. Section 3.2, System Flows, describes the procedures used to account for all the flow components that could affect water quality. Section 3.3, System Water Quality, describes the procedures used to estimate future water quality based on observed concentrations at key locations and changes in the recent past.

3.1 System Representation

The adapted FMC GoldSim model v2 predicts flows and water quality conditions for three sub-areas within the FMC:

1) Anvil Creek and Rose Creek drainages downstream of the FMC
2) Vangorda Creek drainage downstream of the Vangorda/Grum Area
3) Pelly River between its confluences with Vangorda Creek and Anvil Creek and immediately downstream of Anvil Creek.

The Faro Mine Area drains to the Pelly River via Rose Creek and then Anvil Creek, whereas the Vangorda/Grum Area drains to the Pelly River via Vangorda Creek. The Pelly River downstream of the Anvil Creek confluence is the farthest downstream model prediction point (Figure 7B-1). Figure 7B-1 also presents the site-wide stream network, key locations for which historical flow and water quality data are available, locations of the Faro and Vangorda/Grum Areas, and names of the major streams considered in the model.

Figures 7B-2 and 7B-3 provide more detail, showing the Faro and Vangorda/Grum Areas, respectively, along with modelled catchment boundaries and the waste dump configurations. Pre-mining topography of the mine site was used to delineate model catchment for waste dump/groundwater seepage through the system. Current site topography defines the routing of surface water runoff and flows.

Figure 7B-2 shows eight catchment areas within the Faro Mine Area, and Figure 7B-3 shows five catchment areas within the Vangorda/Grum Area, all represented in the FMC GoldSim model v2. The modelled catchments associated with the Faro Mine Area are as follows:

- Faro Main Pit (MP)
- NFRC
- Zone II (ZII)
- Catchment that drains to the X2 monitoring location (X2)
- Rose Creek Valley (RCV)
- Upper Guardhouse (GHU)
- Lower Guardhouse (GHL)
- RCTA, also referred to as Down Valley Tailings (DVT) Area

The modelled catchments associated with the Vangorda/Grum Area are as follows:

- Catchment that drains to the V1 monitoring location (V1)
- Catchment that drains to the V27 monitoring location (V27)
- Catchment that drains to the V8 monitoring location (V8)
- Vangorda Pit
- Grum Pit (GP_Area)

The proportion of waste dump seepage that reports to the modelled catchments is outlined in Table 7B-1 for the Faro Mine Area and Table 7B-2 for the Vangorda/Grum Area. Figure 7B-4 illustrates the general routing of flows through the system from the waste dump or contaminated site to the downstream receiving environment.

Figures 7B-5 and 7B-6 depict the general geographic connectivity of the elements included in the GoldSim model v2 for the Faro and Vangorda/Grum Areas, respectively, whereas Figures 7B-7 and 7B-8 show a more-detailed model schematic including connections among catchments, storage elements, and collection systems, including seepage interception systems(SIS), in the GoldSim model v2. Figures 7B-7 and 7B-8 are referred to as "model schematics" and illustrate the overall direction of flows in the system.

Figures 7B-7 and 7B-8—together with Tables 7B-1 and 7B-2— graphically depict how catchments, flows, waste dumps, and WTP operations could affect the receiving environment. For example, Table 7B-1 shows that 83 percent of the Intermediate Dam (ID) Waste Dump is in the X2 catchment and Figure 7B-7 shows that the X2 catchment has a direct contribution to the receiving environment. On the other hand, a waste dump contained in the MP catchment (e.g., Faro Valley North) will have to flow to the Faro Pit first, then to the WTP where it will be treated, then discharged to the CVD Pond and finally discharged to the environment at X14. Figures 7B-7 and 7B-8 show the catchments that are contributing and eventually affecting water quality concentrations for the receiving environment in the Faro Mine Area and Vangorda/Grum Area respectively. System Flows

The system flows are generated from Hydrological Effective Precipitation (HEP) values, which are expressed in millimetres (mm) per year and defined as the total annual precipitation minus losses to satisfy the soil moisture deficit and evapotranspiration (Younger et al., 2002). HEP values were estimated in previous FMC reports (RGC, 1996; AECOM, 2009) and the values obtained for the FMC catchments are based on a regional analysis comparing HEP and elevations. Several HEP values were estimated for the FMC based on the correlation curve between HEP and elevation developed by RGC (2009) and the different median elevations of the FMC drainage catchments. The catchments and correspondent values for HEP, Area, and Average Annual Flow Volume are presented on Table 7B-3.

The HEP values were developed for average precipitation conditions, and the model scales them up or down proportionally to the annual precipitation used in each stochastic run. The current closest and best precipitation record available is from the Faro Airport Station. The Faro Airport Station is located approximately 14 kilometres (km) from the Faro Valley Waste Dump area at an elevation of 717 metres (m), approximately 457 m lower than the FMC. The monthly precipitation data are presented in Section 4. The assumptions regarding the use of this dataset, including the adjustment of precipitation based on elevation, are presented in Section 5.

Annual average flows from catchments are estimated by multiplying the HEP value by the catchment area and the precipitation scale adjustment as presented in Equation 1, as follows:

$$1. \quad Q=A*HEP*coef$$

where:

Q = total annual flow from unimpaired area (seepage plus runoff) (cubic metres [m^3]/year)
A= total area of the unimpaired catchment (square metres [m^2])
HEP = HEP value for the catchment (m/year)
coef= coefficient that adjusts the HEP based on the current annual precipitation, or the annual precipitation (Faro or Vangorda) divided by 357 mm for catchments in the Faro Mine Area and 369 mm for catchments in the Vangorda/Grum Area (unitless)

For the waste dump areas, it was necessary to separate the seepage and runoff components of the HEP. Sections 3.2.1 and 3.2.2 describe the equations used to estimate the seepage and runoff annual average flows. Section 3.2.3 describes how the annual average flows are converted to monthly average flows.

Once flows were generated at the model boundaries (model boundaries represented as undisturbed catchments and waste dumps), flows are routed through the system. The flow through the system is mainly determined by seepage collection systems efficiency (when available), pump and reservoir operations, and water treatment season and capacity. A more detailed description of the flow routing from upstream to downstream is presented in Section 5.

3.1.1 Seepage

Annual seepage volume is calculated as a function of waste dump area, precipitation, and an infiltration factor that converts precipitation into seepage (function of the cover type). Seepage volumes from each waste dump were computed according to Equation 2, as follows:

$$2. \quad S_{w,c} = A_w * D_{w,c} * I_w * P$$

where:

$S_{w,c}$ = total annual seepage for waste dump "w" located in catchment "c" (m^3)
A_w = total area of waste dump "w" (m^2)
$D_{w,c}$ = fraction of waste dump "w" that drains to catchment "c"
I_w = infiltration factor for waste dump "w" (unitless, 0 to 1 depending on the waste dump cover type)
P = annual precipitation (m)

Seepage volumes generated by the waste dump sources are grouped by catchments, and a monthly factor is applied to the aggregated runoff to distribute the annual volumes into monthly flows. The seepage is then routed through the system according to operational assumptions.

3.1.2 Surface Runoff

The system runoff is computed as a function of the infiltration factor used in Equation 2 to compute seepage and the HEP value for each catchment. The surface runoff is computed according to Equation 3, as follows:

$$3. \quad R_{w,c} = A_w * D_{w,c} * (HEP_c - I_w * P)$$

where:

$R_{w,c}$ = total annual runoff for waste dump "w" located in catchment "c" (m^3)
HEP_c = annual HEP for catchment "c" (m entered as mm in the model)

Waste dumps are then grouped by catchments and a monthly factor is applied to the aggregated runoff to distribute the annual flows into monthly flows. The total annual runoff for a waste dump can also be described as the total annual HEP minus the total annual seepage computed for a specific waste dump within a specific catchment.

The sum of the annual volumes from Equations 2 and 3, plus the boundary condition flows, represent all the inflows to the modelled system and are balanced with all computed outflows, change in storage volume, or losses from the system for a given time step.

3.1.3 Monthly Flow Patterns

The annual average runoff and seepage flows from undisturbed and waste dump areas are converted into monthly flows by monthly flow patterns, or distributions, representing fractions of the annual volume. Several monthly flow patterns are used in the model depending on the location where the flows are being generated and depending if the flows are runoff or seepage. The following bullets provide a description of how the monthly flow patterns were generated. Figures 7B-1, 7B-2 and 7B-3 show the locations of the places described in this subsection; Table 7B-4 presents the actual patterns as a fraction of the annual volume.

- Faro Surface: This monthly flow pattern was developed from historical flows at R7 and it is applied to NFRC inflows, Upper Faro Creek flows, and runoff flows originating from waste dumps located in the X23, RCV, Upper and Lower Guardhouse, Faro Pit, X2, and NFRC catchments.
- Faro WR Seep: This monthly flow pattern was developed based on the assessment of historical flows measured at X23, a well-defined seep at the toe of the Main dump. This distribution is applied to seepage flows originating on waste dumps located in the X23, RCV, Upper and Lower Guardhouse, Faro Pit, X2, ZII, and NFRC catchments.

- Rose Creek: This monthly flow pattern was developed from historical flows at X14 and it is applied to the runoff and seepage from the RCTA area, Upper South Fork Rose Creek (SFRC) and SFRC, flows from the catchment between Anvil Mouth and R4, and flows from the Upper Anvil catchment.
- Rose Creek R4: This monthly flow pattern is similar to the Rose Creek pattern but with attenuated peaks during the freshet months and increased baseflow during the winter months. The pattern was developed using a calibration parameter for the sulphate dilution measured between X14 and R4 and is described in Section 6. This pattern is applied to the flows originating between X14 and R4.
- Vangorda Surface: This monthly flow pattern was developed from historical flows at V8 and it is applied to all creek and surface water flows in the Vangorda/Grum Area except for flows originating at the Vangorda Waste Dump.
- Vangorda WR Seep: This monthly flow pattern was developed from flows measured at the toe of the Grum Dump and it is applied to all seepage flows in the Vangorda/Grum Area except for the Vangorda dumps.
- Little Creek Dam LCD): The monthly flow pattern was developed from estimated inflows into Little Creek Dam and it is applied to all seepage and runoff flows from the Vangorda dumps that drain into LCD.

Monthly flow patterns are important model parameters as they represent the seasonal variations in the magnitude of expected flows during a year, which directly affects the water quality results.

3.2 System Water Quality

The methodology applied to estimate near-term water quality concentrations for the FMC takes into account recently measured water quality concentrations and trends at key locations of the FMC. In this case, 'near-term' refers to the period over about the next 10 years and 'recent' indicates up to the past 9 years, but is generally limited to the past 5 to 6 years. As Section 3.3.2 describes, the period used to fix water quality for each of the source terms was selected based on operational (e.g., S-Wells began to operate in 2009), or data quality considerations. Available water quality concentrations from the key locations were used to generate monthly water quality patterns, incorporating observed trends, where applicable, to represent source terms in the model. Water quality was predicted for the duration of the Faro Mine Interim Works (IW) (2014 through 2023) at key locations in the aquatic receiving environment within and downstream of the FMC. Locations within the model where water quality was predicted include: NF1, X2, X3A, X14, R4, R5, A1, P4 and V8. Based on the analysis performed in the *Aquatic Baseline Characterization Report, Faro Mine Interim Works* (Minnow, 2014b), the following eight constituents of concern (COCs) were identified as the key water quality parameters the model would be used to predict: Ca, Cd, Co, Mg, Mn, Pb, SO_4, and Zn. Hardness is calculated from the predicted Ca and Mg concentrations.

At specific source locations, the water quality concentrations were fixed with a monthly time-series from January 2013 to January 2024 (a longer period than the period reported in the results from January 2014 to December 2023), reflecting the observed monthly pattern and annual trend, if any, to represent the near-term site conditions.

The term "fixed" is used to describe water quality for some of the source locations. The term means that a fixed time-series was developed that includes a monthly pattern and an annual trend, if the available data exhibited a trend.

The fixed time-series of concentrations used as model inputs were created using a four-step process. First, the locations where fixed water quality was applied were chosen based on their potential to impact the receiving environment. Second, monthly patterns for the concentrations were created based on recent observed data. Third, an Ordinary Least Square (OLS) fitting procedure was used on annual concentration values to determine if there were any trends in the concentrations at the defined locations where water quality is fixed. The OLS fitting procedure was then confirmed with a more robust statistical test described under Section 3.3.3.1. Finally, monthly variability was applied to the trended time-series based on the variability observed in the recent past. The following sections explain in detail each one of these four steps.

3.2.1 Locations where Water Quality was fixed

Water quality source terms are fixed at the following three locations within the Faro Mine Area:

- Rose Creek Alluvial Aquifer (RCAA) underlying the RCTA
- S-Wells bypass discharge to NFRC
- Groundwater discharge to NFRC from waste dumps upstream of the Haul Road

Water quality discharge from the Faro WTP is also fixed. The Faro WTP discharge water quality used as model input was generated from expected future performance and past performance. Specifically, concentrations of As, Cu, Ni, Pb, and Zn in the Faro WTP discharge were fixed to expected future WTP performance. Concentrations of Ca, Co, Mg, Mn, and SO_4 were fixed based on water quality in Cross Valley Dam Pond (CVD Pond) discharge (X5) between 2011 and 2012. This period was chosen because site operations changed in 2011, which resulted in shifts in CVD Pond water quality. Concentrations of Cd were also fixed based on water quality in the X5 discharge. Cd concentrations in the CVD Pond were conservatively assumed to be unimpacted by operational changes discussed; therefore, the maximum observed concentration between 2002 and 2012 was selected to represent Cd discharge to Rose Creek. Data through 2013 was not included, because the CVD Pond had been operated differently during the summer of 2013 (i.e., it did not receive inflow of lime-treated effluent). The 2013 site operations are expected to be unique to 2013 and do not represent future conditions.

During the latter part of 2013, elevated Zn concentrations were identified in Rose Creek, sourced from the vicinity of the Haul Road. Beyond incorporating observed trends from groundwater discharge to NFRC from waste dumps upstream of the Haul Road through 2012, these recent Zn concentration increases are not included in model water quality input since it is an unforeseen deviation from current trends and currently being addressed through adaptive management. Additional discussion and consideration of these elevated Zn concentrations and associated potential effects on the receiving environment are presented in Minnow (2014a) and Chapter 6.1 of the *Faro Mine Interim Works Project Proposal* (CH2M HILL, 2014).

For the Vangorda/Grum Area, water quality source terms are fixed at the following seven locations:

- Shrimp Creek (V4)
- Sheep Pad Ponds (V25 BSP)
- V15 (seasonally collected Grum Waste Dump Runoff and Seepage)
- Grum Waste Dump runoff (uncollected)
- Grum Waste Dump seepage (uncollected)
- Vangorda Waste Dump (runoff and seepage)
- West Fork Vangorda Creek (V5)

The discharge water quality from the Vangorda WTP is also fixed. Vangorda WTP discharge quality used as model input was generated from expected future performance and measured past performance.

Table 7B-5 presents the locations and the period of record used to fix water quality. Figures 7B-2 and 7B-3 present the locations referred to in Table 7B-5**.** Table 7B-6 presents the median and maximum water quality for the Faro Interim Works Treatment System and Vangorda WTP discharges, along with discharges downstream of the WTPs from the CVD Pond at X5 and from Sheep Pad Ponds at V25 BSP.

Runoff and seepage from waste dumps located in catchments other than the X2 and NFRC catchments (Figure 7B-2) either report to an intermediate area where water is collected and routed for treatment (e.g., X23 and GDL Waste Dumps drain to ID Pond and MP Waste Dump drains to Faro Pit), or have gradual geochemical changes that are not expected to cause appreciable increases in contaminant loading during the period of the IW (e.g., GHU to Upper Guardhouse Creek).

The GHU Waste Dump catchment (Figure 7B-2) was assigned a background water quality, specifically seepage water quality was assigned based on background groundwater quality (monitoring well TH86-17). Water from the GHU catchments flows to the receiving environment at X14.

Waste dumps located in the GHL, X23 and MP catchments (Figure 7B-2) have also been assigned a background water quality based on background groundwater quality represented by monitoring well TH86-17. These waste dumps are located at areas internal to the Faro Mine Area, which means that the water from these catchments is collected for treatment prior to being released. Collected water from these waste dumps is accounted for in WTP discharge volumes and loads. This simplifying assumption is considered a reasonable approach that does not impact the predicted water quality for the short duration of the IW. This approach was used since load that by-passes collection is expected to require longer travel time for break-through to the receiving environment than the duration of the IW.

Runoff from all waste dumps is assigned a water quality equal to 10 percent of the seepage water quality. The 10 percent of seepage water quality is a simplified assumption used in the long-term model and based on previous water quality observations

Background surface water quality data was generated from reference stations V1, VR, USFR, R7, FC, R6, and W10 (Figure 7B-1) from 2008 through 2012, with pooled background water quality from these stations applied as background surface water quality input at the same locations represented in the model. Key background water quality parameters (mean, minimum, and standard deviation) used as model inputs are consistent with the background reference conditions determined in the Minnow (2014b) and are presented in Table 7B-7.

Background groundwater quality data is generated from the available data from 2004 through 2012 at monitoring well TH86-17, located upgradient of the RCTA.

3.2.2 Water Quality Monthly Patterns

Monthly water quality patterns were developed because the surface water (and, to a lesser extent, groundwater) at the FMC, exhibits monthly and seasonal water quality variation in response to changes in stream discharge, loads from mined material, and WTP discharge. Monthly concentration patterns were developed using the available data from the period of interest for each source term. The period used to fix water quality for each of the source terms is indicated on Table 7B-5. The period used for each source term is based on operational considerations (e.g., S-Wells began operation in 2009), or data quality considerations. Data quality considerations included data gaps or elevated detection limits in historical data. Where data quality issues affected monthly or annual source term water quality, the selected period relied on more recent data (i.e., since 2008 or 2009). Where the period was focused to more recent data, it was done to provide data more representative of current conditions and provides for more conservative estimates of future water quality. Using the commercial software package Tableau (Version 8.0.5, www.tableausoftware.com), the median monthly concentration for each COC from all years within the selected period of interest was selected from the time-series. Figures 7B-9 to 7B-19 present the monthly pattern for the key water quality parameters at the eleven source term locations.

The water quality monthly pattern for each fixed surface water location is generated from a single site location (e.g., Shrimp Creek input water quality generated from measurement data collected at V4). For surface water locations, the spatial scale at which the hydrology data and water quality data are measured is the same. Source terms used to represent groundwater quality discharge to the receiving environment rely upon multiple monitoring locations (Table 7B-5). Water quality data from the group of monitoring locations is pooled and then a median monthly value is selected from the pooled time-series. Multiple locations are grouped to generate an average water quality value to represent water quality over the broad areas the source term represents in the model. For these locations, the hydrology component is generated based on the catchment area; however, at a different spatial scale over which water quality data is collected.

While grouping the data is intended to provide a representative average water quality over the source term area, the water quality likely overestimates the concentrations over the broad area of interest because the groundwater monitoring wells have been installed to target areas receiving deteriorated water from the waste dumps. They will therefore have bias to identifying areas with the highest concentrations, and applying this over the broad area for which the hydrology component of the model applies. This approach provides a conservative estimation of load from the source area to the receiving environment.

As will be discussed in greater detail in Section 4, there are data limitations to developing a monthly pattern at the source term locations. For months without data or with a minimal sample size, an average value of the median monthly concentration from adjacent months is used instead. Sparse data limits development of monthly patterns for groundwater source terms more than for surface water source terms.

3.2.3 Water Quality Trends

Observed site water quality data through 2012 was used in the development of annual water quality trends. The input water quality time-series, beginning January 2013, was developed based on the annual trend applied to the monthly pattern. The median annual concentration was selected from the compiled time-series for each source term location. The annual concentration is selected to reflect long-term changes in water quality. Using the Tableau software package, a linear regression model is applied to the median annual concentration for all years within the selected period of interest for each time-series. The software package uses an OLS fitting procedure to develop a linear trend line for each key water quality parameter at all 11 source term locations.

This linear trend is projected (beginning in 2013 and extending over the 10-year duration of the IW) to develop the source term water quality input concentration time-series. The projected annual concentration increases are added to the monthly pattern to create an input time-series that includes both a monthly pattern and annual trend. The annual trend is directly applied to the individual months. For example, if there is a 0.025 mg/L annual increase for Zn and the initial January concentration is 0.10 mg/L and February concentration is 0.12, Year 2 January concentration is 0.125 mg/L and February concentration is 0.145 mg/L. If no trend is determined from the historical data, or if the trend indicates decreasing concentrations, the median monthly pattern developed is applied consistently to each year of the source term input water quality time-series. Decreasing trends are not applied to the input water quality time-series. Additional discussion about the inclusion of trends is provided in Section 3.3.4.

Projecting the linear trend into the future relies upon the principal assumptions that recent observed changes in water quality data will represent near-term future water quality changes and that fitting the observed data to a linear trend, as opposed to, for example, a power-series, is representative of field conditions. This ignores potential non-linear changes such as would happen if the attenuation capacity for a specific constituent was exceeded or from changes in response to depletion of neutralizing potential that had previously been buffering geochemical changes. Future water quality changes inconsistent with recent observed trends will not be predicted by this model. Instead, those types of changes will be identified through routine environmental monitoring programs during the IW and managed through the Adaptive Management Plan in response to specific changes identified during monitoring.

Figures 7B-20 to 7B-30 present the annual trend for each COC for all source term locations. Table 7B-8 summarizes the parameters for each source term for which trends are applied based on the observed data.

3.2.4 Seasonal-Kendall Statistical Test

The Tableau software package used to reduce the data and generate model inputs includes limited statistical analyses capability. Following the development of the annual trend using the OLS fitting procedure, a check was made on the statistical significance of the trend direction. The Seasonal–Kendall statistical test (Hirsch et al., 1982) was selected to test whether the apparent trend direction applied to the model water quality inputs was statistically significant. The Seasonal-Kendall test was performed in the statistical analyses software package SAS.

The Seasonal-Kendall test is similar to the more commonly known Mann-Kendall test and was used because it appeared that there are seasonal changes in the data, which can be better accounted for by the Seasonal-Kendall test. The Seasonal-Kendall test ranks each value relative to other values in the sample-set to develop relationships for whether the value is higher or lower; the magnitude of the difference is not considered in whether there is an increasing or decreasing trend. To conduct the Seasonal–Kendall statistical test, the observed data time-series was regrouped from median annual averages to seasonal averages; the three seasons used to group the data are consistent with the three hydrology seasons identified for the FMC (i.e., freshet – May and June, Open Water – July to October, and winter – November to April). Grouping the data on a seasonal basis also provides a more appropriate number of values to conduct the analyses on, as compared to the annual trends considered in

development the water quality model inputs. Table 7B-8 compares the trend direction currently applied to the water quality inputs to the trend direction using a Seasonal-Kendall statistical test.

For all except Co at V15 and Cd at V5, the trends used in the water quality model inputs are more conservative in the trend direction. That is, for trends that are not the same direction, the model input trend is either increasing when the Seasonal–Kendall statistical test indicates that there is no significant trend or there is no model input trend when the Seasonal–Kendall statistical test indicates a significant decreasing trend. For Co at V15 and Cd at V5, the model input has no trend, which contrasts with the Seasonal–Kendall statistical test indicating a significant increasing trend. The model input at V15 represents a collected water source (water conveyed to Vangorda Pit) and does not affect the receiving environment. The increasing trend for Cd at V5 (West Fork Vangorda Creek), would increase the concentration by approximately $2x10^{-6}$ milligrams per litre (mg/L) per year and would therefore not appreciably change the load received at V8.

Based on the data grouping, there were insufficient independent values to calculate the statistical significance of identified trends at X5 (using data from 2011 and 2012 only).

The results of the comparison are consistent with the original approach of relying on increasing trends where observed and on average concentrations in the absence of an apparent increasing trend. Including trends, even if they are not statistically significant, is considered a conservative approach because the modelled key water quality parameters are expected to increase with time. The timing and magnitude of the increases are uncertain; regardless, including a trend, whether statistically significant or not, will add some conservatism to the prediction.

The following paragraphs summarize the comparison presented in Table 7B-8 for each area where water quality is fixed. Locations V15 and LCD are shown on Table 7B-5, however since these represent water quality of collected water conveyed to the Vangorda Pit, they are not described in detail.

RCAA

The Seasonal–Kendall test on the pooled monitoring locations concludes that the key water quality parameters have no statistically significant trend (increasing or decreasing), except for Ca and SO_4. If only the seep at X13 is considered, there is statistically significant increase in all COCs except Pb. The initial OLS approach from the group of monitoring locations (Table 7B-5), which includes increasing trends for Ca, Cd, Co, Mg, SO_4 and Zn, was selected to form the model water input, as this provides a more conservative estimate of mine-influenced water quality from the RCAA, which is expected to continue to degrade over time. The water quality input trends for RCAA match trend directions at X13 (X13 S-K column in Table 7B-8) more closely than for the pooled collection of wells.

S-Wells

The trend direction (no trend) from the two approaches is the same for Pb and SO_4. For the trends developed from the OLS approach, all parameters (except Cd, which is increasing) demonstrated no trend. The Seasonal–Kendall test indicates that the concentrations of Ca, Co, Mg, Mn, and Zn have been following a statistically significant decrease and concentrations of Cd, Pb and SO_4 have no trend. Since 2009, the implementation of the S-Wells collection system continues to have a beneficial effect, reducing loadings. However, it is optimistic to assume that the loads will continue to decrease in the S-Wells area over the duration of the IW. A more conservative approach is to not apply a trend for the parameter concentrations that are indicated to be decreasing, and apply an increasing trend for Cd, as determined from the OLS approach.

NFRC

Consistent with the OLS, the Seasonal–Kendall test demonstrates significantly increasing trends for Ca, Mg, Mn, SO_4, and Zn and no significant trend for Pb. The Seasonal–Kendall test indicates Cd (conservatively included in the model water quality inputs with a constant monthly pattern) is significantly decreasing. The Cd decrease is suspected to be related to absence of data from sampling locations BH2 and BH4 in the Zone II Outwash area over the last couple of years, which apparently has a greater effect on the Seasonal–Kendall test than the OLS. These two locations previously demonstrated the highest Cd concentrations. Co is conservatively included in the model water quality inputs with an increasing trend, rather than applying no trend, as suggested by the Seasonal–Kendall test, as this provides a more conservative prediction of water quality impacts.

V4 (Shrimp Creek)

The Seasonal–Kendall test indicates the increasing trend observed in the SO_4 data is significant, which is consistent with the conclusion reached from the OLS approach. The Seasonal–Kendall test indicates a significant decreasing trend for Cd and Co. Cd and Co are conservatively included in the model water quality inputs with a constant monthly pattern. Based on the OLS approach, the water quality model input for Ca, Mg, Mn, Pb, and Zn includes increasing trends, whereas the Seasonal-Kendall test indicates no statically significant trend.

V25BSP (Below Sheep Pad Pond)

The Seasonal–Kendall test indicates that there is no significant trend in the Ca, Cd and Co data, which is consistent with the conclusion reached from the OLS approach. The Seasonal–Kendall test also indicates no significant trend for Mg, Mn, Pb, SO_4, and Zn; however, these constituents are conservatively included in the model water quality inputs with an increasing trend, based on the OLS approach.

Grum Waste Dump runoff

The Seasonal–Kendall test indicates that there is no significant trend in the Ca, Pb, and Zn data, which is consistent with the conclusion reached from the OLS approach. The Seasonal–Kendall test also indicates no significant trend for Cd, Co, Mg, Mn, and SO_4; however, these constituents are conservatively included in the model water quality inputs with an increasing trend, based on the OLS approach.

Grum Waste Dump seepage

The Seasonal–Kendall test indicates the increasing trend observed in the Co, Mn, Pb, and Zn data is significant, which is consistent with the conclusion reached from the OLS approach. The Seasonal–Kendall test also indicates no significant trend for Cd consistent with the OLS fitting procedure. The Seasonal–Kendall test indicates a significant decreasing trend for Ca, Mg and SO_4; however, these constituents are conservatively included in the model water quality inputs with a constant monthly pattern.

V5 (West Fork Vangorda Creek)

The Seasonal–Kendall test indicates that there is no significant trend in the Co, Mn, Pb, and Zn data, which is consistent with the conclusion reached from the OLS approach. The Seasonal–Kendall test indicates no significant trend for Ca, Mg and SO_4; however, these constituents are conservatively included in the model water quality inputs with an increasing trend, based on the OLS approach.

3.2.5 Water Quality Uncertainty

Because the input water quality source terms are derived from median concentrations, a procedure to incorporate the observed variability was included. The minimum, median, and maximum concentration for each month for all key water quality parameters from the observed data at the source term locations was identified and used in the monthly variability computation. A triangular distribution was developed based on the minimum, median, and maximum concentrations for all key water quality parameters at each source term location.
A minimum +-10 percent variability was assigned to locations, months, and water quality parameters that did not have enough historical data. Figure 7B-31 shows an example of the triangular distribution applied to SO_4 at the S-Wells in January. The figure shows that at the beginning of each stochastic realization, the model samples a value (multiplier on the Abscissa axis) in the triangular distribution, with the highest chance to get 1 (0.36 probability) and no chance to be lower than 0.038 or higher than 5.52. The value sampled is then used as the multiplier of the SO_4 January median concentration that was fixed for the S-wells location. The maximum and minimum values (0.038 and 5.52) show that, historically, SO_4 concentrations in January reached a maximum concentration of 5.52 times the median and a minimum concentration of 0.038 times the median.

For each fixed water quality location, as well as for each month of the year and each water quality parameter, a triangular distribution was created.. As described in Section 5, the model runs for 200 realizations during each time step, and for each realization, a new concentration is selected based on the triangular distribution.

SECTION 4

Input Data

There are two meteorological stations installed at the FMC: one on the top of a waste dump within the Faro Mine Area and one on the top of a waste dump within the Vangorda/Grum Area. These meteorological stations were installed in December 2003; site recorded data is available for a significantly shorter period than from the Faro Airport meteorological station. In addition, according to the *Hydrology Baseline Report, Faro Mine Interim Works* (CH2M HILL, 2014c), the FMC meteorological stations have large data gaps in the precipitation record for 2008 and since 2009. Monthly precipitation data from the Faro Airport Station is the only long-term reliable source available that is close to the mine site. Data from this station is available from 1978 to 2011, and is presented in Table 7B-9.

Flow data used to help calibrate the hydrological portion of the model is available for Faro Creek Diversion, Rose Creek (at stations X2, X10, and X14) and CVD Pond discharge (X5). For the Vangorda/Grum Area, flow data is available for V1, V2, V4, V27, V8, and the Grum Creek Weir. In addition, water transfers are documented from the following locations:

- Faro Pit to the Faro WTP
- ID Pond to the Faro WTP
- Vangorda Pit to the Vangorda/Grum WTP
- Grum Pit to Vangorda Pit
- V15 to Vangorda Pit
- Little Creek Dam Pond to Vangorda Pit
- Discharge from the Sheep Pad Ponds (V25 BSP)

Of these stations, X2, X14, Grum Creek Weir, V1, and V8 have continuous stream flow monitoring gauges installed; however, the X2 continuous flow record is limited to 2011. Data for stations V2, V4, V27, X10, and X5 rely on spot flow measurements. Spot flow measurements are generally collected monthly, although there are gaps in the data record (Figure 7B-32). Locations with continuous stream flow monitoring gauges have a more complete flow record than locations where only spot flow measurements are collected (Figure 7B-32).

Water quality inputs are generated from available data stored in the EQuIS database, maintained as the central data repository for the FMRP. It is necessary to note that, although many efforts have been undertaken to ensure data quality, challenges are presented in the historical data because samples have been collected by different contractors using different sample collection methods and with sample analyses completed by different analytical laboratories. Further, over the period of interest, analyses methods have changed along with detection limits. Additional steps taken to improve the reliability of water quality prediction based on the data availability include reliance on more recent data, selection of median concentrations when averaging to remove the effect of outliers and high detection limits, and the accounting of uncertainty based on the range of historical data to capture the variability in the model water quality predictions.

Data from about 70 monitoring locations (representing 16,477 data points) were relied upon to inform the source term location water quality. Despite the volume of data, there is limited information for some specific areas of the FMC and for specific periods. For locations with no water quality data from specific months, an average concentration was generated from available data in the preceding and subsequent months. For locations with limited water quality data from seasons, typically winter, an average concentration was generated for the entire season based on the available data.

Total metals concentrations are used as input, though groundwater and seeps rely on dissolved metals concentrations. Constituents reported as less than the detection limit were kept in the water quality time-series to inform source term concentrations using half the detection limit value.

Background surface water quality data and analyses used in the model for V1, VR, USFR, R7, FC, R6, and W10 are consistent with the background water quality reported in Minnow (2014b). Variability in background surface water quality is accounted for by including a truncated normal distribution element within the model to generate

background water quality within the range observed at the site during the stochastic simulations. The truncated normal distribution limits the distribution about the mean from producing negative concentrations.

Average concentrations from monitoring well TH86-17 between 2004 and 2012 were used to generate background groundwater input concentrations. This water quality dataset was applied as input data for waste dumps not expected to affect the receiving environment during the IW or those that drain to internal water management systems for collection and treatment, as described in Section 5.

Figure 7B-33 provides a simplified plot of the data availability for all locations used as source term model input. The plot presents the sampling event frequency for each source term location. For source terms that pooled data from more than one location (e.g., S-Wells bypass), the plot indicates a sampling event occurred, regardless of the number of pooled locations sampled.

The groundwater monitoring wells used to inform source term water quality inputs are generally sampled seasonally in the spring and fall (Figure 7B-33). Where no or limited data were available, an average concentration was used based on available data, as follows:

- For the NFRC, observed data were not available from the selection of wells for December through April; therefore, average concentrations from September to November were used to develop the input time-series for these winter months. There were also no data available for July at the NFRC, so the input time-series was created from the average of June and August data.
- For the S-Wells, observed data were not available from the selection of wells for October or from December through April; therefore, average concentrations from September and November were used to develop the input time-series for these winter months. There was only one observation available for the S-Wells for August, so the input time-series was created from the average of concentrations from June, July, and September.
- For RCAA, observed concentrations were available for all months, but there are limited data from a small number of locations over the winter, so average concentrations were used for October through April. In addition, August input concentrations were created from the average of June, July, and September data.
- For the water quality parameters fixed based on recent historical X5 concentrations (Ca, Co, Mg, Mn, and SO_4), no data were available from January, February, and October; therefore an interpolated concentration based on the concentration from the month prior, and month following, the missing month was used to develop the water quality input time-series.
- For LCD input water quality, observed concentrations were not available for November through April, so average concentrations from September and October were used to develop the input time-series for these winter months.

Inconsistent data-sets also presented a data gap. For the NFRC source term, data have not been available since 2006 for the following locations included in the grouping of wells used to develop the input time-series: BH1, BH2, BH4, BH12A, BH12B, and BH13A. Data was only available from one sampling event in 2006 for BH7B. The input water quality time-series for Grum Waste Dump seepage predominantly relies upon data from Moose Seep, as no data have been available for Moose Well since 2009. Similarly, the input water quality time-series for Grum Waste Dump runoff predominantly relies upon data from V2, as available data from Sheep Creek were limited to a total of four observations in 2010 and 2011.

SECTION 5

Model Assumptions

As described in Section 3, the model estimates flows at the FMC as a function of annual HEP and annual precipitation change from an average value. This approach assumes a direct linear correlation between precipitation and HEP values. This is a simplistic approach, yet reasonable given the availability of site data.

Monthly precipitation data from the Faro Airport Station is the only long-term reliable source available. Data from this station are available from 1978 to 2011, and are presented in Table 7B-9. Missing data were filled with the monthly average values. The model assumes that there is an adjustment between the Faro Airport precipitation and the FMC. The adjustment is a function of elevation; AECOM (2009) reported precipitation at the FMC between 7 and 10 percent higher than that occurring at the Faro Airport Station. An FMC precipitation factor that is used to increase the precipitation rates recorded at the Faro Airport Station can be defined in the model by the user. The default FMC precipitation factor is set at a 20 percent increase, based on more recent estimates (CH2M HILL, 2013b). In addition, Vangorda/Grum precipitation is 3.3 percent higher than the Faro Mine area.

When running the model in a stochastic mode, an index sequential methodology is used to loop the 35 years of historical monthly precipitation data. Under stochastic mode, the model will randomly select a year between 1978 and 2011 as the start of the hydrological sequence for each stochastic run (called realization). If the number of years the model is running exceeds the 34 years of hydrology, the model loops back from 2011 to 1978. This methodology incorporates historical precipitation variability to the model, and makes use of the entire available precipitation sequence between 1978 and 2011. The current model runs 200 stochastic realizations.

All the pits and ponds in the system have an elevation-capacity curve that defines the pit volume at a given elevation. The elevation–capacity curve defines the incremental change in elevation for a given change in the volume of the pits, and vice-versa. The model was calibrated with the best currently available elevation –capacity curves, presented on Table 7B-10.

The water quality projections assume that the current site conditions will remain the same and recent trends will continue linearly for the next 10 years. Any major deviation on trends will be addressed by the Adaptive Management Plan. The model assumes mass is conserved for all constituents and no attenuation of load is considered downstream of where loads are being fixed (i.e., there is no reactive mixing included in the model). It is assumed that the past measured concentration monthly patterns will remain the same in the near-term, and the past monthly variability observed around the median are applied for the next 10 years, as described in Section 3.3.3.

The locations chosen to fix water quality are those currently impacting water quality in the receiving environment or expected to over the next 10 years. As described in Section 3.2.1, background groundwater quality, based on TH86-17 concentrations, is used to represent drainage quality from the waste dumps in catchments GHL, GHU, X23 and MP which are not expected to contribute significant load to the receiving environment during the IW. Drainage from these waste dumps is assumed to have water quality similar to background because either the seepage is collected for treatment (and therefore accounted by the WTP discharge) or travel time for the load to reach the receiving environment is greater than the duration of the IW. Undisturbed catchments are assigned with background water quality (see Section 3.3.1).

The seepage and runoff from waste dumps that are not directly connected to the receiving environment are either being collected (by draining into collections systems or pits and ponds) or are being discharged to the RCTA. Concentrations in the discharge from the RCTA are fixed based on a selection of wells downgradient of CVD Pond as presented on Table 7B-5.

The most downstream location considered in the model is the Pelly River downstream of Anvil Creek and Vangorda Creek. Flow in the Pelly River upstream of the confluence with Vangorda Creek averages 192,900 litres per second [L/s]. Intermediate flows (average 830 L/s) join the system between Pelly/Vangorda and Pelly/Anvil confluences. Both upstream Pelly River and intermediate Pelly River flows are estimated from monthly records. The model does not scale these flows for change in precipitation.

Sections 5.1 and 5.2 describe the assumptions particular to the Faro Mine Area and Vangorda/Grum Area, respectively. The description is from upstream to downstream, and includes how the flows are being generated (HEP values, areas, and monthly patterns) and where the inputs are inserted in the model. The description also includes where the water quality is being fixed and the waste dumps upstream of those locations.

5.1 Faro Mine Area Assumptions

The assumptions for the Faro Mine Area are described from upstream (Upper Faro Creek catchment) to downstream (Pelly River). The description includes the origin of the flows, an approximate flow value, the monthly pattern used to convert flows from annual to monthly average flows, and the water quality assigned to the flows. Water flows generated in the model are based on the precipitation received over the individual catchment area. Stream flow, seepage or pumped volumes which are assumed, rather than determined in the model were generated from past studies, site operations or review of available data. Locations with assumed flow volumes are described below and additional discussion on the data availability was provided in Section 4. The catchments and locations mentioned in the assumptions were previously presented on Figure 7B-2; Figure 7B-34 is a simplified schematic containing only the components relevant to this modelling effort. The flows reported here and on Figure 7B-34 are the averages of a stochastic simulation and the result of Equations 1, 2 and 3 previously presented, and consider an annual average precipitation of 370 mm.

5.1.1 Upper Faro Creek to R7

Starting at the Faro Creek Diversion, at the North-end of the system, flows in the Faro Creek Diversion originate in the Upper Faro Creek catchment and are estimated to be on average 177 L/s. Equation 1 can be used to compute the flow with an Upper Faro Creek catchment area of 15.3 square kilometres (km^2), 352 mm of HEP for that catchment and 1.0367 (an annual precipitation value of 370 mm is used for the flow estimates presented below, which is 1.0367 of the average precipitation) as the coefficient to scale HEP.. The annual precipitation varies through the simulation and stochastic run. The Faro Surface monthly flow pattern is applied to the volume at this location to convert it to monthly volumes or average monthly flows. The water quality assumed for Faro Creek Diversion is surface water background.

A portion of the flows from the Upper Faro Creek catchment seep to the Faro Pit. It is estimated that the seepage from Faro Creek Diversion into the Faro Pit is 26 percent of the Faro Creek Diversion flow, or 46 L/s. The current 26 percent value is a result of past water balance calculations (RGC, 1996) and currently used as a calibration parameter, as this value is an estimate. The Faro Creek Diversion Seepage monthly pattern is applied to the volume at this location to convert it to monthly volumes or average monthly flows.

Flows from the Faro Creek Diversion join flows from R7, or NFRC (monitoring location R7). Flows from R7 are calculated following the same assumptions described for Faro Creek Diversion, with a catchment area of 103.5 km^2 and the HEP for that catchment is 325 mm, yielding an average flow of 1,109 L/s. The Faro Surface monthly flow pattern is applied to convert the annual volume into monthly volume based on historical distribution from the R7 location described in Section 3.2.3. The water quality assumed for R7 is surface water background, described in Section 4.

5.1.2 R7 to X2

The first flow contribution from waste dumps and the first location where concentrations are fixed is downstream of the R7 and Faro Creek Diversion junction and upstream of NF1. Portions of the NEU, NEL ZIIE, OHRE, and ID Waste Dumps contribute to the concentrations fixed at this location. The average flow from these waste dumps is 3.4 L/s (seepage plus runoff). A selection of wells and seeps at the base of these waste dump are used to represent the water quality entering NFRC upstream of Haul Road (see NFRC Zone II and NE Waste Dump in Table 7B-5).

S-Wells seepage and runoff that bypasses the collections system enters NFRC between NF1 and X2. Portions of the RD, RZD, MDE, ID, IDSC, OHRW, and OHRE Waste Dumps drain to the S-wells. The average contributing flows to the S-Wells are estimated to be approximately 5.31 L/s, with 4.2 L/s being seepage. The model assumes that the S-Wells collection system has an efficiency between 40 and 80 percent that varies stochastically for each

simulation run. The flows that are not collected (seepage and runoff) end up in the receiving environment, at an average of 2.8 L/s. The water quality from those waste dumps is represented by the average water quality of a selection of wells around the perimeter of the S-Wells collection system, to represent the water quality of water that bypasses the S-Well collection system.

5.1.3 X2 to X14

Between X2 and X3A, the system receives 758 L/s from Upper SFRC (74.25 km^2 and 342 mm of HEP minus 75 L/s considered to be groundwater that enters the RCAA), and 1.6 L/s from runoff originating on undisturbed areas of the RCV catchment. It is believed that water quality from waste dumps in the RCV catchment (MDE and OHRW) will not reach the discharging environment for the next 10 years; therefore, flows from these waste dumps are replaced with undisturbed catchment flows. This is also the reason why the percentage of each waste dump in each catchment does not add to 100 percent for OHRW and MDE on Table 7B-1, the table does not show the percentage of WRD in undisturbed areas. It is believed that RCAA inflows originate in the Upper SFRC, so 75 L/s are subtracted from the Upper SFRC flows and added to the RCAA.

Between X3A and X10 the system receives 174 L/s from SFRC (18 km^2 with 292 mm of HEP)It is also assumed that approximately 205 L/s leave the Rose Creek diversion and enter the ID Pond and CVD Pond in the RCTA. It is believed that 205 L/s leaving RCD into RCTA is overestimated, but only a limited amount of data are available in this area.

Parallel to the Rose Creek Diversion between X3A and X10, the Rose Creek Tailings Area (RCTA) and RCAA drain to the ID Pond and CVD Pond. Inflows to this area comprise 205 L/s from the Rose Creek Diversion, 75 L/s from the Upper SFRC, and 33 L/s from local seepage and runoff, uncollected waste dump seepage, and X23 runoff. The water quality for the Rose Creek Diversion flows are a mix of the different water qualities upstream of X3A. The water quality for the 75 L/s from the Upper SFRC is fixed to the water quality measured from a selection of wells downgradient of the CVD. The water quality from uncollected seepage and runoff is fixed to background from TH86-17 (described in Section 4). The assumption behind the water quality fixes is that the concentrations at X23 or from uncollected waste dumps are not currently showing up at X14 and are not expected to reach X14 in the next 10 years. The CVD Pond receives an annual average of 48 L/s from seepage and 88 L/s from the Faro WTP. The CVD Pond seepage was estimated mainly through pond elevation data during the winter season when there were no discharges or other inflows going to the pond.

The WTP effluent is discharged at the CVD Pond. The model assumes that the maximum WTP capacity will be 378 L/s (6,000 United States gallons per minute [USgpm]) for the next 10 years and the treatment season is assumed to be 5 months, from May to the end of September. Flows from the Faro Pit will be sent to the IWTS to keep the Faro Pit at an elevation target of 1,141 m at the end of the treatment season. The CVD Pond will discharge to X5 to keep elevation below a target of 1,027.9 m at the end of the treatment season and no more than 1,029 m at any time. The CVD Pond discharges to X5 are limited by a maximum siphon capacity of 630 L/s (10,000 USgpm), and the X5 average annual flow is 137 L/s. The water quality at the CVD Pond is a mix of WTP effluent water quality and the mixed water quality entering the RCTA area. However, water quality discharged from the CVD Pond via X5 was fixed based on past performance of the CVD Pond for Ca, Cd, Co, Mg, Mn, and SO_4. This was a conservative approach taking into account the uncertainty related to future water quality entering the CVD Pond from seepage and WTP effluent discharges. Pb and Zn were fixed based on expected future Faro WTP performance and therefore limit discharge concentrations below a maximum of 0.05 and 0.5, respectively for the Faro WTP and below 0.0002 and 0.5, respectively for the Vangorda WTP. Results of an earlier model calibration used fixed WTP quality only, and mixing in the CVD Pond resulted in a poor fit with measured loads for the constituents being represented by the CVD Pond discharge water quality.

The Upper Guardhouse annual average flow is estimated at 1.6 L/s and contributes to the X14 flows. Water quality for Upper Guardhouse Waste Dump is fixed at background.

The next downstream flow location is X14, which receives discharges from X5, flows from X10, RCAA, and Upper Guardhouse Creek. The current model estimates that X14 receives a total of 2,400 L/s on average. Water quality is not fixed and it is a mix of the upstream loads.

5.1.4 Downstream X14

Between X14 and R4 the system receives 882 L/s of natural flows (105 km^2 and 255 mm of HEP). The monthly flow pattern used for these flows was the Rose Creek R4. Water quality is not fixed and it is a mix of the upstream loads.

Between R4 and A1 the system receives 5,629 L/s (643 km^2 and 267mm of HEP). Rose Creek joins the Anvil Creek between these two monitoring locations. The estimated annual volume from HEP was converted into monthly flows with the Rose Creek monthly flow pattern in absence of better data. Anvil Creek then joins the Pelly River.

5.2 Vangorda/Grum Area Assumptions

The assumptions for the Vangorda/Grum Area will be described from upstream (V1) to the most downstream location (V8). The description includes the origin of the flows, an approximate flow value (provided as an annual average), the monthly flow pattern used to convert flows from annual to monthly average flows, and the water quality assigned to the flows. Water flows generated in the model are based on the precipitation received over the individual catchment area. Stream flow, seepage or pumped volumes which are assumed, rather than determined in the model were generated from past studies, site operations or review of available data. Locations with assumed flow volumes are described below and additional discussion on the data availability was provided in Section 4. The catchments and locations mentioned in the assumptions below were previously presented on Figure 7B-3. Figure 7B-35 is a simplified schematic containing only the components relevant to this modelling effort. The flows reported in the following subsections and on Figure 7B-35 are the averages of a stochastic simulation and the result of Equations 1, 2, and 3 previously presented and consider an annual average precipitation of 361 mm.

5.2.1 From V1 to V27

The main flows in the Vangorda /Grum Mine Area come from Vangorda Creek, at V1. The system receives 232 L/s of natural flows (20 km^2 and 374 mm of HEP). The Vangorda Surface monthly flow pattern is applied to the volume at this location to convert it to monthly volumes or average monthly flows. It is assumed that 8.1 L/s or 3.5 percent of the V1 flows seep into Vangorda Pit. The 3.5 percent value was obtained from the model calibration and is close to a previous value estimated to be 4 percent (Bryan, 2012).

Between V1 and the next flow monitoring location V27, there are five other flow contributions: discharges from V25BSP, seepage from Moose Pond, V2 runoff and seepage flows, Grum Overburden Dump flows, and residual undisturbed area flows. The assumption in the model, based on design and current performance of the Vangorda waste dump, is that all the Vangorda waste dump drainage is collected and sent to the Vangorda pit. Water quality is fixed to measured values and trends for inflows to V25BSP (except WTP inflows), Moose Pond inflows (or V15), Moose Pond seepage, and V2. The surface water background concentrations are used for V1 and residual areas.

- **V25BSP, outflow from** Sheep Pad Ponds (SPP) is not modelled as a storage pit, and it is assumed that monthly inflows equal monthly outflows. The pond discharges an average of 47 L/s to Vangorda Creek. The SPP receives Vangorda WTP effluents and flows from the Grum Interceptor Ditch and Grum Overburden catchment. It is assumed that the Grum Interceptor diverts 90 percent of the flows to V25BSP, and the remaining 10 percent flows to the Grum Pit. It is assumed that 73 percent of the Grum Overburden catchment goes to the V25BSP pond and the remaining 27 percent flows to the Grum Pit. The model assumes that the Vangorda WTP has a 2,000 USgpm (126.18 L/s) capacity and will be operating from June through August. Flows are sent from Vangorda Pit to the WTP to keep the Vangorda Pit water surface elevation below 1,083 m at the end of the treatment season.
- The **G3 Overburden** Waste Dump is within the Grum Overburden catchment and it drains straight to V27 with an average flow rate of 2.6 L/s. The overburden material is assumed to contain low leachable concentrations of the key water quality parameters considered and therefore the water quality is fixed to background water quality from TH86-17.

- **Moose Pond** receives inflows from Grum dumps (G1B, G2 and G3O) via Grum Creek and V15. It is assumed that 35 percent of the seepage from G1B, G2 is flows to Moose Pond. The remaining 65 percent drains to V2. It is also assumed that 70 percent of the runoff from G1B, G2, and G3O goes to V15, then to Moose Pond, and the remaining 30 percent flows to V2. Seepage from G3O (2.6 L/s) flows to V27. Moose Pond receives flows from V15. The flows exceeding natural flows to the pond are pumped to Vangorda Pit. Natural monthly flows to Moose Pond were calculated from an estimated catchment area of 0.41 km^2 and 202 mm of HEP. The monthly flow pattern applied was similar to the Vangorda Waste Dump seepage monthly flow pattern with the freshet peak flows in May attenuated and shifted to the following months (July through October). The result of these assumptions yield an average flow pumped from V15 to Vangorda Pit to be 0.75 L/s, with maximum monthly average value at 9 L/s.

  It is assumed that the 2.5 L/s of seepage flows from Moose Pond to Vangorda Creek. It was verified, using measured concentrations, that there is attenuation of some metals, including zinc, from Moose Pond to Vangorda Creek, which is the reason why seepage water quality from Moose Pond was fixed. The water quality from Moose Pond seepage is different than the water quality fixed at the pond, and was fixed based on actual pond seepage water quality data.

- **V2** flows join Vangorda Creek with an average of 4.5 L/s. The V2 location receives 30 percent of the runoff flows from G1B plus G2, and 65 percent of the seepage flows from G1B and G2 Waste Dumps. It is believed that there is some attenuation of concentrations at that location because upstream waste dump concentrations are not currently being observed at V2. Based on this information, the water quality at V2 is fixed based on observed concentrations from V2 and Sheep Creek (see Table 7B-5).

- **Undisturbed areas** are estimated to contribute an extra 17.9 L/s to the Vangorda Creek. The concentrations for these flows are fixed to surface water background.

There are other assumptions on the Vangorda/Grum Area that impact the amount of flow being discharged to Vangorda Creek but do not directly impact the water quality at the stream. Other assumptions impact flows to the Grum or Vangorda pits, or flows being treated at the Vangorda WTP.

The G1-S Waste Dump (i.e., Grum Sulphide Cell) is considered to be covered from the beginning of the simulation; its flows are collected in the lined pond at the toe of the waste dump and sent to Vangorda Pit. The Vangorda Pit receives seepage flows from the Vangorda Creek Diversion (8.4 L/s), local drainage (3.5 L/s), pumped flows from the LCD pond (3.4 L/s), pumped flows from V15 (0.76 L/s),and flows from Grum pit (14.6L/s). Although the water quality in Vangorda Pit is not fixed, the Vangorda WTP effluent is. Flows from the Vangorda Pit are pumped to the Vangorda WTP from June through August at a maximum pumping rate of 2,000 USgpm to keep the Vangorda Pit at a target elevation of 1,083 m at the end of the treatment season.

The Vangorda Waste Dump was constructed on an extensive native till layer with a seepage collection system around the perimeter of the dump to limit seepage/run-off migration to the receiving environment (RGC, 1996). There are limited groundwater monitoring wells downgradient of the Vangorda Waste Dump, however concentrations of the groundwater underlying the Vangorda Waste Dump show signs of moderately-elevated mine impacts (RGC, 2013). Over the duration of the IW it is not anticipated that impacts from the Vangorda Waste Dump will reach Vangorda Creek based on the performance of the containment facility and due to the expected attenuation capacity between the waste dump and Vangorda Creek. The LCD pond is assumed to receive all flows from the Vangorda Waste Dump, seepage and runoff. The model assumption is that LCD flows will be pumped as soon as possible once they reach the pond.

The Grum Pit receives flows from residual areas draining to the pit (7.9 L/s), flows from seepage (3.7 L/s), uncollected flows from the Grum Overburden Dump (27 percent of the Grum overburden or 2.1 L/s), and an assumed 10 percent of the flows collected at the Grum interceptor (1.4 L/s). Flows from the Grum Pit are pumped to the Vangorda Pit at a maximum rate of 1,800 USgpm from May through September, assuming that the target pit elevation at the end of the season is 1,213.4 m. The water quality for the Grum Pit is not relevant to this study as seepage, if any, is assumed to provide an insignificant load to the receiving environment.

5.2.2 From V27 to V8

Downstream of V27, the system receives contributions from undisturbed areas between V27 and V8, Shrimp Creek flows, and V5 flows. Shrimp Creek contributes approximately 81 L/s (13.6 km^2 and 182.2 mm of HEP)) to the V8 flows. V5 contributes approximately 192 L/s to V8 (32 km^2 and 182.2 mm of HEP, plus any other leaks from Grum Waste Dump). Undisturbed areas of the V8 catchment contribute 68 L/s to the V8 location. The Vangorda Creek monthly flow pattern is applied to Shrimp Creek, V5, and undisturbed area flows, to convert them to monthly volumes or average monthly flows. The V8 location (approximately 640 L/s) discharges into the Pelly River upstream of the Pelly/Anvil confluence.

SECTION 6

Calibration

This section describes the differences between the calibration and the predictive model, and presents the comparison between model results and measured data. The section is divided into Flow and Water Quality subsections, which provide a more detailed explanation about what model variables were adjusted and fixed.

Continuous flow and water quality measurements are not available for the site; most of the flow and water quality data are temporally scattered, as presented in Section 4, and most of the locations have had less than 100 measured flow records since 2006. This amount of data does not support a robust model calibration. Therefore, flow data were generally used to identify if modelled results had the right magnitude and monthly pattern. The best historical data available are for water elevations in pits and ponds; therefore, the model calibration process is based mainly on these elevations. The calibration focused on the period between January 2006 and December 2012, because it is a period where pit elevations and some flow data were available.

The assumptions for model calibration are different from the assumptions used for the predictive model. Given the data gaps on measured flow and water quality data, the calibration goal was to make sure all major flows were taken into account and the order of magnitude and seasonal patterns were reasonably close to measured values and differences could be explained.

The calibration assumes that the model starts in January 2006 and runs until December 2011. The annual precipitation for those years is available and was used in this model version.

Flows from pumps with known discharge rates used for seepage collection and water conveyance were fixed in the model. The pump flows fixed were the Emergency Tailings Area to Faro WTP, S-Wells, Zone II, LCD and Vangorda Pit outflows. The Faro Pit outflows were not fixed because of data gaps, but the assumption was that the maximum capacity of the WTP was 5,000 USgpm and the pit was lowered to an elevation of 1,141 m at the end of the treatment season. The treatment season was set to be from May through September. The ID Pond and CVD Pond were set to follow an elevation rule curve based on average monthly historical pit elevations, meaning that releases from those ponds would happen only if the storage was above the rule curve elevation for a given month.

The following subsections show the model versus measured data comparison for flows, storage elevations, and water quality, and describe which parameters were adjusted.

6.1 Flow and Storage Comparison

Figure 7B-36 presents a comparison of the model results versus the measured elevation at all the storage locations modelled in the system. Figure 7B-37 presents a comparison of the model results versus measured flows at key locations at the Faro Mine Area. Figure 7B-38 presents a comparison of the model results versus measured flows at key locations at the Vangorda/Grum Area. It is noteworthy to mention that the measured flows are instantaneous measurements and the model results are monthly averages. The monthly averages do not show daily peak flows recorded at the site but instead average those peak flows throughout the month.

6.1.1 CVD Pond

Figure 7B-36a shows the CVD Pond model versus measured elevation comparison. There weren't enough flow data measurements to fix inflows or outflows to the pond. The assumption is that the pond will receive flows from the WTP (which were not fixed to measured values) and an average of 48 L/s of seepage from the Rose Creek Diversion. Releases from CVD Pond happen when elevation at the pond is above a set monthly target, developed from average historical operations. Figure 7B-36a shows that the model results are within the range of measured values and that some historical operations brought the pond to elevations close to 1027 m. The parameter calibrated for the CVD Pond was the seepage from Rose Creek Diversion. Outside the treatment season, the pond does not receive any inflow except runoff and seepage. Measured elevation data, however, indicate that the pond elevation rises outside of the treatment season (winter). The winter seepage inflows were estimated based on pond elevation-capacity curves and historical change in elevation. Occasional flow discharges from the CVD Pond were measured and are presented on Figure 7B-37a, which shows that modelled discharges are in the order of

magnitude of measured flows and are also matching the seasonal discharge. Additional flow measurement at X5 and WTP effluent discharges could result in a more accurate estimate of the seepage flow from the Rose Creek diversion to the CVD Pond.

6.1.2 ID Pond

Figure 7B-36b shows the ID Pond model versus measured elevation comparison. Pumping out of the pond was not fixed: pump-out of the pond to the WTP happens when elevation at the pond is above a set monthly target and when the WTP is operational. The monthly target elevation was developed from average historical operations. Figure 7B-37c shows a reasonable comparison between modelled and measured pumping out of the pond to the WTP (Intermediate Pond to Faro Mill), with model flows in the same order of magnitude of measured flows. Three measured data points show significantly higher pumping rates, which could be daily peak in pumping operations that is not reflected in the averaged model flows. The inflows to the ID Pond are Emergency Tailings Area- seepage (fixed to measured flows), Lower Guardhouse seepage and runoff, RCTA area runoff, and seepage from the Rose Creek diversion. The calibration parameter adjusted for the ID Pond was the seepage entering the pond, currently estimated to be 21.9 L/s. A more consistent time-series record of pond outflow (pumping to WTP) and Faro WTP total inflows is needed for a more accurate estimate of pond inflows. Figure 7B-36b shows that the assumptions above result in a reasonable comparison of pond elevation between model and measured observations except for an increase in pumping in 2010 and 2011 that brought the ID Pond to lower levels than what is allowed by the model rule curve.

6.1.3 Faro Pit

Figure 7B-36c shows the Faro Pit model versus measured elevation comparison. Water is pumped out of the pit to the WTP when water elevation is above a set monthly target developed from average historical operations, generally intended to have the pit elevation near 1,141 m at the end of the treatment season. The inflows to the pit were fixed to measured flows from the Zone II pumping well and the S-wells collection system. Other inflows to the pit that were not fixed include local seepage and runoff and seepage inflows from the Faro Creek Diversion. The calibration parameter used for the Faro Pit was seepage from the Faro Creek Diversion, estimated to be 26 percent (46 L/s) of the Faro Creek diversion flows. The Faro Pit outflow (Faro Pit to WTP) was not fixed; however, Figure 7B-37b shows a reasonable match of modelled versus available measured flows from the Faro Pit to the WTP. The correlation coefficient between modelled and measured data points is 0.69. A more consistent Faro Pit outflow dataset and total inflows to the WTP would be necessary to refine the current Faro Creek seepage coefficient.

6.1.4 X14 to R4

Originally, the flows entering the system between X14 and R4 were estimated as 849 L/s of natural flows (105 km^2 and 255 mm of HEP) with a monthly flow pattern based on Rose Creek flows. Measured water quality data from X14 and R4 indicate that there was an average 51 percent reduction in SO_4 concentration from January through April, and an average 22 percent reduction from May through December. Model results that used the Rose Creek monthly flow pattern for the undisturbed flows between X14 and R4 indicated an average SO_4 concentration reduction of only 20 percent from January through April and 25 percent from May through December. An adjustment in the shape of the monthly flow pattern resulted in a better comparison of concentration reduction from X14 to R4. The modified monthly flow pattern had the May peak attenuated and more baseflow during the winter, as is expected from an undisturbed catchment (pattern Rose Creek R4 on Table 7B-4). The adjusted final model presents a SO_4 concentration reduction between X14 and R4 of 56 percent from January through April and 25 percent from May through December).

6.1.5 Other Flows compared in the Faro Mine Area

Other Faro Mine Area locations that had measured flows include the monitoring stations at X2, X10 and X14. The comparison between model results and measured flows are presented in Figures 7B-37d, 7B-37e, and 7B-37f. The flows at X2, X10 and X14 are 1 to 2 orders of magnitude higher than the collected seepage, aquifer seepage, inflows to the ponds, and overall system pumping. This order of magnitude difference, plus the scattered nature of the flow data collected, make the model calibration challenging. The comparison presented on the figures show that model results are generally at the same order of magnitude and with the same monthly flow pattern (peak

flows in May). The comparison of model results versus measured data at those locations does not justify a calibration of system inflows or different routing of flows.

6.1.6 Grum

The Grum Pit is assumed to be a closed system and no water is pumped out of the pit during the calibration time window; pumping water from Grum Pit to Vangorda Pit began in 2013. Flows to the Grum Pit include local runoff and seepage for the catchment draining to the pit, and for some fraction of what is not diverted at the Grum interceptor ditch and a fraction of the flows from the overburden. The current fractions of the seepage that bypasses the Grum Interceptor Ditch and the Grum Overburden Dump were used as calibration coefficients. In addition, the seepage that reached the Grum Pit was not originally included, and it is estimated to be close to 60 USgpm (Bryan, 2012). The Vangorda Waste Dump seep monthly distribution is applied to an annual seepage volume, which is also scaled up and down as a function of the precipitation. The annual seepage value is a calibration parameter.

Figure 7B-36d shows that although the overall elevation of the pit follows the measured elevation, the monthly flow pattern has some differences; the model inflows are greater during the freshet period, then lower during the winter when compared with the measured elevation data.

6.1.7 Vangorda

The Vangorda Pit had enough outflow measured data that could be used in the model. By fixing the volume of water pumped out of the pit to historical values and comparing measured versus model elevation, the inflow assumptions were determined to be close to observed inflows. Figure 7B-36e shows that model versus measured elevations compare well except for the second half of 2012. The increase in the water surface elevation after the second half of 2012 is due to the lack of historical pumping flows, the model assumes zero when in reality there was some pumping on the 2012 treatment season. The calibration parameter used for the Vangorda Pit was the seepage fraction from the Vangorda Diversion. The coefficient was set to be 3.5 percent; previous water balance calculations estimate the seepage to be around 4 percent of the Vangorda Creek flows (Bryan, 2012). The Vangorda Waste Dump runoff collection efficiency was set to 70 percent and the Vangorda Waste Dump seepage collection efficiency was set to 50 percent.

6.1.8 Little Creek Dam

The Little Creek Dam water quality does not impact the outcome of this study. It is assumed that LCD is pumped to Vangorda Pit then to the WTP before being discharged into V25BSP and eventually into the Vangorda Creek. The LCD will impact only the inflows to the Vangorda Pit and inflows to the Vangorda WTP. Some outflow data from LCD are available, however more reliable data are found from the water elevation of the pit. The LCD outflows were fixed so that the inflows could be calibrated. LCD receives seepage and runoff from the Vangorda Waste Dump mainly through the collection trench on the toe of the Vangorda dumps. The calibration adjusted the efficiency of the trench to collect runoff and seepage, and also the monthly flow pattern. Figure 7B-36f shows that the first 2 years of the simulation have a good correlation with the measured elevation. After 2008, elevation data are more scattered and outflow data might not be accurately being converted from daily to monthly flows, which might explain the significant difference between model and measured elevation values after the 2 first years of the simulation.

6.1.9 Other Flows compared in the Vangorda/Grum Area

Figure 7B-38 shows the model versus measured flow comparison at six locations in the Vangorda/Grum Area. Although Figure 7B-38 shows that the measured flow data are limited, the magnitude and monthly flow pattern modelled generally match the measured records. Flows from V15+GC include all the flows upstream of V15 and the flows captured by the lined pond at the base of the Grum Sulphide Cell. Measured data (Figure 7B-38a) show flow peaks not seen in the model results, this could be daily peak readings that are averaged in the model results. Figure 7B-38b shows the outflows from the V25 BSP pond. Flows could be calibrated at that location by adjusting the flows from the Grum Overburden Dump and Grum Interceptor Ditch, but a more complete flow dataset would be needed. The flows from V4 (Shrimp creek) seems to be at the right order of magnitude and monthly pattern (Figure 7B-38c); at this point the available dataset does not support further calibration.

Flows at V1, V27, and V8 were not directly calibrated and are a function of the parameters adjusted upstream of those locations.

6.2 Water Quality

Within the Faro Mine Area, groundwater sources are used as input water quality terms (NFRC GW, S-Wells bypass, and RCAA discharge). As described in Section 3.3.1, the groundwater monitoring wells used to generate the input time-series specifically target areas receiving deteriorated water from the waste dump. This results in the groundwater quality input to the model having higher concentrations than what would actually be expected over the broad area being represented in the model. Further, attenuation of trace metals (Cd, Co, Mn, and Zn) is known to occur within the subsurface alluvial aquifer material at the FMC, reducing the load received in NFRC (*Geochemical Characterization Report, Faro Mine Remediation Project* [CH2M HILL, 2014]). Metal attenuation can be a result of adsorption to natural organic matter or to secondary oxyhydroxides, or coprecipitation of secondary mineral phases. This attenuation may act to slow the migration of trace metals away from the waste dumps within the shallow groundwater system, especially in the early stages of seep development when pH is near neutral but Zn and SO4 are elevated. Therefore, a calibration factor is applied to Cd, Co, Mn, and Zn concentrations at the source terms (S-Wells bypass and NFRC GW) to produce input water quality more representative of site conditions. The calibration factor applied to Cd, Co, Mn, and Zn at the source terms was adjusted until model predictions provided an acceptable match to observed concentrations at X2 (Figure 7B-39). A calibration factor of 0.1 (0.1 x median monthly source term concentration) was selected to be applied in the model for those 4 parameters.

The black line on the plots from Figure 7B-39 presents average monthly concentrations from available data between 2009 and 2012. The two bar graphs on Figure 7B-39, below the calibration line plots present the observed concentrations (i.e., not the average monthly concentration) for the parameters of interest between 2009 and 2012, which show that there is variability in the observed concentrations, but no obvious trend, and therefore it is reasonable to attempt to match to the average monthly concentrations.

Figure 7B-39 includes the base-case-X2-predicted concentrations when no calibration factor is applied (orange line).

The calibration factor improves the initial condition as compared to the base case (no calibration factor) while maintaining conservative inputs. Figure 7B-40 presents a comparison between the measured data and the predicted values. The predicted concentrations provide a reasonable match to the monthly pattern and magnitude, reducing or removing the initial step function increase seen when the base case source terms are used (beginning of orange line). For Zn and Cd, where a smaller step function increase still persists, the median predicted results are within the historical range.

After applying the calibration factor, the predicted concentrations show an improved match to the observed concentrations, although there are some remaining differences in the monthly pattern (Figure 7B-39). One of the reasons the model monthly pattern does not match the observed X2 monthly pattern is because of the limited data available from winter months for the fixed water quality source terms (S-Wells bypass and NFRC GW).

Using the input water quality source terms described in Section 3.3, and after applying the calibration factor described above, a comparison was performed for the key water quality parameters between the predicted concentrations and the observed concentrations at X14 and V8 (Figure 7B-41). Figure 7B-41 presents the comparison of model results to measured 2013 concentrations as model water quality inputs rely on source concentrations up to 2012. This check against a dataset not used in model input demonstrates that the modelled water quality inputs provide a reasonable approach to predict near-term water quality. Model results (median, minimum, and maximum) relying on the four source areas on the Faro side and seven source areas on the Vangorda/Grum side were considered to provide a good match to the magnitude of measured concentrations and a reasonable representation of monthly patterns for the key water quality parameters (Figure 7B-41).

It is important to note that the model calculates an average concentration on a monthly time step. Measured concentrations reflect an instantaneous snapshot of the concentrations at the moment sampled. Samples at X14 and V8 are collected between a weekly and monthly frequency.

SECTION 7

Results

The calibration results described in Section 6 show that the model, at its current state and limitations, is a valuable tool to understand the seasonal concentration changes, flow magnitudes, origin of loads, dilution of concentrations between given locations, and impact of operational changes in the system.

Water quality was predicted for the duration of the IW (2014 through 2023) at key locations in the aquatic receiving environment within and downstream of the FMC. Locations within the model where water quality was predicted include: NF1, X2, X3A, X14, R4, R5, A1, P4 and V8. Specifically, water quality was predicted for the following eight constituents of concern (COCs): Ca, Cd, Co, Mg, Mn, Pb, SO_4, and Zn (Minnow, 2014b). Hardness was also predicted, calculated from the predicted Ca and Mg concentrations.

The predicted water quality results for the COCs were provided to Minnow Environmental Inc. to support the assessment of potential effects of the IW on the aquatic receiving environment, which can be found in Minnow (2014a). Although a detailed assessment of the predicted water quality is outside the scope of this study, a preliminary summary of the model results is presented in the following sections.

7.1 Load Contribution

The proportion of load contribution by season at X14 and V8 from the source terms for the key water quality parameters is presented on Figures 7B-42 and 7B-43. Figure 7B-42 provides the proportion of load contribution at X14 considering the load contribution from RCAA, S-Wells bypass, NFRC, CVD Pond discharge, and background. Figure 7B-43 provides the proportion of load contribution at V8 considering the load contribution from V1, V25BSP, Grum Runoff, Grum Seepage, V15 bypass, V4, V5, and residual flows in the V8 catchment. Load contribution is determined and presented on an average seasonal basis. The three seasons used to group the data are consistent with the three hydrology seasons identified for the FMC (i.e., freshet – May and June, open water – July to October, and winter – November to April).

7.1.1 Faro Mine Area

The proportion of contribution for all key water quality parameters are shown on Figure 7B-42. The largest contributor of all constituents during the open water season is the CVD Pond. During freshest, discharge from the CVD Pond also provides the largest source of the key water quality parameters, except for Mg, Cd, and Pb, which have the greatest contribution from background stream flows, followed by CVD Pond discharge. A large contribution (greater than 10 percent) of load for Ca, Mg, and SO_4 during freshet and open water is provided by RCAA. S-Wells provide a large contribution of Cd and Zn during freshet and open water.

During lower flow winter conditions, the largest load is contributed from RCAA for Ca, Mg, SO_4, and Mn. The largest contributor of Cd is the S-Wells, followed closely by background stream flows. The NFRC, specifically source loadings to NFRC, provides the largest source of Zn during winter flow conditions, with Pb primarily sourced from background stream flows.

7.1.2 Vangorda/Grum Area

The proportion of contribution for all key water quality parameters are shown on Figure 7B-43. The largest contributor of all constituents during the open water season (except for Co, Mg, and Pb) is discharge from V25 BSP. For Co and Mg V5 provides the greatest contribution and V25BSP provides the second-largest contribution. For Pb, V4 provides the greatest contribution and V5 the second-largest contribution. During freshet, discharge from V25BSP also provides the largest source of SO_4, Mn, and Zn, and is the second largest source of Cd. V5 provides the greatest contribution of Ca, Mg, Cd, Co, and Pb during freshet; the Mn and Zn load from V5 is the second largest during freshet. V4 provides the second largest contribution of the Pb during freshet.

During lower flow winter conditions, the largest or second largest load is contributed from V5 for all parameters except Pb. Grum Waste Dump seepage provides a large contribution (greater than 10 percent) of load for Mg,

SO_4, Cd, and Co. The contribution of Ca, Cd, Co, Mn, Pb, and Zn from V1 is greater than 10 percent during winter low flows. A large contribution of load for Cd is provided by V15 bypass.

7.2 Predicted Water Quality

The complete set of water quality estimates are presented in tables and figures in Appendix 7C (Minnow 2014a). The tables present a summary for all stochastic realizations done for the 2014-2023 period. The figures show the seasonality, range of stochastic results, and trends of water quality at different stations for Ca, Cd, Co, Mg, Mn, Pb, SO_4, Zn, and hardness (calculated from the predicted Ca and Mg concentrations).

The tables summarize (by location) the water quality results for the above noted parameters. The specific information provided includes monthly exceedance probabilities, monthly concentrations (5th, 50th, and 95th percentiles), and seasonal concentrations (5th, 50th, and 95th percentiles).

The monthly exceedance probability represents the percentage of months that exceeded guidelines out of the total 24,000 months considered in the simulation. For example, a 3 percent monthly exeedance value for Cd indicates that the variable exceeded guidelines in 720 months out of the 24,000 months considered in the stochastic simulation. The 24,000 months are from the monthly model results of a 10-year stochastic simulation with 200 realizations (12 months times 10 years times 200 stochastic realizations).

The monthly concentrations are values that were not exceeded x percent of the months, where “x” represents the 5th, 50th, and 95th percentiles of all simulation results. For example, the 95th percentile represents 95 percent of the months having concentrations below the value on the table. In other words, 1,900 out of the 2,000 individual months simulated (10 years times 200 stochastic simulations) had concentrations below that value.

The seasonal concentrations table shows the average percentile threshold concentration for the months that represent each season.

Two figures are presented for each variable except for hardness. The first figure shows the range of the stochastic simulations represented by 5th, 50th, and 95th percentiles of all 200 stochastic realizations; for example, the top line indicates that 95 percent of the simulation results were below the indicate concentration. The second figure summarizes all months in the 10 year window and 200 stochastic simulations, and shows the percentage of all months that exceeded the guideline threshold.

Results show that although none of the water quality parameters are likely to be above guideline thresholds at the most downstream location (P4), there is a probability that some of the parameters at some locations upstream P4 will exceed the determined guidelines.

Future median surface water concentrations of SO_4, Cd, and Pb are expected to be below water quality guidelines for protection of aquatic life during winter baseflow, spring freshet, and summer/fall periods at all stations. However, the predicted range of values for Cd and Pb suggest that peak concentrations may occasionally exceed guidelines at some locations. Median as well as peak concentrations of Co, Mn, and Zn are predicted to be above guidelines at some stations and/or during some seasons.

Median concentrations of Cd are predicted to be less than the hardness-adjusted water quality guidelines in all local and regional study areas, but the guidelines may sometimes be exceeded in localized stream reaches within the local study area (e.g., NFRC and in Rose Creek immediately downstream from the Faro Mine Area); however, the predicted concentrations are not expected to be toxic to fish and effects on other aquatic biota are expected to be minimal. Co concentrations are predicted to exceed the water quality guideline in Rose Creek at X14 and R4 in approximately 45 percent and 35 percent of the months respectively, particularly during the open water seasons; however, predicted concentrations are not expected to be toxic to fish and effects on other aquatic biota are expected to be minimal. Mn concentrations are not predicted to change substantially from baseline conditions, except that concentrations may decrease slightly in winter months and increase slightly in other months at Rose Creek stations at and downstream from X14. Overall, Mn concentrations are predicted to be above the hardness-adjusted guidelines in approximately 65 percent of months at X14 (65 percent) and in an increasingly lower percentage of months at stations farther downstream. The available data indicate that aquatic

effects, if any, of Mn in surface waters around the FMC would be limited to the vicinity of X14 (i.e., within the local study area) and would likely be minor in magnitude.

During the 10-year IW, concentrations of Zn under normal operating, winter, and summer/fall conditions, are predicted to be above guidelines throughout the Rose Creek system downstream of NF1 to the mouth at Anvil Creek (R4). At these stations, probabilities of monthly guideline exceedance range from 60 percent to 80 percent, but decline from 80 percent at X14 to 70 percent at the mouth of Rose Creek (R4), to 30 percent after the confluence of Rose Creek, and to 20 percent at the mouth of Anvil Creek (R5). The water quality guideline for Zn is also expected to be exceeded in approximately 30 percent of months at V8, near the mouth of Vangorda Creek, but will not be exceeded at P4 in the Pelly River downstream of Vangorda Creek and Anvil Creek. Despite these conditions of elevated Zn, the available data indicate that aquatic effects, if any, in surface waters around the FMC would be comparable to those currently observed at X14. This means that concentrations would rarely exceed fish toxicity thresholds, effects to other aquatic biota would be minor (i.e., affecting only a few sensitive species), and the effects would be limited to the local study area.

A more comprehensive assessment of the aquatic effects is provided in Minnow (2014a).

SECTION 8

Limitations

The model results are limited to monthly average estimates of flow and water quality at specific locations. The water quality is predicted for Ca, Cd, Co, Mg, Mn, Pb, SO_4, Zn, and hardness (calculated from the predicted Ca and Mg concentrations), and the locations of prediction are NFRC at NF1, X2, X3A, X14, R4, R5, A1, P4, and V8. Water quality predictions assume no reactive mixing of waters, and that water quality trends into the future for more than 10 years and. Spikes in concentrations at specific locations resulting from new source areas, like the one recently observed at NF1 (TEES, 2013), are nor addressed by this model. They will be addressed by the Adaptive Management Plan.

The model hydrology is based on annual values of precipitation and HEP with applied fixed monthly flow patterns. The model results do not account for climate change. It is possible that within the next 10 years, changes in precipitation volume and shifts in precipitation patterns might impact the water quality at the site. This assumption also limits the use of the model and its results to the next 10 years.

The model assumes that peak events happening in a period shorter than a month are averaged through the month. Therefore, it is not suitable for evaluating peak daily hydrology and daily water quality scenarios.

The modelled system conserves mass and flows, thus this model is not suitable to evaluate changes in concentrations between flow locations caused by any reactive processes. Concentrations between flow locations change only as a function of flows and loads added to the system.

Intermediate model flow locations mentioned in Section 5 that were (1) not calibrated, (2) not in the list of water quality prediction locations, or (3) not presented on Figures 7B-37 and 7B-38, should not be used for further analysis or reference. Those flows are subjected to calibration parameters and the values may change in the future, when additional data is available.

TABLE 7B-5

Locations and the Period of Record Used to Fix Water Quality

Description of Water Modelling & Results—Faro Mine Remediation Project

Model Catchment/ Location	Location	Description	Period
Faro Mine Area			
RCAA – GW discharge to SW	RCAA	Selection of wells downgradient of CVD to represent current WQ conditions for GW discharge to SW *(P01-01A/B, P01-2A/B, P01-11, P03-09-01 through -09, P05-01-02 through -06, P05-02, P05-03, X13, X16A/B, X17A/B, X18A/B)*	2008 to 2012
S-Wells bypass	S-Wells	Selection of perimeter wells to represent WQ of S-Well collection system bypass *(S1A, S2A, S3, SRK05-SP1A, SRK05-SP1B, SRK05-SP2, SRK05-SP3A, SRK05-SP3B, SRK08-SBR3, SRK08-SP7A, SRK05-SP7B)*	2009 to 2012
NFRC (Zone II and NE WRD)	NFRC	Selection of wells/seeps to represent WQ entering NFRC upstream of Haul Road *(BH1, BH2, BH4, BH5, BH6, BH7B, BH10A, BH10B, P05-04, SRK08-P12A, SRK08-P12B, BH12A, BH12B, BH13A, BH13B, BH14A, BH14B; NE1, SRK-FD05, SRK-FD06)*	2006 to 2013
WTP - select parameters	CVD	X5 - Ca, Mg, SO_4 and Mn only (operational change in 2011)	2011 to 2012
Vangorda/Grum Mine Area			
Shrimp Creek	V4	Shrimp Creek	2007 to 2012
Sheep Pad Pond	V25BSP	Receives flows form the Grum Interceptor, upstream catchment and a portion of the Overburden Catchment	2008 to 2012
Grum WRD - V15 Collected	V15	V15 is either pumped to Vangorda or drains to Moose Pond (represented by V2a)	2006 to 2012
Grum WRD - Runoff	V2	Uncollected Runoff from Grum WRD that discharges to V27 (represented by Sheep Creek and V2)	2009 to 2012
Grum WRD - Seepage	Moose Seep	Seepage flowing from Moose Pond to V27 (represented by MOOSEw2 and MOOSE SEEP)	2009 to 2012
Vangorda WRD - Runoff/Seepage	LCD	Vangorda WRD is designed to intercept runoff/seepage and direct to LCD Pond. LCD is pumped to Vangorda Pit and subsequently treated. Limited GW data downgradient of Vangorda WRD.	2004 to 2012
West Fork Vangorda Creek	V5	West side of the V8 catchment	2008 to 2012

Notes
A - trend from linear regression on average annual data
S-K - Seasonal Kendal test
↑ - indicates a trend of increasing concentration
→ - indicates no trend or trend was negative
← - indicates no significant trend
↓ - indicates significant decreasing trend
↑'- indicates significant increasing trend at 0.05 significance
↑'' - indicates significant increasing trend at between 0.05 and 0.1 significance
↑''' - indicates significant increasing trend at between 0.1 and 0.2 significance
i - insufficient independent data points to determine significance

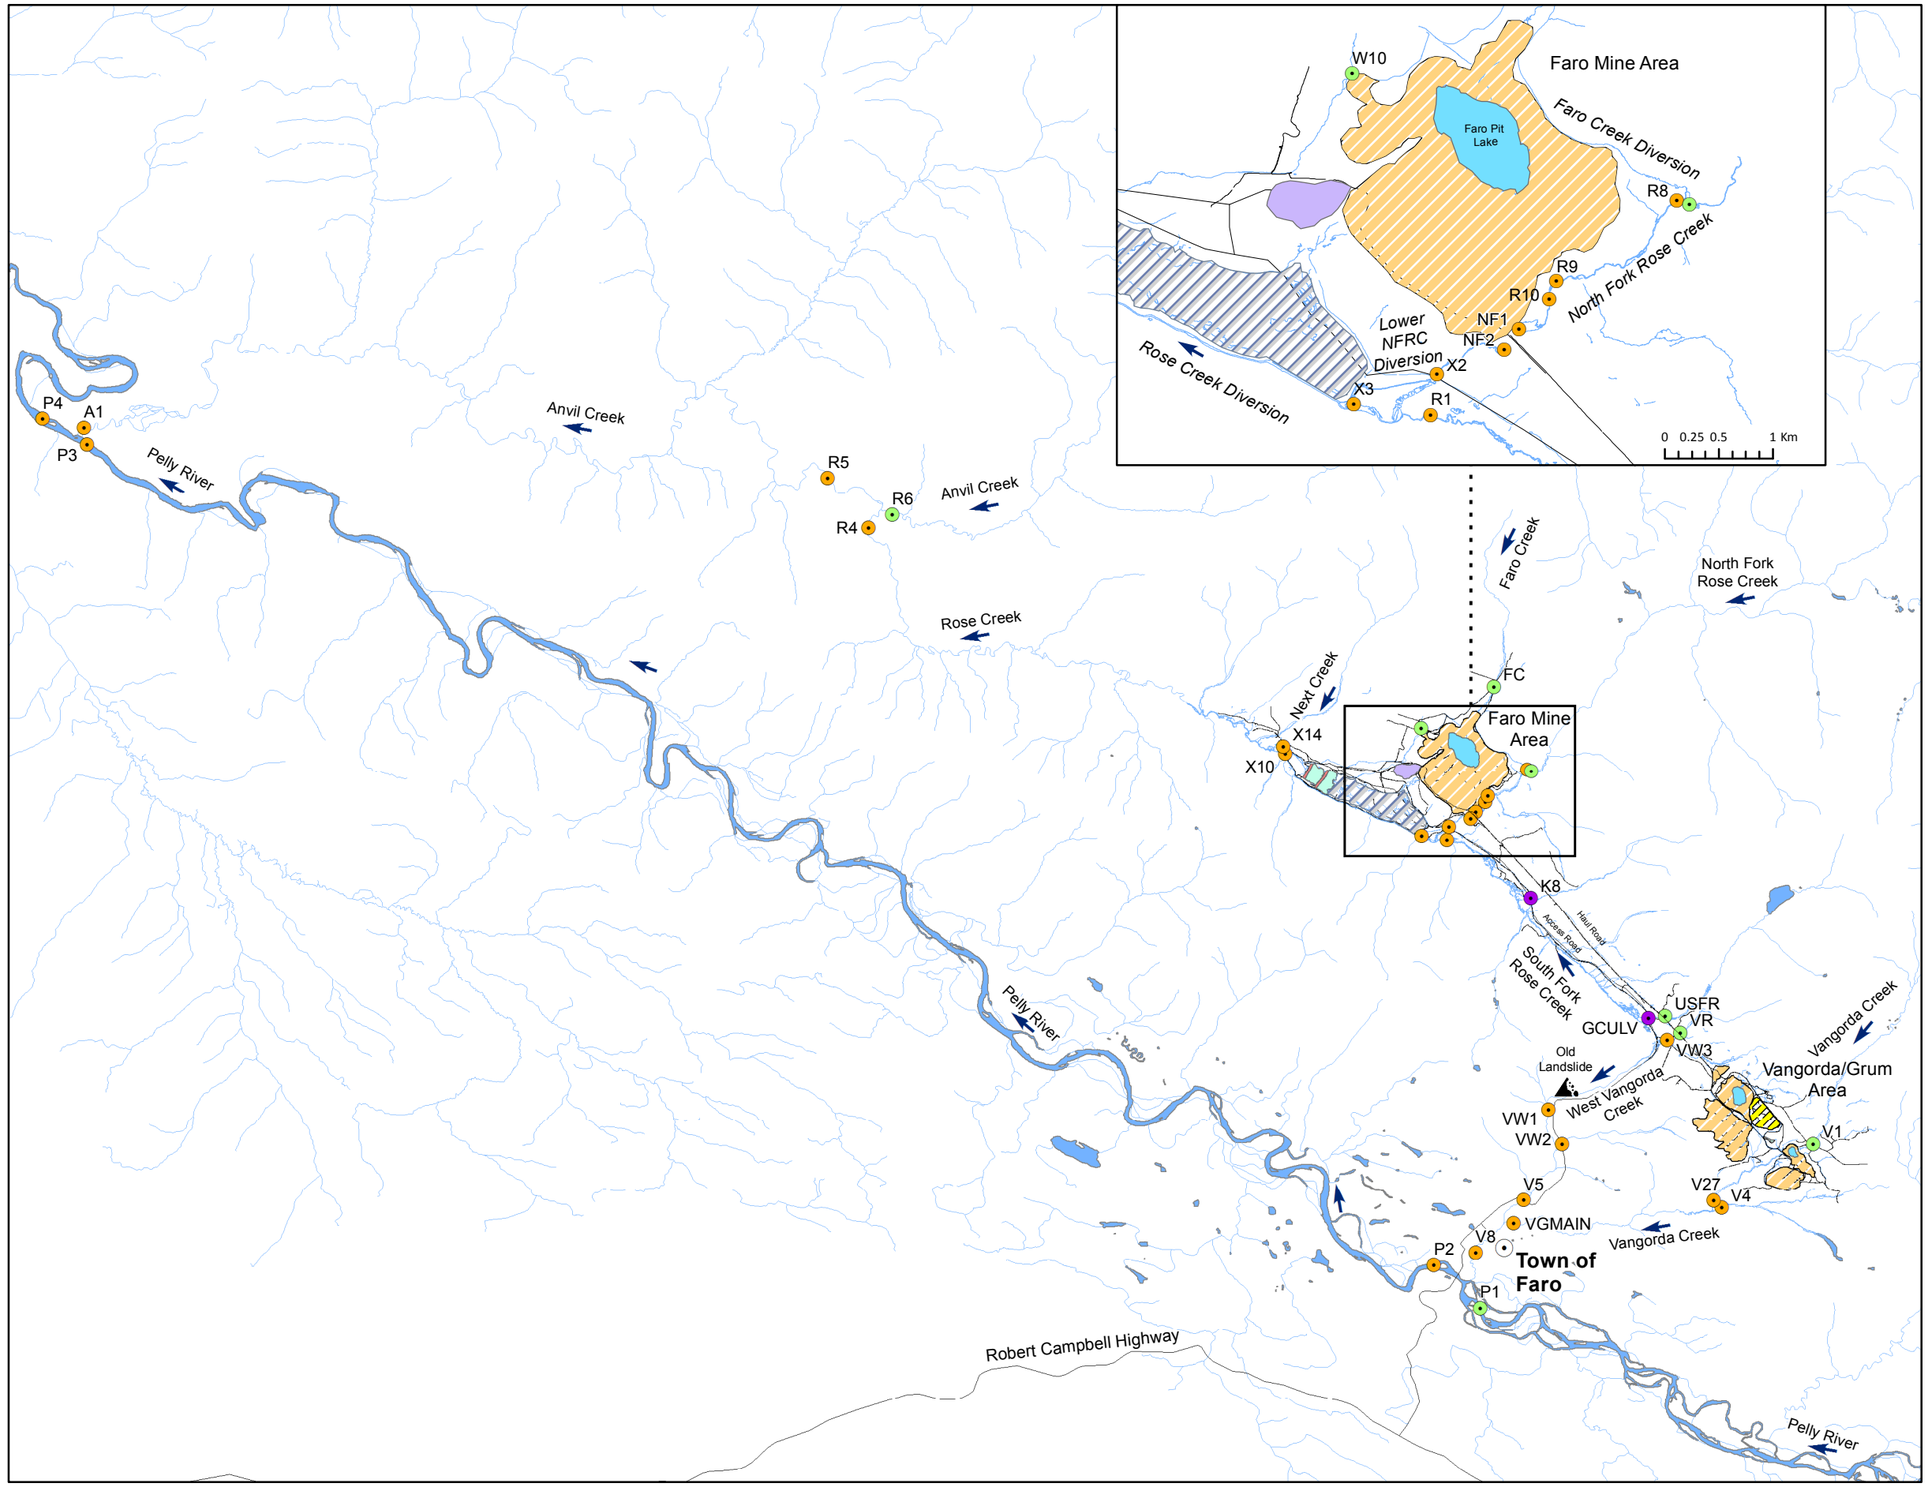
LIST OF ACRONYMS

µg/L – micrograms per litre
AANDC – Aboriginal Affairs and Northern Development Canada
AMP – Adaptive Management Plan
BMP – Best Management Practices
BCMOE – British Columbia Ministry of the Environment
CCME – Canadian Council for Ministers of the Environment
ChV –Chronic Value, typically derived as the geometric mean of the NOEC and LOEC determined in the same test
d – day
DOC – dissolved organic carbon
DOM – dissolved organic matter
EC10– the concentration that causes effective response to 10 percent of the test organisms
EC50 – the concentration that causes effective response to 50 percent of the test organisms
FAV – Final Acute Value
FMC - Faro Mine Complex
FMRP – Faro Mine Remediation Project
g - gram
GEI - GEI Consultants Inc.
h – hour
IC10– the concentration that causes inhibition to 10 percent of the test organisms
IC25– the concentration that causes inhibition to 25 percent of the test organisms
IC50 – the concentration that causes inhibition to 50 percent of the test organisms
IW – Interim Works
LC10– the concentration that will be lethal to 10 percent of the test organisms
LC50 – the concentration that will be lethal to 50 percent of the test organisms
Ln – natural logarithm
LOEC/L – Lowest Effect Concentration or Level
Log - logarithm
LSA – local study area
m - metre
MATC – Maximum Acceptable Toxicant Concentration, typically derived as the geometric mean of the NOEC and LOEC determined in the same test (same as ChV)
mg/kg – milligrams per kilogram
mg/L – milligrams per litre
mm - millimetre
NFRC – North Fork Rose Creek

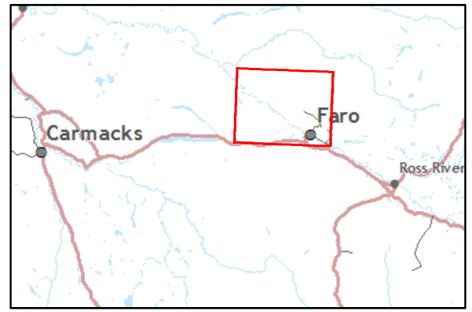
NOEC/L – No Effect Concentration or Level
NR – not reported
RCTA – Rose Creek Tailings Area
RSA – regional study area
SFRC – South Fork Rose Creek
TLM – Threshold Limit median
TSS – Total Suspended Solids
USEPA – United States Environmental Protection Agency
VC – valued component
Wk - week
YG – Government of Yukon

1.0 INTRODUCTION



1.1 Background

The Faro Mine Complex (FMC) was formerly owned by the Anvil Range Mining Corporation, which produced lead and zinc concentrates that were extracted for lead, zinc, silver, and gold. Mine operations were terminated in April 1998 and the site went into receivership. Site Care and Maintenance responsibilities are being managed by contractors acting on behalf of the Government of Yukon (YG), while efforts continue towards development of the final scope and implementation of the overall Faro Mine Remediation Project (FMRP). In the meantime, YG seeks authorization for 10 years of interim site management, maintenance, and investigation activities, referred to as the Interim Works (IW).



The FMC occupies portions of both the Rose Creek and Vangorda Creek watersheds. Both creeks are tributaries to the Pelly River, which is a major tributary to the Yukon River. Slimy sculpin (*Cottus cognatus*) and Arctic grayling (*Thymallus arcticus*) are the most abundant fish species in the Rose-Anvil Creek system. Both species appear to utilize surface waters around the Faro Mine Area year-round, although some Arctic grayling migrate to the Pelly River for overwintering. Juvenile Chinook salmon (*Oncorhynchus tshawytscha*) have occasionally been observed in the Rose Creek system near the FMC, but adults have rarely been observed and the Rose-Anvil Creek system has been classified as having only low to moderate suitability for Chinook salmon spawning. Blind Creek, to the east of Vangorda Creek, is recognized as a local stream providing more important habitat for salmon. Downstream of the Vangorda/Grum Area, in lower Vangorda Creek, juvenile Chinook salmon are typically the most abundant fish because this area provides valuable rearing habitat.

Baseline water quality data for the FMC (2008-12) indicate that concentrations of a variety of non-metals and metals are presently elevated in surface waters relative to the typical range of background (reference station) concentrations (Minnow 2014)[1]. Alkalinity, conductivity, hardness, sulphate, total dissolved solids, calcium, cobalt, magnesium, nickel, sodium, strontium, and zinc occur at concentrations above background levels in approximately half or more of samples collected downstream of the Vangorda/Grum Area (station V8; Figure 7C-1) and the Faro Mine Area (station X14). Current concentrations of non-metal analytes, including pH and sulphate, would not be expected to adversely affect

aquatic biota; however, concentrations of various metals, especially zinc, in surface waters around and downstream of the FMC, sometimes exceed water quality guidelines for protection of aquatic life. Recent studies of benthic invertebrate communities have concluded that mine-related effects on aquatic biota are minor in magnitude and confined to localized areas having highest concentrations of mine-related contaminants (e.g., portions of North Fork Rose Creek [NFRC] and in Rose Creek immediately downstream of the Rose Creek Tailings Area [RCTA]). Mine-related effects on water quality and biota do not presently extend into the Pelly River.

1.2 Report Objectives and Overview

Many of the site management and maintenance activities that have been in place, and are proposed to continue as part of the IW, are intended to minimize release of contaminants from the site, such as diversion of clean water around disturbed areas and collection and treatment of contaminated water. Regardless, contaminants will continue to be released from mine sources such as waste rock, tailings, and open pits, via direct or indirect surface and groundwater pathways (including treated effluents), into receiving environments around and downstream of the FMC during the IW period. The progression of acid-rock drainage conditions at the site means that contaminant mobilization from waste materials will likely increase through the IW period. These deteriorating conditions are one of the primary drivers for the eventual implementation of the FMRP that includes aggressive source control and contaminant collection measures. However, these measures require further planning, design and permitting before they can be implemented and the IW activities entail measures to mitigate effects prior to FMRP implementation. This report describes the expected interactions of the IW with surface water and aquatic biota and presents a detailed analysis of potential effects. However, predicted changes from baseline conditions are expected to develop as a result of existing conditions at the site rather than from proposed human activities associated with the project. This is an important context for interpretation of the results of the aquatic effects assessment.

2.0 INTERACTIONS, EFFECTS PATHWAYS, MITIGATION

As described in Section 7.2 of the main IW project proposal, the first step in conducting the effects assessment for the IW entailed a comprehensive identification of interactions between IW activities and Valued Components (VCs). This was done in two workshops, one for environmental VCs and one for socio-economic VCs, to promote consistency in decision-making among the different technical disciplines. Each interaction was classified to highlight those that warrant detailed consideration in the effects assessment. The classifications were defined as follows:

"0" = No Interaction: no measurable interaction that could cause an effect.

"1" = Minor Interaction: minimal interaction where measureable effects are possible, but the effects will be avoided or suitably mitigated through compliance with regulatory requirements and application of standard Best Management Practices (BMPs).

"2" = Major Interaction: potential interaction where measurable effects are likely even with application of best management practices, or where understanding the scale or magnitude of effects requires detailed analysis.

This systematic approach created a matrix of project activities and VCs, promoting thorough consideration and identification of all potential interactions, regardless of scale, magnitude, or direction. Only the interactions identified in this process that were associated with surface water quality and fish and fish habitat are assessed within this document.

Mine-related contaminants measured in surface waters around and downstream of the FMC originate mainly from waste rock piles, open pits, and the Rose Creek Tailings Area (RCTA). The contaminants are released to the environment via controlled surface discharges (e.g., treated effluent from the Faro and Vangorda Water Treatment Systems), uncontrolled surface discharges (e.g., untreated runoff and seepage), and groundwater. Table 7C-1 lists all of the specific project characteristics that have potential to influence surface water quality, along with a brief description of each interaction. Various BMPs will be implemented to control contaminant releases associated with each activity (Table 7C-1). These include continued treatment of surface water from the RCTA, as well as collection and storage of contaminated water in the Faro and Vangorda Pits, as well as the seasonal treatment of contaminated water at the Faro and Vangorda Water Treatment Systems. These systems are described in Section 5.0 of the main IW Project Proposal and it is expected that effluent limits will be applied to control concentrations and loads in

Table 7C-1: Project interactions with aquatic value components and associated mitigation and residual effects

Project Activities/Physical Works		Interaction Ranking[a]		Description of Interaction	Mitigation	Residual Effects
Category	Specific	Surface Water Quality	Fish and Fish Habitat			
Site Operations	Storage of tailings material in the RCTA	2	2	Contaminants will continue to be released into surface waters via treated effluent and groundwater, with potential to affect aquatic biota in downstream areas.	Effluent from the RCTA will continue to be treated and groundwater releases will be managed via the AMP.	The aggregate effects of project activities on surface water quality are incorporated in the site water quality model. Potential effects to fish may occur through effects on water quality. Therefore, potential effects on surface water quality and associated toxicity to aquatic biota are assessed through evaluation of water quality predictions relative to baseline conditions, water quality guidelines, and toxicity thresholds published in the literature. Low to medium effects are expected in some areas, after mitigation, based on concentrations being above water quality guidelines for some mine-related variables. See text for detailed assessment.
	Seasonal treatment and discharge of water at Interim Faro Water Treatment System	2	2	Contaminants will continue to be released into surface waters via treated effluent with potential to affect aquatic biota in downstream areas.	Effluent from the RCTA will continue to be treated and meet appropriate discharge requirements.	
	Storage of waste rock	2	2	Contaminants will continue to be released into surface waters via surface runoff, groundwater, and treated effluent with potential to affect aquatic biota in downstream areas.	Groundwater collections systems at the S-Wells area and ETA intercept and pump contaminants back to Faro Pit. Waste rock releases reporting to the RCTA will be treated continue to be treated before discharge and groundwater releases will be managed via the AMP. Water from collection systems at Vangorda and Grum Waste Rock Dumps (seepage and surface water) is directed to Vangora Pit and eventually treatment.	
	Storage of contaminated water in pit lakes and backfilled pits (Faro, Vangorda, Grum and Zone II)	2	0	Contaminants will continue to be released via treated effluent and potentially through groundwater.	Pit water will continue to be treated at Faro and Vangorda/Grum Areas before release to the environment. Groundwater releases will be managed via the AMP.	
	Storage of contaminated water in ponds (e.g., Little Creek Pond, Intermediate Pond, Cross-Valley Pond, Sheep Pad Pond, Moose Pond, Groucho Pond, Vangorda Water Treatment Pond)	2	2	Contaminants will continue to be released via treated effluent and potentially through groundwater. Also potential for TSS release from some ponds, which could affect fish habitat.	Contaminated pond water will be pumped for treatment prior to release. Groundwater releases will be managed via the AMP. Solids loads will be managed via the Sediment and Erosion Control Plan.	
	Interception, collection and transfer of contaminated water from S-Wells to Faro Pit	2	2	Contaminants will continue to be released as a result of incomplete interception. Pipeline break would result in discharge of pit water to the environment.	Groundwater releases will be managed via the AMP. Pipeline break is considered to be an extreme event (see Section 7.3.13)	
	Seasonal discharge of contaminated water into Moose Pond	2	2	Potential contaminant release via groundwater to Vangorda Creek	Groundwater releases will be managed via the AMP. AMP also addresses pumping back of pond water to Vangorda pit as needed.	
	Seasonal treatment and discharge of water at Vangorda Water Treatment System	2	2	Contaminants will continue to be released into surface waters via treated effluent and have potential to affect aquatic biota in downstream areas.	Effluent will continue to be treated at the Vangorda Water Treatment System.	
	Transfer of contaminated water from Zone II Pit to Faro Pit	1	0	Pipeline break could occur, resulting in discharge of pit water to the environment	Pipeline break is considered to be an extreme event (see Section 7.3.13)	Any such occurences are expected to be localized, short duration, and reversible and can be effectively mitigated through Best Management Practises and adherence to applicable regulations. No signficant residual effects predicted.
	Interception, collection and transfer of contaminated water from ETA to Faro Pit	1	0	Contaminants released through incomplete interception. Pipeline break would result in contaminants reporting to tailings or Rose Creek aquifer.	Effluent from the RCTA will continue to be treated and groundwater releases will be managed via the AMP. Pipeline break is considered to be an extreme event (see Section 7.3.13)	
	Seasonal transfer of contaminated water from Grum Pit, Grum Dump and Little Creek Pond to Vangorda Pit and V15	1	1	Pipeline break could occur, resulting in discharge of pit water to the environment	Pipeline break is considered to be an extreme event (see Section 7.3.13)	
	Disposal of sludge from water treatment systems. Original Impoundment at Faro, and Vangorda Pit	1	0	Potential remobilization of contaminants from disposed treatment sludges.	Manage using BMP.	
Site Investigations	Boreholes/test pits	1	1	Potential TSS release and/or contaminants from water use and release during drilling	Manage using BMP.	
	Monitoring equipment installation including wells, thermistors, flow measurement facility	0	1	Potential TSS release and/or contaminants from water use and release during drilling	Manage using BMP and adherence to regulatory requirements respecting protection of fish and fish habitat.	
	Aquifer and pump testing	1	1	Potential TSS release and/or contaminants from water use and release during drilling	Manage using BMP.	
	Access route development (may include stream crossings)	1	1	Potential channel disturbances	Manage using BMP for suspended solids control and adherence to regulatory requirements respecting protection of fish and fish habitat.	
Down-Valley Interim Hydraulic Upgrades	Excavation of Intermediate Dam Spillway	1	0	Potential TSS release	Manage using BMP.	
	Sourcing and transport of borrow material	1	0	Potential TSS release	Manage using BMP.	
	Construction of erosoion protection in spillway	1	0	Potential TSS release	Manage using BMP.	
	Geomembrane and dam raise (gabion) construction	1	0	Potential TSS release	Manage using BMP.	
	Removal of vegetation in RCD	1	1	Potential TSS release and/or stream channel disturbances	BMP for controlling suspended solids losses plus adherence to regulatory requirements respecting protection of fish and fish habitat.	
	Removal of bank sloughs in RCD	1	1	Potential TSS release and/or stream channel disturbances	BMP for controlling suspended solids losses plus adherence to regulatory requirements respecting protection of fish and fish habitat.	
	Repair of RCD dyke	1	1	Potential TSS release	Manage using BMP.	
Accessory Activities	Transport fuel and materials	1	1	Potential fuel spill	Manage using BMP and adherence to regulatory requirements related to fuel/chemical handling.	
	Transport of personnel and supplies	1	1	Potential spill of chemical supplies	Manage using BMP.	
	Hazardous materials storage and use (reagents, fuel and hydrocarbons)	1	1	Potential spills	Manage using BMP and adherence to regulatory requirements related to fuel/chemical handling.	
	Temporary Camp	1	0	Potential for sewage contamination	Manage using BMP.	
	Sourcing and transport of borrow material	1	1	Potential TSS release	Manage using BMP.	

[a] Ranking: 0 = No Interaction: no measurable interaction that could cause an effect.
1 = Minor Interaction: minimal interaction where measureable effects are possible, but the effects will be avoided or suitably mitigated through compliance with regulatory requirements and application of standard best management practices.
2 = Major Interaction: potential interaction where measurable effects are likely even with application of best management practices, or where understanding the scale or magnitude of effects requires detailed analysis.

downstream surface waters. Mine-related chemicals may also enter surface waters via surface runoff, shallow seepage, and groundwater pathways. Except where interception systems already exist, such as at the S-wells area south of the Faro waste rock dumps, timing and magnitude of loading from groundwater discharges are uncertain (see Appendix 7B Description of Water Modeling and Results). Operators will continue to use on-going monitoring of seeps, groundwater, and surface water around the FMC to identify new load sources as they emerge, and the Adaptive Management Plan (AMP) describes how mitigation plans will be developed and implemented, as appropriate. Even with mitigation and the AMP in place, the combined sources of the eight project activities listed at the top of Table 7C-1 are expected to sufficiently affect downstream surface water quality that they were scored a "2." The associated effects are assessed in more detail in the following sections of this report.

Table 7C-1 identifies several minor interactions (scored "0" or "1") for surface water quality. The pathways of effects for these minor interactions are not generally associated with mobilization and transport of metal contaminants from the site. Instead, they relate mainly to potential release of particulates, which tends to occur episodically in response to weather and/or specific work activities. Interactions involving potential effects of particulate releases will be minimized by BMPs and adherence to regulations respecting protection of fish and fish habitat. In addition, BMPs and regulatory requirements related to fuel and chemical (e.g., reagent) handling will mitigate any effects that might otherwise be associated with fuel or chemical spills during site investigations or accessory project activities. Consequently, all such interactions have been rated as a "1" in Table 7C-1. Based on past site experience and professional judgment, such interactions are considered very unlikely to result in a significant environmental effect, either in the absence of mitigation or with the application of standard mitigation practices. Residual effects of such practices, if any, are expected to be minor, so these interactions are not assessed further.

3.0 ASSESSMENT OF RESIDUAL EFFECTS

3.1 Approach

3.1.1 Assessment Scenarios and Indicators

Table 7C-1 identifies a series of "major interactions" (scored "2") between the IW and surface water quality, all of which are associated with on-going storage of mine waste materials, storage of contaminated water, and release of treated water. While these interactions will affect water quality to varying degrees at different surface water locations throughout and downstream of the FMC, the assessment considers the combined loads of mine-related chemicals on surface water quality around and downstream from the FMC. This was done based on predictions from a water balance and load model that incorporates inputs from all of the mine-related sources and develops estimates for key receiving environment locations.

Surface water quality was evaluated by considering relevant water uses. There is no agriculture in the vicinity of the FMC, so the assessment did not consider surface water quality guidelines for protection of agricultural uses. Consideration was initially given to assessing water quality relative to drinking water guidelines; however, this would be relevant only for the two areas within the FMC where First Nations have historically collected drinking water: station K8, located where a small tributary to the South Fork of Rose Creek (SFRC) (sometimes referred to as Reservoir Creek) crosses the mine Access Road, and GCULV, located where the upper SFRC crosses the mine Access Road (Figure 7C-1). These stations are located upstream of most existing and anticipated mine-related disturbances (e.g. the only upstream mine-related disturbance is the Haul Road crossing), so water quality is not expected to change at these stations relative to baseline conditions. Therefore, protection of aquatic life is considered to be the most relevant and sensitive water use at the site and in downstream areas. Also, the water quality guidelines for protection of aquatic life tend to be most stringent of the different guidelines, providing a relatively conservative basis for surface water quality evaluation. By considering surface water quality relative to guidelines for protection of aquatic life, the surface water quality assessment also addresses potential effects on fish and fish habitat that may occur as a result of exposure to mine-related contaminants (i.e., toxicity). In this context, fish habitat includes the aquatic plant and invertebrate communities that contribute to ecosystem function and which represent a food source for fish. By comparison, potential effects of the IW on the physical characteristics of fish habitat are most likely to occur through particulate loads to surface water bodies, resulting in

increased suspended solids and turbidity concentrations and sedimentation on bottom substrates. As noted in Section 2.0, interactions involving particulate loads to surface waters were judged to be relatively minor, and will be controlled through BMPs. Water monitoring will also continue at these stations.

The effects assessment focuses mainly on a "normal" operating scenario, which uses a water and load balance model to predict water quality conditions in the streams affected by the FMC. A realistic adverse scenario was also assessed involving a localized, rapid increase in zinc load to surface water, which is assumed to affect water quality for a limited time period until a mitigation solution can be developed and implemented. Concentrations for this latter scenario are based on real data from recent events at the FMC.

The characterization of baseline water quality (Minnow 2014) showed that sulphate, cadmium, cobalt, iron, lead, manganese, and zinc are the mine-related contaminants that are sometimes observed at concentrations above water quality guidelines for protection of aquatic life at surface water stations located around and downstream of the FMC. Future surface water quality was predicted for all of these substances, except iron (see Appendix 7B - Description of Water Modeling and Results). Iron was excepted because elevated concentrations are usually associated with elevated particulate loads caused by snowmelt and rainfall events, as indicated by coincident elevated total suspended solids (TSS) concentrations (Figure 7C-2). Baseline data (2008-12) showed that TSS concentrations are relatively more elevated at far-field stations (e.g., station A1 at the mouth of Anvil Creek) than nearer the FMC (e.g., station X14) and occur even at minimally mine-disturbed areas (e.g., station R1 on SFRC). Also, contributions from the landslide mid-way down West Fork Vangorda Creek confound interpretation of relative mine-related inputs of suspended solids and iron. Lastly, mine-related particulate loads associated with the IW are expected to be modest and controllable through BMPs (Section 2.0, Table 7C-1). These mechanisms are expected to also control iron loading associated with IW activities. Therefore, the assessment of surface water quality is based on evaluation of expected sulphate, cadmium, cobalt, lead, manganese, and zinc concentrations.

Of the mine-related contaminants included in the assessment, zinc is considered to be an important indicator of future geochemical changes at the site and is the mine-related substance considered most likely to be observed at concentrations above water quality guidelines for protection of aquatic life. Consequently, zinc is identified as an indicator separately from the other mine-related variables in the effects assessment (Table 7C-2). However, concentrations of zinc and the other mine-related variables were assessed in a

Table 7C-2: Assessment criteria for effects on surface water quality and associated chemical effects on fish and fish habitat for Faro Mine Interim Works Project

Valued Components	Effects Assessment Indicator	Rationale for Selection	Measurements	Effect Attributes	Significance Ranking	Ranking Criteria
Surface Water Quality and Associated Chemical Effects on Fish and Fish Habitat	Water quality (zinc)	Protection of aquatic species is predicated on exposure to water concentrations that do not cause impairment. Water quality concentrations can be predicted and concentrations toxic to aquatic organisms have been characterized in the scientific literature. Mine-related effects on surface water quality are expected to be dominated by zinc.	Concentrations of zinc in fish-bearing reaches relative to baseline and predicted conditions, water quality guidelines, toxicity thresholds.	Magnitude and Likelihood/Duration	Low	Water concentrations, after effluent mixing in the receiver are predicted to usually meet water quality guidelines (i.e., ≥50% of months) and will rarely or never exceed fish toxicity thresholds (<50% of months) throughout the 10-year project period.
					Medium	Concentrations after effluent mixing may frequently exceed water quality guidelines (>50% of months) but will usually not exceed toxicity thresholds for relevant fish (<25% of months). Temporary exceptions may occur when a new source or pathway results in a sudden increase in zinc concentration; during this time fish toxicity thresholds may be temporarily (<1 year) exceeded while a mitigation plan is developed and implemented.
					High	Water concentrations are predicted to be above levels likely to harm fish species in >25% of samples for indefinite periods (>1 year).
				Geographic Extent	Low	"Low" water quality effects will apply to all surface waters within and downstream of the FMC footprint (local and regional study areas).
					Medium	"Medium" water quality effects described above will be limited to the Rose Creek and Vangorda Creek system (i.e., mainly confined to local study, possibly extending to mouths of both creeks). In Anvil Creek and Pelly River, water quality effects are predicted to be "low" as defined above.
					High	"High" water quality effects described above may occur within the Rose Creek or Vangorda Creek system and "medium" or "high" water quality effects described above may extend into Anvil Creek and/or the Pelly River (regional study area).
				Reversibility	Low	Periods of elevated concentrations will naturally be followed by periods of lower concentration as a result of normal seasonal cycles of contaminant release and available dilution.
					Medium	Water quality effects are likely reversible through mitigation, although it may take months for solutions to be found and mitigation to be put in place.
					High	Water quality effects are not expected to be reversible.
	Water quality (sulphate, cadmium, cobalt, lead, manganese)	Protection of aquatic species is predicated on exposure to water concentrations that do not cause impairment. Water quality concentrations can be predicted and concentrations toxic to aquatic organisms have been characterized in the scientific literature. Next to zinc, sulphate, cadmium, cobalt, lead, and manganese are the mine-related variables having greatest potential to adversely influence surface water quality.	Concentrations of sulphate, cadmium, cobalt, lead, manganese, and zinc relative to baseline and predicted conditions, water quality guidelines, toxicity thresholds.	Magnitude and Likelihood/Duration	Low	Water concentrations, after effluent mixing, are predicted to meet water quality guidelines in most (≥95% of) months and are not predicted to exceed toxicity thresholds for relevant fish species throughout the 10-year project period.
					Medium	Concentrations are predicted to often meet water quality guidelines (>50% of months) and rarely or never (<5% of months) exceed concentrations shown in the literature to be harmful to relevant fish species.
					High	Water concentrations are predicted to sometimes or often (>5% of months) exceed levels expected to be harmful to relevant fish species.
				Geographic Extent	Low	"Low" water quality effects will apply to all surface waters within and downstream of the FMC footprint (local and regional study areas).
					Medium	"Medium" water quality effects described above will be limited to the Rose Creek and Vangorda Creek system (i.e., mainly confined to local study, possibly extending to mouths of both creeks). In Anvil Creek and Pelly River, water quality effects are predicted to be "low" as defined above.
					High	"High" water quality effects described above may occur within the Rose Creek or Vangorda Creek system and "medium" or "high" water quality effects described above may extend into Anvil Creek and/or the Pelly River (regional study area).
				Reversibility	Low	Periods of elevated concentrations will naturally be followed by periods of lower concentration as a result of normal seasonal cycles of contaminant release and available dilution.
					Medium	Water quality effects are likely reversible through mitigation, although it may take months for solutions to be found and mitigation to be put in place.
					High	Water quality effects are not expected to be reversible.

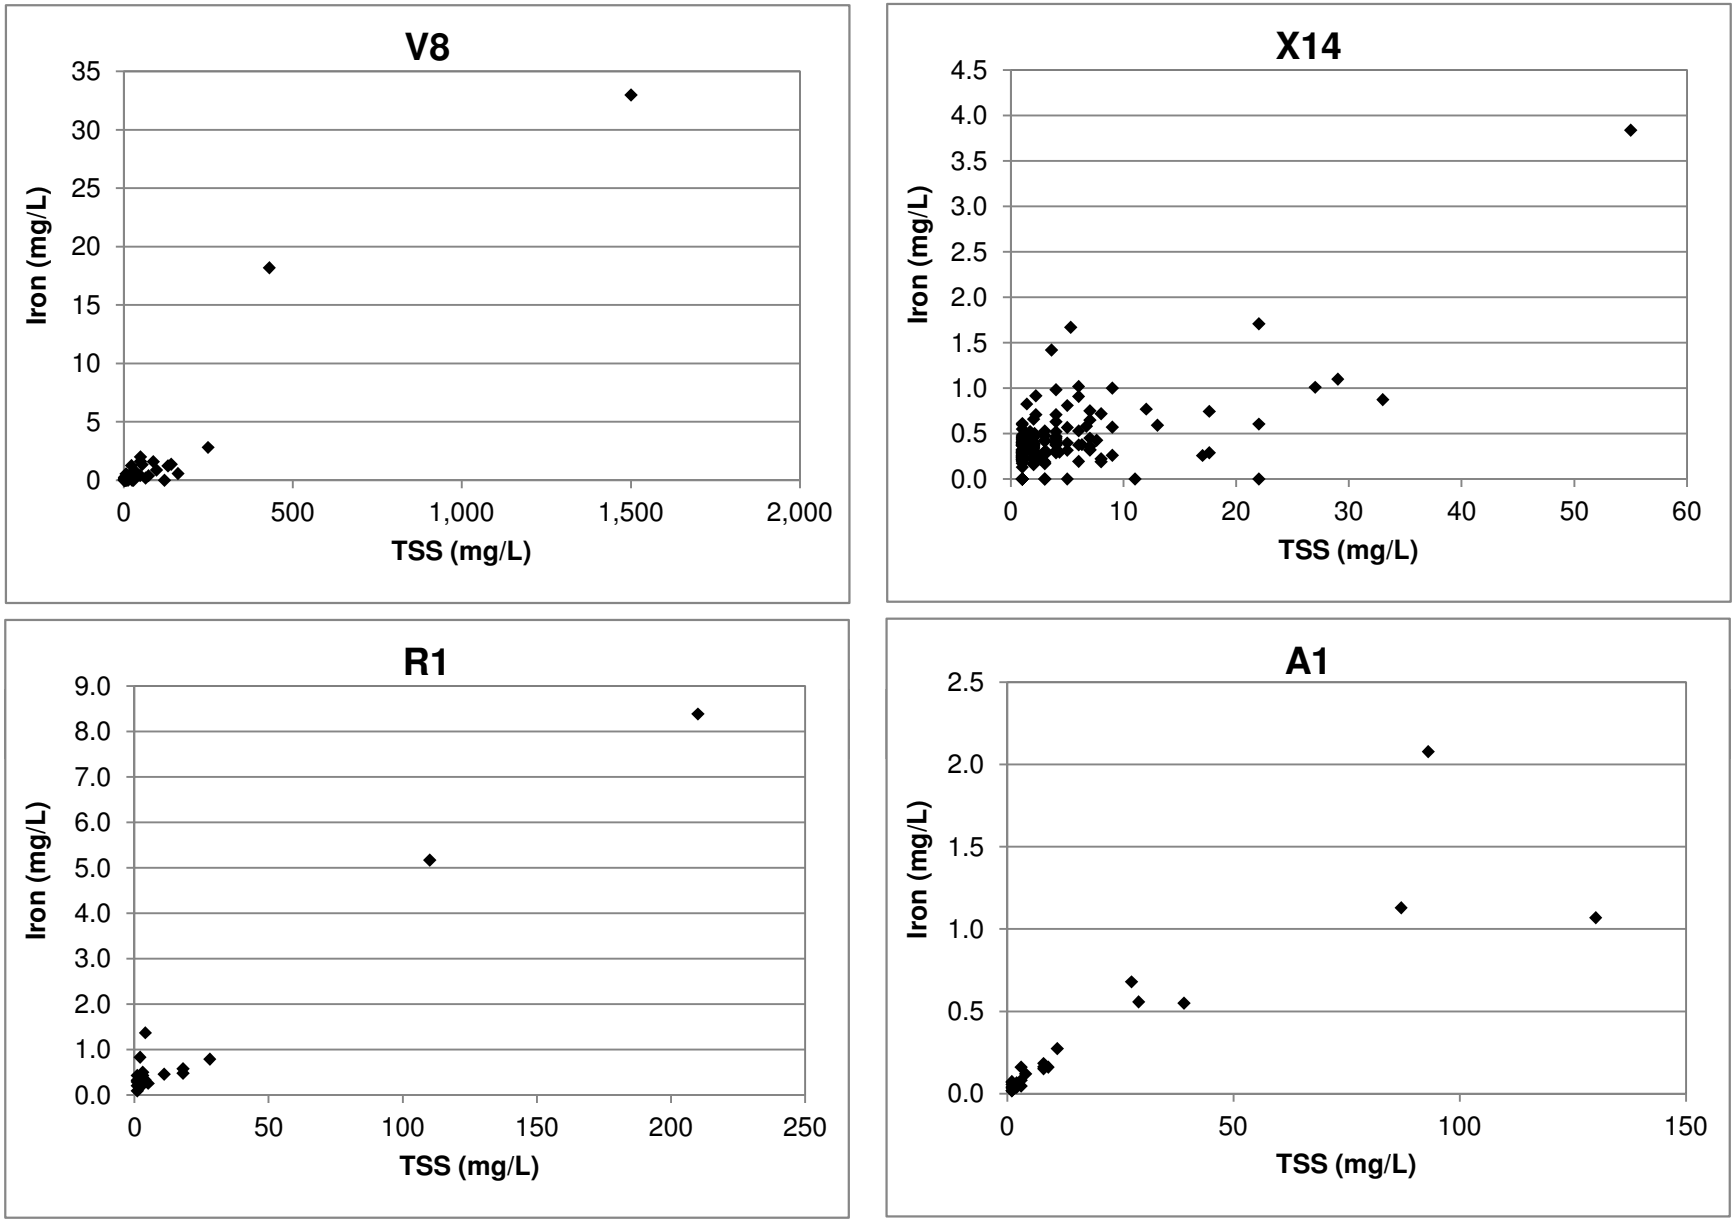

Figure 7C-2: Water concentrations of iron relative to total suspended solids at routine monitoring stations V8, X14, R1 and A1, 2008 - 2011.

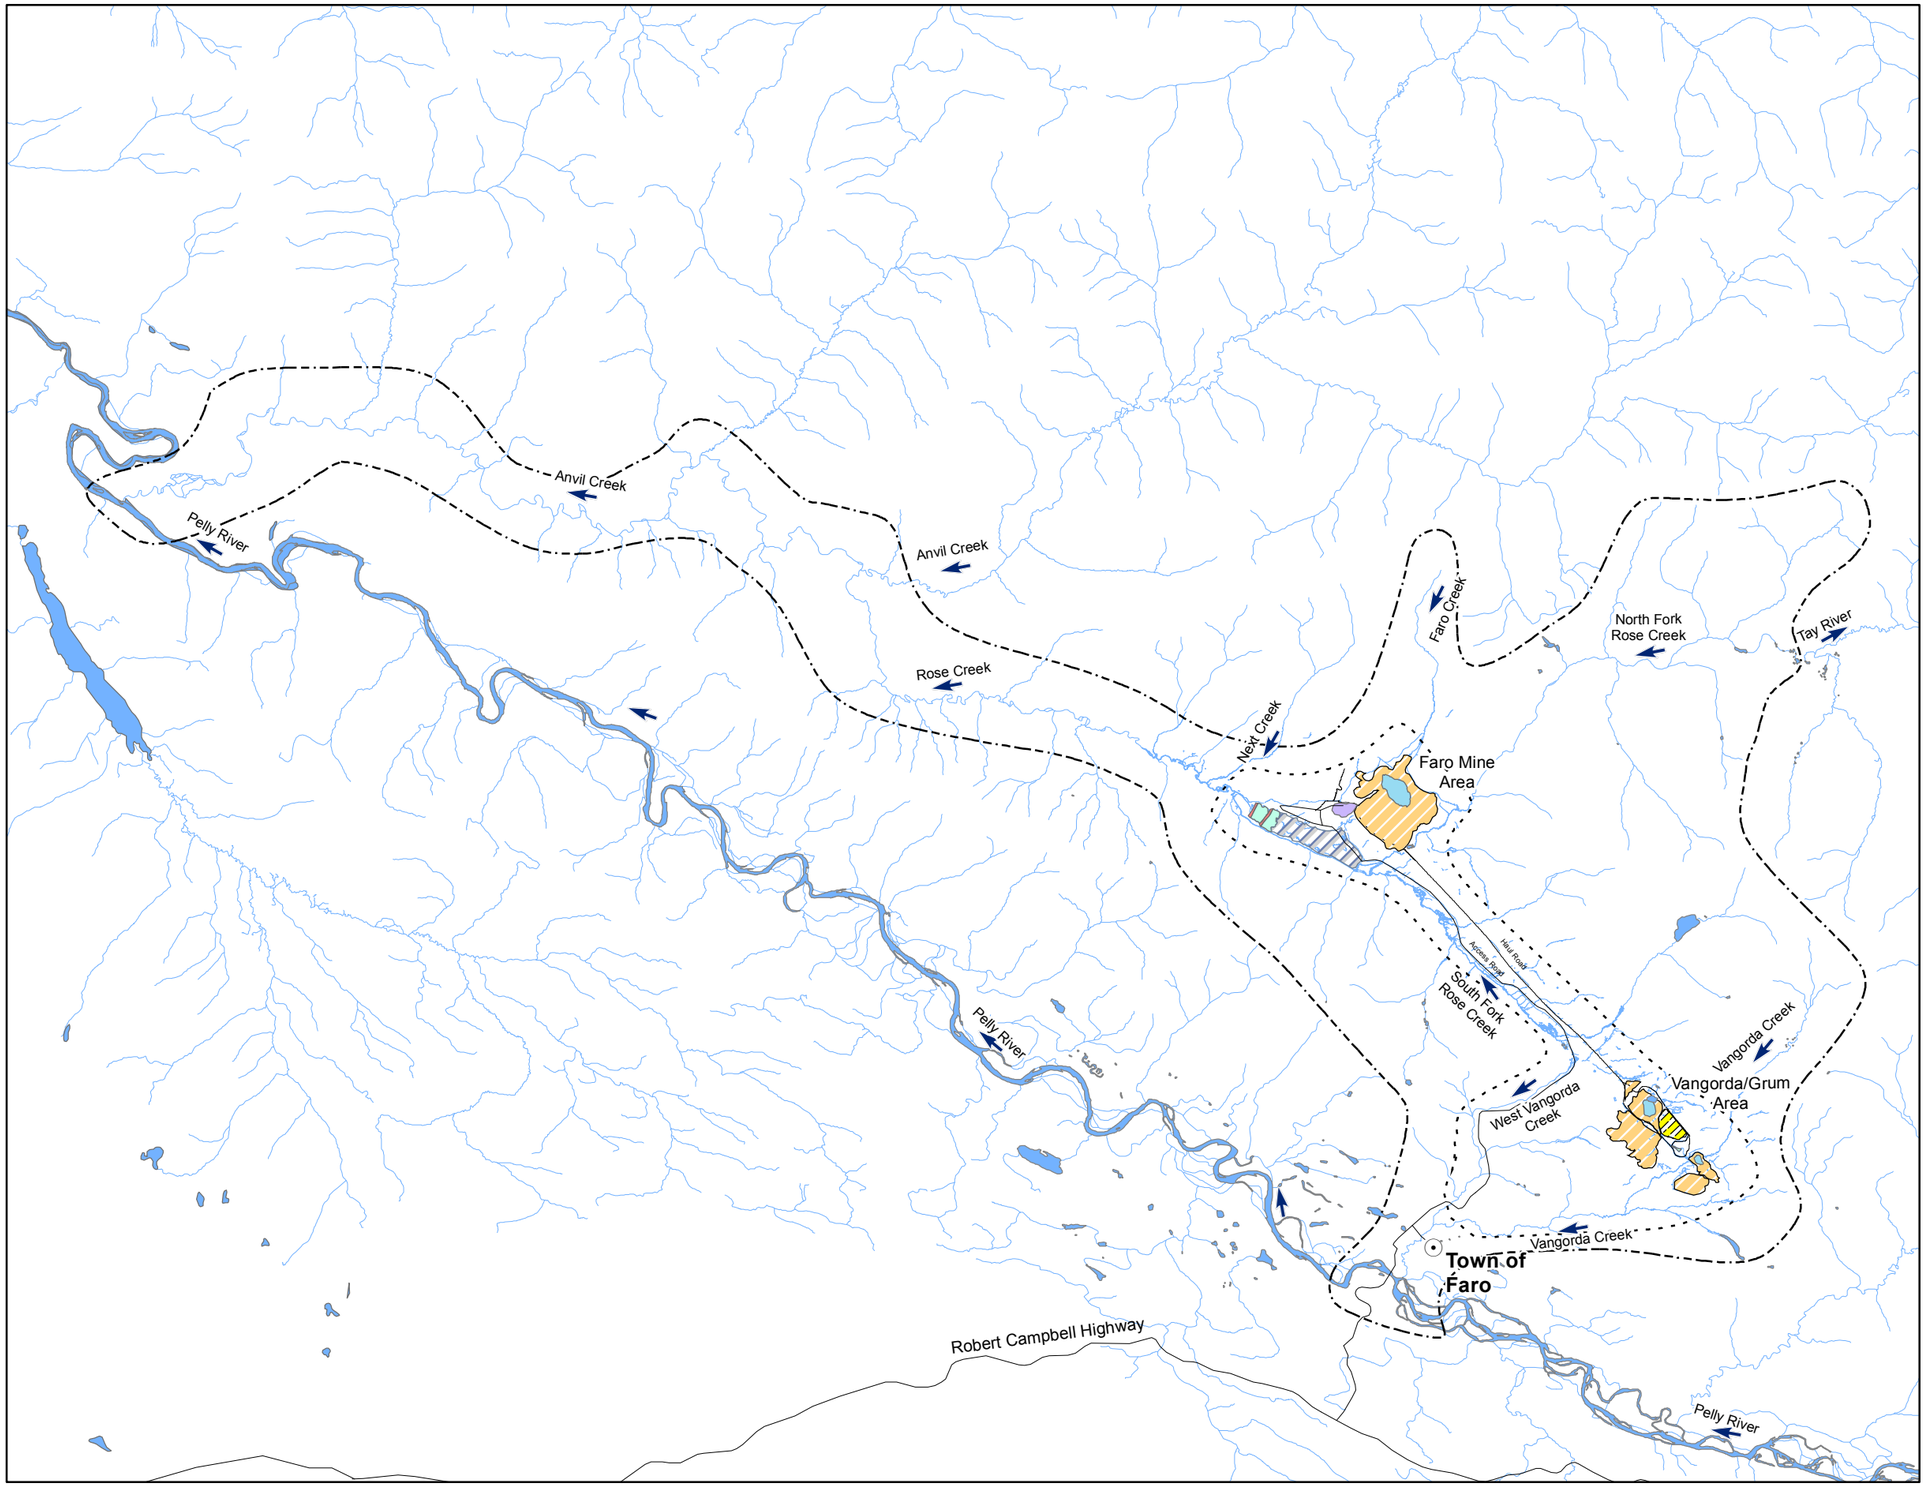
similar manner, namely by comparison to baseline concentrations (2008-12), water quality guidelines for protection of aquatic life, and toxicity data presented in the scientific literature for relevant aquatic species.

3.1.2 Spatial Boundaries

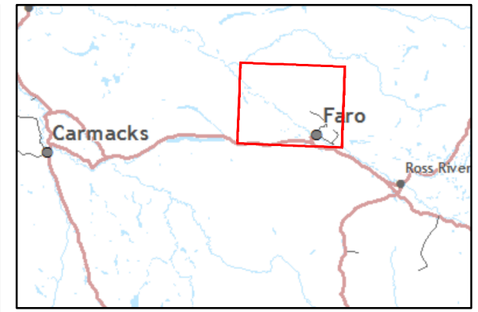
Both local and regional study areas are shown in Figure 7C-3 and described below, although, in the context of describing aquatic effects, these two areas are not functionally separate or distinct. Therefore, the effects assessment refers to local and regional study areas, where it is appropriate to do so, and otherwise refers to conditions in specific streams and locations within streams. Figure 7C-1 depicts locations of routine water monitoring stations that are specifically referenced within this document.

3.1.2.1 Local Study Area



The local study area (LSA) is the area within which the activities of the IW will take place and where associated effects, if any, are most likely to be realized. The LSA encompasses the footprint of the former FMC operations and streams within approximately 500 metres (m) of the mine disturbance footprint (Figure 7C-3). The mine disturbance footprint includes the Faro Mine Area to the west, and the Vangorda/Grum Area to the east, as well as the area between the two in which the mine Access Road and the Haul Road are located. The western and middle portions of the LSA include portions of Faro Creek and NFRC/SFRC, as well as the Rose Creek Diversion and Rose Creek immediately downstream from the tailings impoundment area (Figure 7C-3). The eastern portion of the LSA, includes sections of the west and main branches of Vangorda Creek.

3.1.2.2 Regional Study Area



The regional study area (RSA) is defined as the maximum area over which there is potential for measureable project-related effects. For the purpose of the IW Project, the RSA has been defined as the drainages downstream from the LSA to the Pelly River, including the areas within the Pelly River immediately upstream and downstream of the mouths of Anvil and Vangorda creeks (Figure 7C-3).

3.1.3 Protection Goals and Determining the Significance of Effects

An important context for determining the significance for aquatic environmental effects is that the FMC is an abandoned mine site storing a huge volume of potentially mobilizable contaminants in open pits, waste rock dumps, and tailings (Appendix 6A, Geochemical Characterization Report). Much is known about the site geochemistry and the sources that are currently contributing contaminant loads to surface water, and various forms of

Faro Mine Interim Works

Minnow Project No.: 2499 Date: January 2014

CH2MHILL

C:\WORKSPACE\PROJECTS\FARO\FAROMAPSERVICES\FAROFIGURESTANDARD\CH2M_FARO_MAPSERVICE_11X17_LANDSCAPE.MXD MWHITE5 11/29/2012 12:05:14 PM

mitigation have been put in place to mitigate effects (e.g., clean water diversions, contaminated water collection and treatment systems). However, there is potential for new pathways to develop between source areas and surface waters over time. Despite extensive groundwater monitoring programs, groundwater pathways, in particular, may go undetected until surface water quality begins to change. Consequently, an important component of future site management will continue to be the AMP, which is designed to allow for rapid detection of, and response to, emerging changes. Nevertheless, months may elapse between identification of and response to a newly emerged condition, during which time water quality may be unavoidably degraded. This means that it may not be possible to consistently control the magnitude of adverse effects, only the duration (i.e., response time). This situation contrasts starkly to that of an environmental assessment at a Greenfield site, where effects can be wholly prevented through appropriate design or denial of regulatory approval to proceed. At the FMC, YG and Aboriginal Affairs and Northern Development Canada (AANDC) are seeking regulatory approval to authorize continued maintenance and management activities that will mitigate environmental impacts, to the degree practicable, and to move the site towards an acceptable closure plan.

The purposes of the IW, as stated in section 1.2 of the Project Proposal are to control and reduce the effects of the existing FMC on human health and safety, and the environment and to compile sufficient site and environmental information to support design, assessment and permitting for the FMRP. Significant adverse environmental effects on the aquatic environment would almost certainly occur in the absence of the proposed project activities. With respect to fish and fish habitat, the overall protection goal of the IW is to avoid significant, direct, adverse effects on fish species. Criteria were developed to allow for the ranking of surface water quality effects as low, medium, or high based on the magnitude, likelihood, duration, geographic extent, and reversibility of predicted changes in water quality (Table 7C-2). Magnitude and likelihood/duration are considered together because potential effects on aquatic biota depend on the combined effects of these exposure characteristics at any given location.

As noted above, potential zinc effects were considered differently than those associated with the other mine-related contaminants (e.g., sulphate, cadmium, cobalt, lead, and manganese), because it is the dominant contaminant of concern at the FMC and a key indicator of changing geochemical conditions. Baseline data indicate that zinc concentrations in surface water around the FMC currently exceed water quality guidelines more often at more stations than do the other mine-related variables (Minnow, 2014).

Therefore, for the aquatic effects assessment, predicted surface water zinc concentrations are considered to have low significance if they do not exceed toxicity thresholds for relevant fish species throughout the local and regional study areas, based on normal seasonal cycles of water flow and concentration (Table 7C-2). An effect of medium significance was defined as the situation in which water concentrations may occasionally exceed the water quality guideline and fish toxicity thresholds for zinc; however, the latter condition could prevail only in the event of a new load source and would be sustained only as long as would be required to develop and implement a mitigation plan (likely less than 8 months) to return prevailing concentrations below fish effect thresholds (i.e., temporary condition). Effects would also be considered to be of medium significance if limited to the LSA or possibly extending to the mouth of Rose Creek or Anvil Creek, but not extending into Anvil Creek or the Pelly River. Predicted zinc concentrations are considered to have high significance if sustained indefinitely at levels that might be expected to harm fish, especially if such concentrations might extend into Anvil Creek or the Pelly River.

Concentrations of the other mine-related variables (e.g., sulphate, cadmium, cobalt, lead, and manganese) are considered to be of low significance if they are predicted to always, or almost always, meet water quality guidelines throughout the local and regional study areas, based on normal seasonal cycles of water flow and concentration (Table 7C-2). Potential effects of water concentrations of these variables are assigned medium significance if levels are expected to sometimes exceed water quality guidelines in the LSA and perhaps in lower Rose Creek or Anvil Creek, but are not expected to exceed toxicity thresholds for relevant fish species. Effects are ranked highly significant if concentrations are expected to be above levels that may harm relevant fish species, especially if such concentrations were to be sustained over time and extend into Anvil Creek or the Pelly River.

3.1.4 Water Quality Predictions

“Normal” surface water quality associated with the 2014-2023 period of the IW was modeled as described by Appendix 7B - Description of Water Modeling and Results. Resulting predictions are presented in Attachment A Figures A.1 to A.4, which show the results of 200 stochastic simulations for representative mine-related variables (zinc, cadmium, cobalt, manganese), including predicted 5^{th}, 50^{th} and 95^{th} percentiles for each month over the 10-year period at representative stations. Monthly summary statistics derived from all stochastic realizations of the predictions are presented for these and additional variables (sulphate, lead, hardness) in Attachment A Tables A.1 to A.9.

Hardness was included because of its effect in modifying the toxicity of some of the relevant water quality variables.

The predicted monthly concentrations presented in the tables of Attachment A are values that were not exceeded in x percent of months, where "x" represents the 5th, 50th and 95th percentiles of all simulation results. For example, 95th percentiles mean that 95 percent of the months had concentrations below the value shown on the tables. In other words, 1,900 out of the 2,000 individual months simulated (10 years multiplied by 200 stochastic simulations) had concentrations below that value. Each table summarizes, for a specific location, the monthly concentrations at the three percentiles for hardness, sulphate, cadmium, cobalt, lead, manganese, and zinc, and the percentage of months that applicable water quality guidelines will likely be exceeded at each location (i.e., "monthly exceedance probabilities"). The monthly exceedance probability represents the percentage of months that guidelines were exceeded out of the total 24,000 months considered in the simulation. For example, a 3 percent monthly exceedance value for cadmium means that predicted cadmium concentrations were above the guidelines in 720 months out of the 24,000 months considered in the stochastic simulation. The 24,000 months are from the monthly model results of a 10-year stochastic simulation with 200 realizations (12 months times 10 years times 200 stochastic realizations). Further details regarding the modelling assumptions and approach are presented in Appendix 7B - Description of Water Modeling and Results.

Annual variation in water quality at the FMC is generally associated with three seasons: winter baseflow, spring freshet, and the summer/fall ice-free period. Therefore, water quality predictions were further summarized according to season and compared to baseline conditions and water quality guidelines (Attachment A Tables A.10 to A.17).

Predicted concentrations were first compared to water quality guidelines for protection of aquatic life (Table 7C-3), using federal guidelines, if available (e.g., cobalt, cadmium, lead, zinc), otherwise guidelines developed by the British Columbian Ministry of Environment were used (e.g., sulphate, manganese). Predictions were then compared to toxicity data presented in the literature for any variables predicted to exceed water quality guidelines during the 10-year IW period.

3.1.5 Aquatic Toxicity Data

For water quality variables predicted to exceed guidelines for protection of aquatic life at some stations (cadmium, cobalt, manganese, zinc; see Section 3.2), the predicted concentrations were also compared to toxicity data reported in the scientific literature for

Table 7C-3: Summary of water quality guidelines relevant to selected stations at FMC (units mg/L)

Variable	Generic Guideline	Guideline Applied to Each Station for Evaluation of Water Quality Predictions[a] (and median station hardness 2008-12)							
		NF1 (91 mg/L)	X2 (108 mg/L)	X3 (115 mg/L)	X14 (217 mg/L)	R4 (156 mg/L)	V8 (301 mg/L)	A1 (161 mg/L)	P4 (173 mg/L)

The zinc guideline is currently being updated to incorporate relevant scientific literature published since the original guideline was developed (1987) and is expected to be based on water hardness.

[d] Environment Canada. 2013. Federal Environmental Quality Guidelines: Cobalt. February 2013.

aquatic biota. Data were compiled for both acute (short-term) exposures and chronic (long-term) exposures (Attachments B-E). Raw data tables present the available details of each toxicity test. Depending on the species and life-stage tested, short-term exposures were typically defined as less than one day (algae), four days (invertebrates and larval fish), or seven days (older fish), consistent with current Environment Canada protocols (CCME 2007). However, long-term exposure data are generally considered most relevant and conservative for assessing potential effects of predicted concentrations, because conditions cannot be reliably predicted for periods as brief as hours or a few days.

Cobalt toxicity data were taken from the federal water quality guideline recently developed by Environment Canada (2012) as well as the guideline used in British Columbia (Nagpal 2004) (Attachment D, Tables D.1 to D.3). The aquatic toxicity of the other metals of interest (cadmium, manganese, zinc) is influenced by water hardness, although the current guideline for zinc, developed in 1987, does not reflect this[2]. In order to rank the relative sensitivities of different aquatic species to these metals, it was necessary to convert reported effect concentrations to a common water hardness. Data sources and the approaches used for adjusting toxicity data to the different water hardnesses are discussed below for each metal.

3.1.5.1 Cadmium

The federal water quality guideline for cadmium (CCME 2014a) was used as the basis for assessing potential effects to aquatic species. The guideline rationale document (CCME 2014b) presents the water hardness-cadmium toxicity slopes for a range of aquatic species and explains how the data were combined to derive average slopes for both short-term and long-term exposures. For species that were tested in water with different water hardness, the derived slopes were used to adjust all toxicity data to a common water hardness of 50 milligrams per litre (mg/L). The tables of toxicity data presented by CCME (2014b), adjusted to a common water hardness of 50 mg/L, are presented in Attachment C, Tables C.1 and C.2, and the same slope factors were used to also express the toxicity data for water hardnesses of 100 and 200 mg/L.

3.1.5.2 Manganese

No federal water quality guideline exists for manganese but guidelines have been developed in British Columbia (Reimer 1999) and the United States (GEI 2009). Data

[2] An update is underway and the revised guideline is expected to be hardness-based.

from these sources, plus USEPA (2010) were combined and hardness-toxicity slopes derived by GEI (2009) were used to convert all toxicity to water hardnesses of 50, 100, and 200 mg/L (Attachment E, Tables E.1-E.3)

3.1.5.3 Zinc

For zinc, hardness-toxicity relationships were developed from data reported in the scientific literature following procedures similar to those used by other authors for cadmium (CCME 2014b) and manganese (GEI 2009) (Attachment B, Figure B.1). Raw data were examined to identify toxicity tests for which the hardness of the exposure water was reported and then identify species for which there were data for the same or similar endpoints over a range of exposure water hardness levels (>2-fold range), including at least one exposure with water hardness of at least 100 mg/L. Only zinc toxicity tests that were conducted at pH ≥ 7.4 were included to minimize the confounding influence of pH on the available toxicity data[3]. If there were replicate test results within a study for the same endpoint at the same or similar water hardness, geometric mean hardness and effect concentrations were computed before using the data to define the hardness-toxicity relationship for the substance.

The resulting data were then plotted for each species based on a regression of natural logarithm (Ln) of toxicant concentration as the dependent variable against Ln of hardness as the independent variable. This yielded the species-specific slopes for the hardness-toxicity relationship. There were sufficient data to derive a slope for at least one plant/alga, invertebrate, and fish species. The slopes for the hardness-toxicity relationships were tested for differences among species and then, not being different, were combined to derive an average slope.

To assess relative species sensitivity, the lowest toxic effect concentration corresponding to an exposure hardness of 100 mg/L was identified for each study and species. A hardness of 100 mg/L as $CaCO_3$ was selected as the basis for ranking species sensitivities, because water hardness downstream of the Faro Mine is rarely lower than this level (Minnow 2014). For studies not including an exposure hardness of 100 mg/L, the toxic effect concentration for each study-species combination was adjusted to an exposure hardness of 100 mg/L based on the combined slope for the hardness-toxicity relationship. The lowest value for each species (at hardness of 100 mg/L) was then identified and used to rank all species in terms of relative sensitivity. In cases where there

[3] Also, more relevant toxicity data were available for a basic than neutral-acidic range of exposure pH and the pH range for surface waters around and downstream from the FMC are expected to usually be circum-neutral to slightly basic.

were both effect (e.g., EC10, IC25, maximum acceptable toxicant concentration [MATC], etc.) and no-effect (NOEC) endpoints reported, the lowest effect concentration was selected.

For species for which the original test hardness was reported, the same slope factors described above were also used to estimate toxicity at water hardness values other than 100 mg/L. If test hardness was not reported, an adjustment could not be made and the same reported effect concentration for the species was assumed for all water hardness.

3.2 Analysis of Potential Effects

As noted in Section 3.1.1 the assessment focuses on potential effects associated with a normal operating scenario for the IW. However, there is potential for worse conditions to periodically develop, and water quality may be degraded relative to normal conditions until a remedial solution can be developed and implemented (e.g., a period of up to 8 months). In such circumstances, it is expected that, as during normal operations, zinc will be the dominant contaminant of concern. So the assessment also considers the potential effects of zinc during an episodic adverse scenario.

3.2.1 Initial Evaluation of Predicted Water Quality

For the normal operating scenario, predicted concentrations were initially compared to baseline concentrations for representative local and regional monitoring stations (Table 7C-4) and to water quality guidelines (Table 7C-3). Some water quality guidelines vary based on water hardness, so station specific guidelines were developed based on observed water hardness over the baseline period (Table 7C-4). Future median surface water concentrations of sulphate, cadmium, and lead are expected to be below water quality guidelines for protection of aquatic life during winter baseflow, spring freshet, and summer/fall periods at all stations (Table 7C-4; Attachment Tables A.10-A.17). Even predicted 95th percentile values for sulphate and lead are not expected to exceed the guidelines[4] (Attachment Tables A.1-A9). Therefore, it is assumed that no significant adverse effects to aquatic biota will arise as a result of exposure to sulphate or lead, and these substances were not evaluated further. However, the predicted range of values for cadmium suggests that peak concentrations may occasionally exceed guidelines at some locations (Attachment Tables A.1-A.9) so potential effects of cadmium were evaluated. Also, median as well as peak concentrations of cobalt, manganese, and zinc are predicted to be above guidelines at some stations and/or seasons (Table 7C-4; Attachment Tables

[4] Only the 95th percentile values at X14 in April and V8 in August were slightly above the sulphate guideline and judged to be inconsequential in the context of all other results.

Table 7C-4: Current (2008-2012) versus predicted (2014-2023) median (50th percentile) of seasonal water concentrations for key mine-related variables. Shaded values are above the water quality guideline.

[a] Table 7C-3

[b] Insufficient data

A.1-A.17). Therefore, potential surface water quality effects associated with cobalt, manganese, and zinc are also discussed in detail below.

3.2.2 Cadmium

3.2.2.1 Aquatic Chemistry

Cadmium is a relatively rare element, ranking 64th in relative abundance of elements in the earth's crust at concentrations of about 0.2 milligrams per kilogram (mg/kg) (CCREM 1987). It is a minor nutrient for plants at low concentrations (Lane and Morel 2000, Lee et al. 1995, Price and Morel 1990), but has no nutritional value for animals (USEPA 2001). Cadmium concentrations in uncontaminated surface waters are typically <0.1 micrograms per litre (µg/L) (Hollis et al. 2000a). In most well oxygenated fresh waters with low organic carbon content, free divalent cadmium (Cd^{2+}) will be the predominant form (USEPA 2001).

Cadmium has only a moderate affinity for dissolved organic material and binding decreases with increased water hardness (Pentinnen et al. 1998). Adsorption of cadmium onto soil particles, silicon or aluminum oxides is strongly pH-dependent, increasing as conditions become more alkaline (USEPA 2008). However, cadmium has considerably less affinity for such absorbents than copper, zinc, and lead and is therefore relatively more mobile in aquatic environments (USEPA 2008). The portion of cadmium absorbed to mineral surfaces (e.g., clay) or organic materials may be released in the dissolved state when sediments are disturbed (USEPA 2008). Cadmium found in association with carbonate minerals, precipitated as stable solid compounds, or co-precipitated with hydrous iron oxides may be less readily mobilized by re-suspension of sediments or biological activity (USEPA 2008). Desorption from sediment particles may also be enhanced at pH below 6 or 7 (Van Deuren et al. 2002). Overall, precipitation of cadmium by carbonate or hydroxide and formation of soluble complexes by chloride, sulfate, carbonate, and hydroxide is usually of limited importance in aquatic environments (USEPA 2001).

3.2.2.2 Mode of Toxicity

The Cd^{2+} ion is the most bioavailable and toxic form of Cd to aquatic organisms (Pagenkopf 1983). Cadmium is taken up through chloride cells in external membranes of fish (e.g., gills) and invertebrates (Verbost et al. 1989, Wicklund-Glynn et al. 1994; Silvestre et al. 2004). These are the cells regulating calcium uptake from water (Galvez et al. 2006). At cell surfaces, Cd^{2+} competes with Ca^{2+} for specific, high-affinity calcium-binding sites (Playle 1998, Playle et al. 1993a and 1993b; Croteau and Luoma 2007), although low-affinity, high-capacity binding sites may also play a role in cadmium toxicity,

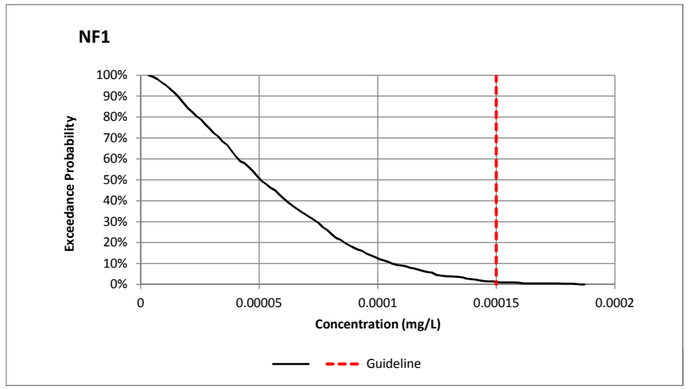
at least for some aquatic species (Niyogi et al. 2004). Binding site characteristics are altered in chronic versus acute exposures to calcium or cadmium (Hollis et al. 2000a and 2000b; Niyogi et al. 2004).

The effect of the above is that cadmium blocks calcium uptake and causes calcium deficiency (hypocalcemia) (Roch and Maly 1979; Verbost et al. 1987 and 1989). Unlike for zinc (Section 4.2.2), the inhibition of calcium uptake by cadmium may not be readily reversible (Reid and McDonald 1988). Internally, cadmium accumulates primarily in kidney, liver, and gills of fish (Benoit et al. 1976, Hollis et al. 1999, 2000a, and 2000b).

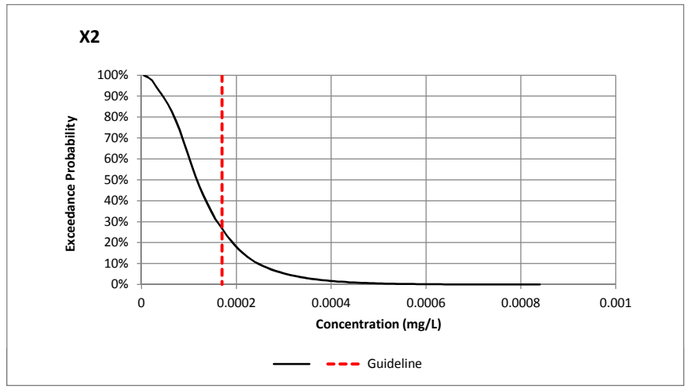
At acute waterborne concentrations, cadmium severely disrupts calcium homeostasis, which ultimately leads to death (Verbost et al. 1987; Reid and McDonald 1988). Cadmium effects may also be manifested as reduced growth (Peterson et al. 1983, Borgmann and Ralph 1986) and/or reduced reproductive performance (Dobson 1992, Brown 1994), although growth is not always a more sensitive endpoint than survival (Eaton et al. 1978, Anderson 1980; Hollis et al. 2000a and 2000b). Survival was the most sensitive test endpoint for *Hyalella azteca* exposed to cadmium in water whereas *H. azteca* exposed to dietary cadmium showed growth effects at concentrations lower than those affecting survival (Ball et al. 2006). This suggests that dietary cadmium may have a different mechanism of toxicity than water-borne cadmium. Reproduction of *Daphnia magna* was affected at aqueous cadmium concentrations almost an order of magnitude lower than those causing mortality (Barata and Baird 2000). Typically, the maximum cadmium concentration that can be tolerated by a species is 0.002 times the acute lethal concentration or higher (Marshall 1979, U.S. EPA 2001). Among fish, swim-up alevins or young juveniles appear to be more sensitive to cadmium exposure than younger or older life-stages (Benoit et al. 1976, Chapman 1978, Eaton et al. 1978, Buhl and Hamilton 1991).

Cadmium toxicity to biota may be greater from waterborne exposure than dietary exposure (Abel and Barlocher 1988, Spry et al. 1988, Sofyan et al. 2007) or the converse (Roy and Hare 1999). Greatly elevated Cd levels in diet were required compared to waterborne exposures to achieve the same gill burden in rainbow trout, suggesting that the gut provides a better barrier than the gill to internal accumulation (Szebedinszky et al. 2001). At similar cadmium burden in gills, trout with dietary pre-exposure had lower accumulation in liver and kidney of new Cd from water than in trout pre-exposed to cadmium via water only, indicating the route of cadmium exposure affects cadmium uptake and tissue distribution characteristics (Szebedinszky et al. 2001).

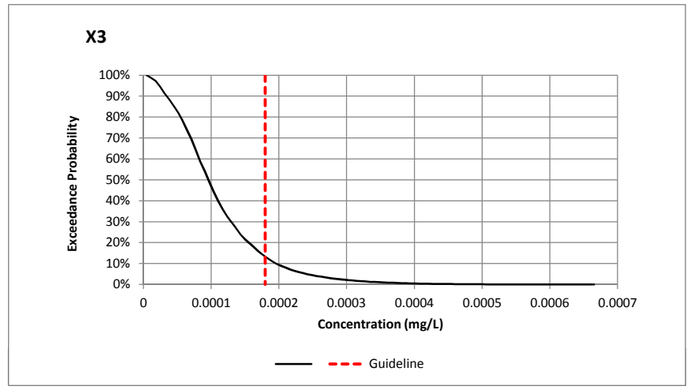
Among various water quality characteristics that could potentially influence Cd uptake and toxicity (e.g., hardness, pH, alkalinity, and dissolved organic matter (DOM)), hardness is often reported to be the dominant factor (Calamari et al. 1980; Hollis et al. 1997 and 2000b; Pentinnen et al. 1998; Hansen et al. 2002).



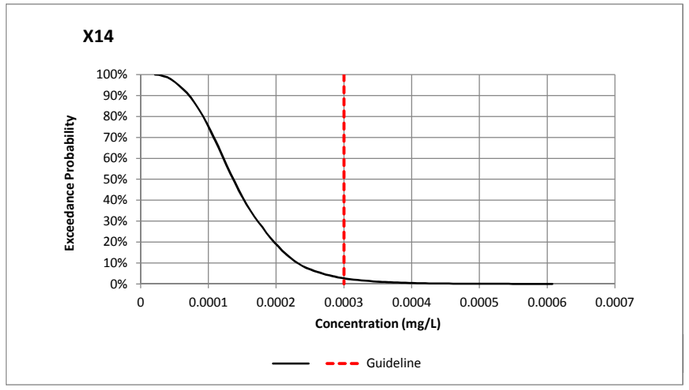
3.2.2.3 Predicted Concentrations and Effects



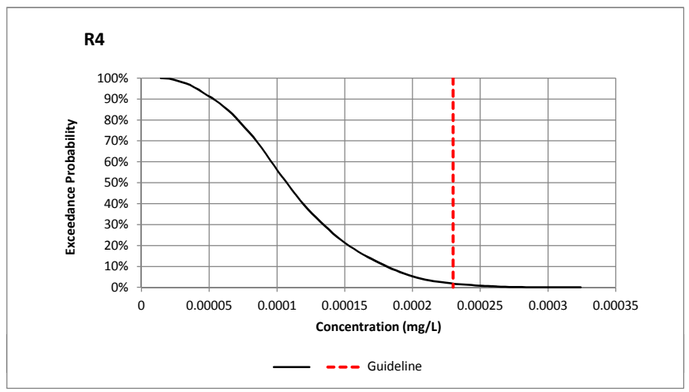
Under the normal operating scenario, median concentrations of cadmium are predicted to be slightly higher than baseline conditions during the IW period, but will still be less than water quality guidelines for protection of aquatic life (Table 7C-4). However, peak concentrations may occasionally exceed the guidelines in lower NFRC (X2), RCD (X3), in Rose Creek immediately downstream of the Faro Mine Area (X14) and in lower Vangorda Creek (V8) (Attachment Tables A.2-A.4, A.9). The probabilities of such exceedances range from approximately 3 percent at X14 to 25 percent at X2 (Figure 7C-4). However, toxicity to most aquatic species occurs at concentrations of 0.0005 mg/L or more, and fish are typically unaffected until concentrations are at or above approximately 0.0017 mg/L (Table 7C-5). Concentrations are not expected to be above 0.0005 mg/L in the Rose-Anvil creek system and will be below 0.0007 in lower Vangorda Creek (Figure 7C-4). Therefore, cadmium concentrations associated with the IW are not expected to affect fish and will likely also have negligible effects on most other aquatic biota in both local and regional study areas.



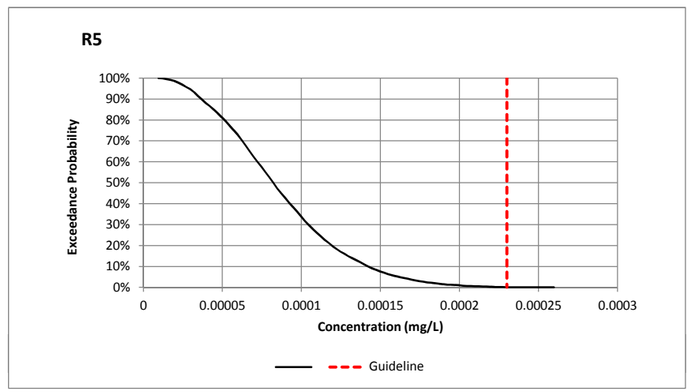
3.2.3 Cobalt

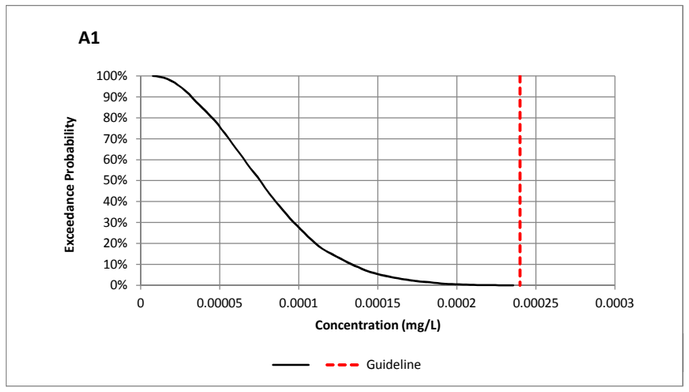


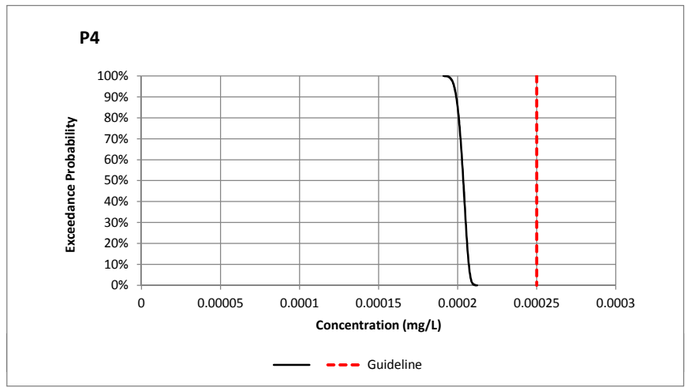
3.2.3.1 Aquatic Chemistry



Cobalt is the 33rd most abundant metal in earth's crust and is usually found only in a chemically combined form (Hamilton 1994; Blust 2012). In aquatic environments, cobalt mainly occurs in Co(II) and Co(III) valence oxidation states, forming organic and inorganic salts and complexes (Nagpal 2004). The solubility of cobalt salts is highly variable in water, depending on its form. Dominant species in fresh water are Co^{2+}, $CoCO_3$, $Co(OH)_3$ and CoS (Moore 1991). Cobalt strongly associates with dissolved and colloidal organic carbon (Blust 2012) and also adsorbs to particles and settles into sediment (Hamilton 1994). Cobalt tends to be associated with particulate phases in aquatic systems, with a lower proportion being present in dissolved form (Horowitz 1985, Environment Canada 2013). Concentrations of cobalt in aquatic environments have been shown to correlate inversely with pH and positively with suspended solids (Moore 1991).







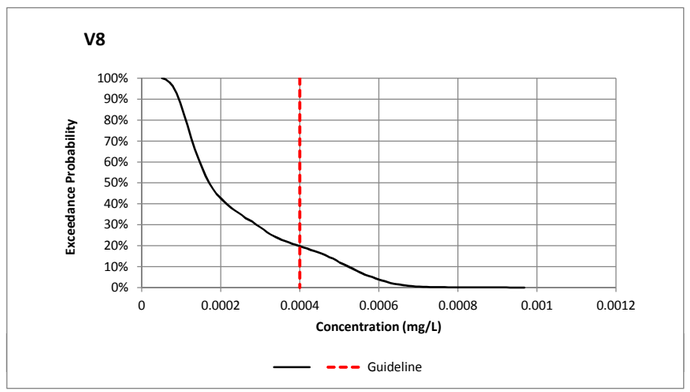


Figure 7C-4: Percentage of months when water concentrations of cadmium are expected to be above the water quality guideline.

Table 7C-5: Water quality guidelines for protection of aquatic life and approximate toxicity thresholds for key mine-related variables at the FMC. Detailed toxicity data for each metal are presented in Attachments B - E.

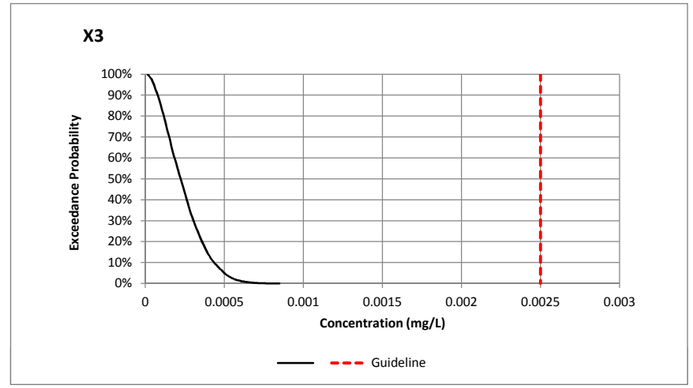
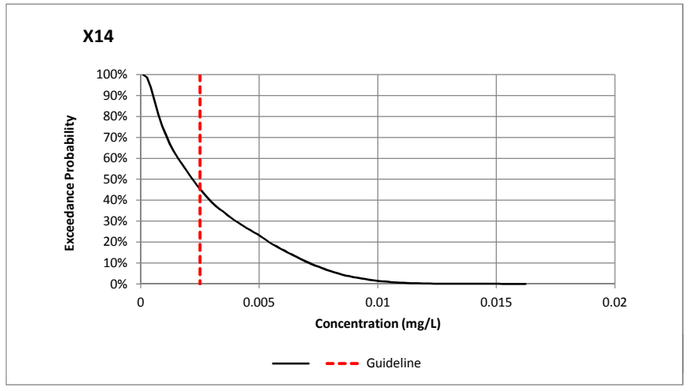
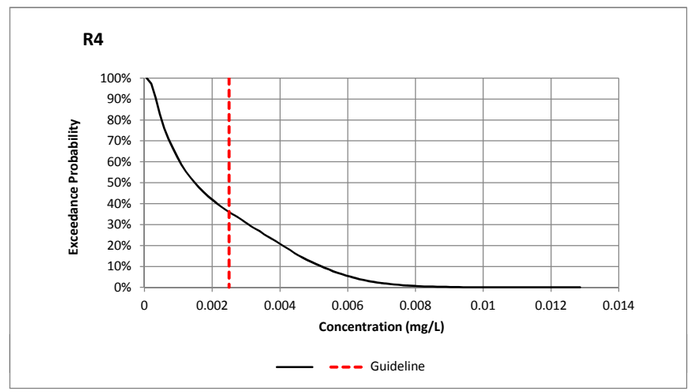
3.2.3.2 Mode of Toxicity



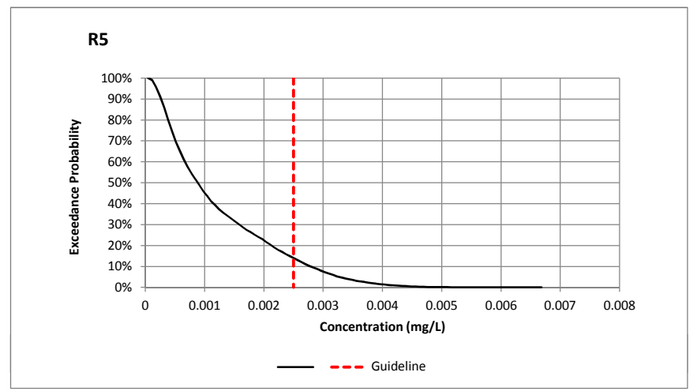
Cobalt is an essential element to animals, being an intrinsic part of vitamin B_{12} (cobalamin) and is also an active nutrient for bacteria, algae, and fungi (Blust 2012). Uptake of cobalt in freshwater fish is strongly dependent on speciation and calcium concentrations (Blust 2012). However, very little is known about the specific molecular mechanisms of cobalt uptake and toxicity and most inferences regarding mechanisms are from mammalian studies (Blust 2012). Generally, it is thought that cobalt inhibits various enzymes which causes a reduction in tissue respiration and metabolism (Smith and Carson 1981, as cited in Environment Canada 2013). For example, cobalt impedes the citric acid cycle and can also inhibit or stimulate different enzymes in the liver (Environment Canada 2013). In its Co(II) oxidation state, the cobalt ion can substitute for other divalent cations, reacting with the thio group of amino acids, proteins and other coenzymes and cofactors, resulting in altered enzyme activity (Smith and Carson 1981). In aquatic environments, invertebrates are generally more sensitive to cobalt exposure than fish (Environment Canada 2013).

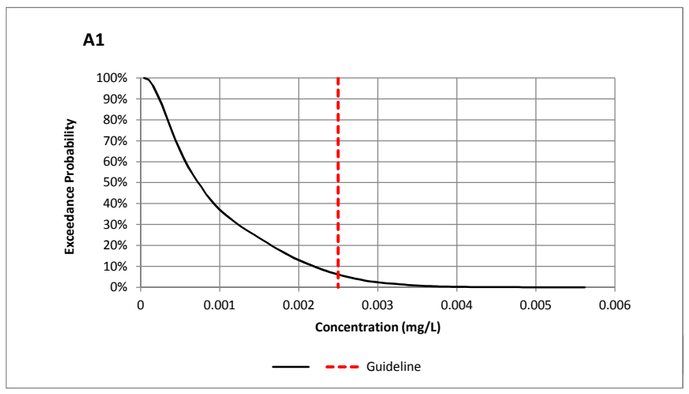


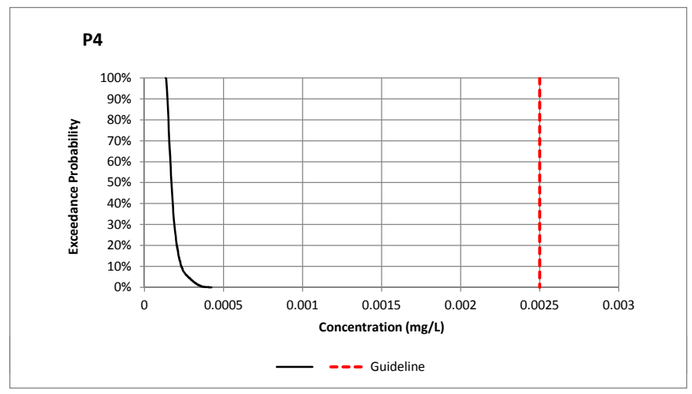
3.2.3.3 Predicted Concentrations and Effects



For the normal operating scenario, median concentrations of cobalt associated with the IW are predicted to be comparable to the range observed during the baseline period at most stations, but may increase in Rose Creek at X14 and R4 during the ice-free period, and also at V8 (Table 7C-5). A water quality guideline for cobalt of 0.0025 mg/L was recently developed by Environment Canada (2013) to protect against effects associated with long-term exposure. Water concentrations higher than the guideline are predicted for some stations in the Rose-Anvil system but not in Vangorda Creek (V8) (Figure 7C-5 and Attachment A). Concentrations in Rose Creek at X14 and R4 are predicted to exceed the guideline in approximately 45 percent and 35 percent of months, respectively (Figure 7C-5). The toxicity data used to derive the Environment Canada guideline are provided in Attachment D, Table D.3. In addition, toxicity data associated with acute exposures to cobalt were summarized by Nagpal (2004) (Attachment Tables D.1-D.2). Effects to sensitive invertebrates and algae have been reported at cobalt concentrations as low as 0.003 mg/L, but most organisms are not affected at concentrations below 0.02 mg/L (Tables 7C-5). Maximum cobalt concentrations are not expected to rise above 0.02 mg/L at any stations during the IW period (Figure 7C-5). Therefore, cobalt concentrations associated with the IW are not expected to affect fish and effects on most other aquatic biota are expected to be negligible.







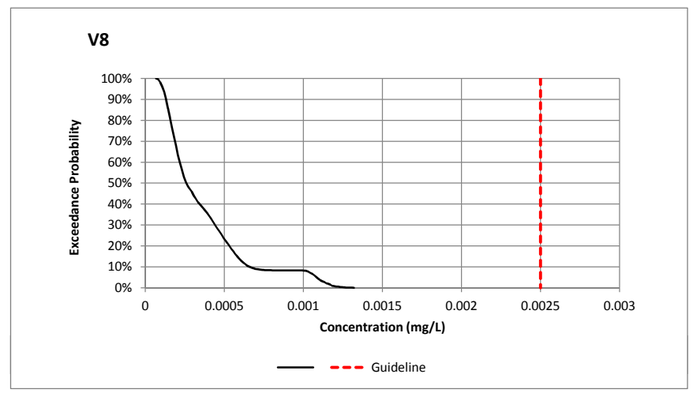


Figure 7C-5: Percentage of months when water concentrations of cobalt are expected to be above the water quality guideline.

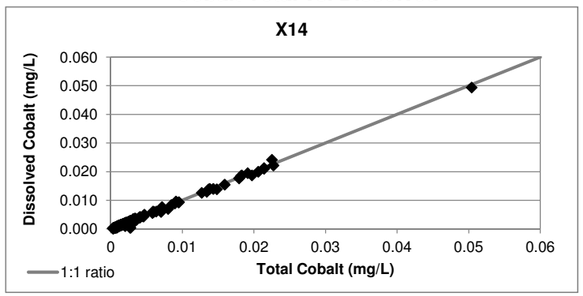
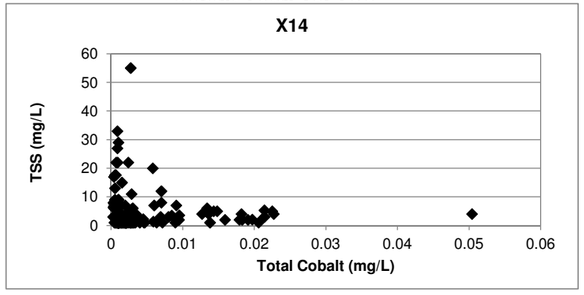
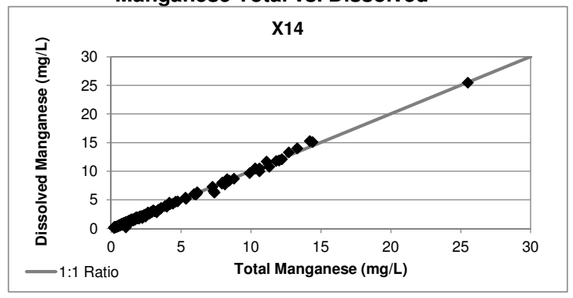


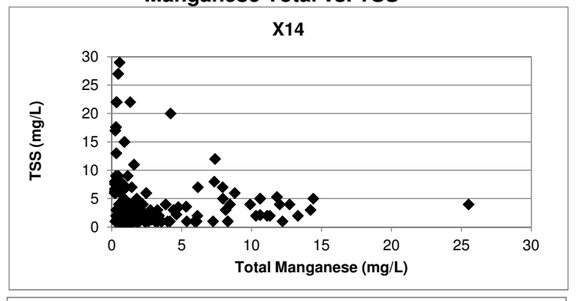
Furthermore, as noted in Section 3.2.3.1, cobalt tends to be associated with particulate phases in aquatic systems. Therefore, although cobalt is released at X14 mainly in the dissolved phase, highest concentrations in areas farther downstream tend to be increasingly associated with particulates than the dissolved phase (Figure 7C-6). Metals tend to be more bioavailable to interact with aquatic organisms in the free ion form than when complexed or speciated with other components in water (Luoma 1983, Morel 1983, Pagenkopf 1983, DiToro et al. 2001, Luoma and Rainbow 2008). Therefore, aquatic cobalt concentrations are expected to be increasingly less bioavailable farther downstream from the FMC as a result of partitioning to suspended and bottom sediments.



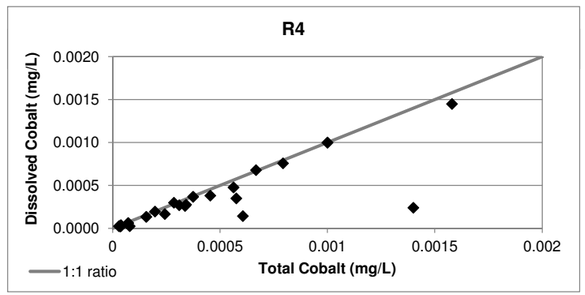
Based on all of the information presented above, it is expected that cobalt concentrations associated with the IW will have negligible effects on aquatic biota in either the local or regional study areas.



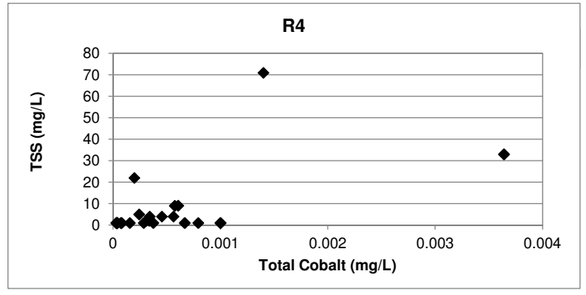
3.2.4 Manganese

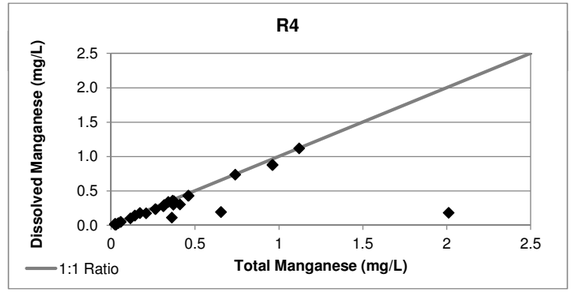


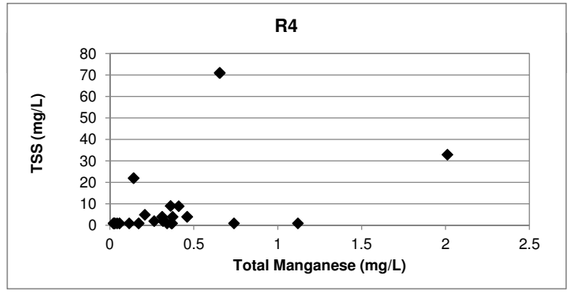
3.2.4.1 Aquatic Chemistry

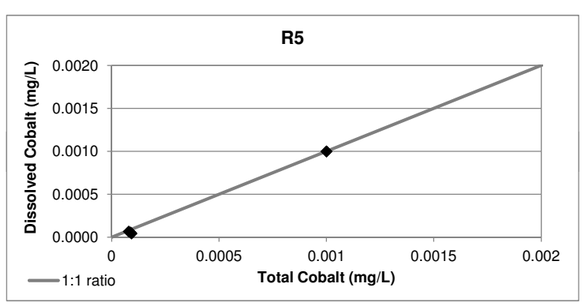


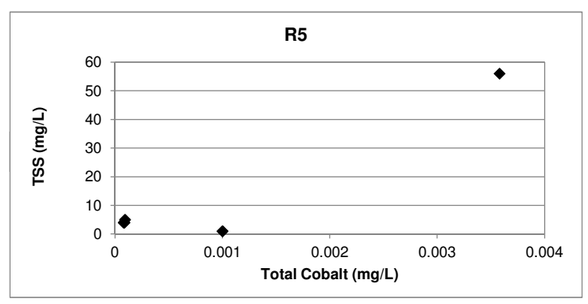
Manganese is the 12th most common element, the 4th most abundant metal, and is universally distributed in the earth's crust and waters (IMI 2013). Manganese naturally occurs in rocks and soils, most abundantly in metamorphic and sedimentary rocks, with overall crustal abundance of 0.085 percent to 0.095 percent (Reimer 1999). In aerobic surface waters with pH above 7, concentrations of dissolved manganese are low due to equilibrium reactions that favour conversion to Mn(IV), which tends to precipitate in the form of manganese oxides (MnO_2) (Moore 1991; Stumm and Morgan 1996). However, Mn(IV) is readily reduced under anoxic conditions to the soluble Mn(II) species (Stokes et al. 1988). Manganese solubility also increases under low pH conditions. As a result, manganese is most common in the Mn(II) and Mn(IV) oxidation states in aquatic systems, precipitating mainly as Mn(IV) and re-solubilizing in the water mainly as Mn(II) (Moore 1991). The binding constant for manganese with organic ligands is relatively weak (Irving and Williams 1953); consequently, divalent manganese exchanges rapidly between water and ligands (Baden and Eriksson 2006). Typically, 90 percent to 95 percent of the total waterborne manganese residue is associated with particulate matter (Nagpal 2001). Total manganese concentrations in surface water are usually highest during high runoff periods (e.g., spring snow melt), when particulate concentrations are high, and lower during periods of stable stream flow (Reimer 1999).

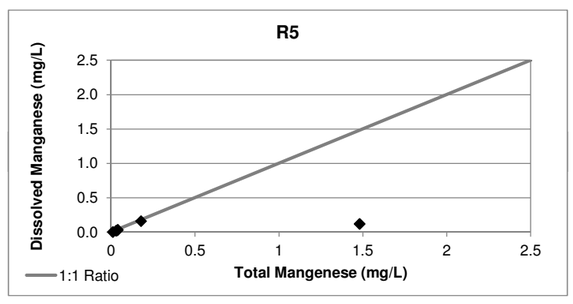


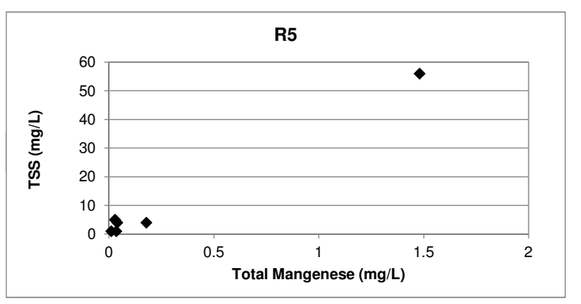


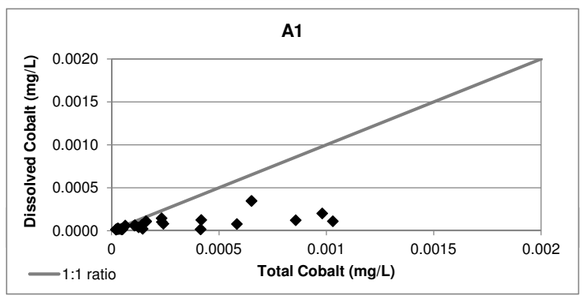


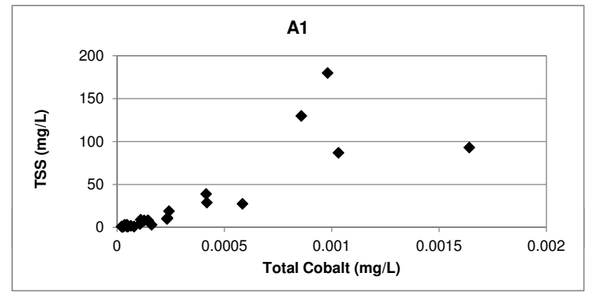


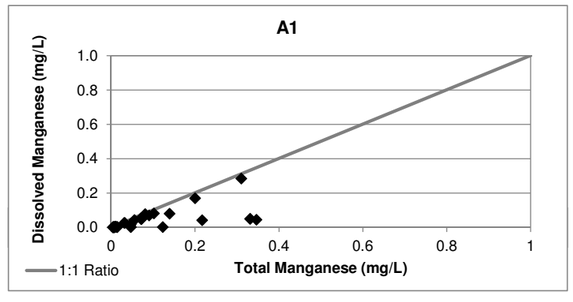












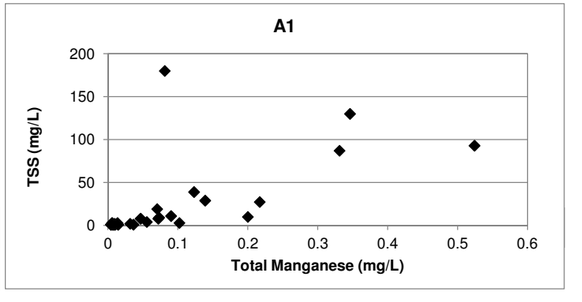


Figure 7C-6: Concentrations of total cobalt and manganese compared to dissolved concentrations and total suspended solids concentrations at stations X14, R4, R5 and A1 in the Rose-Anvil Creek system.

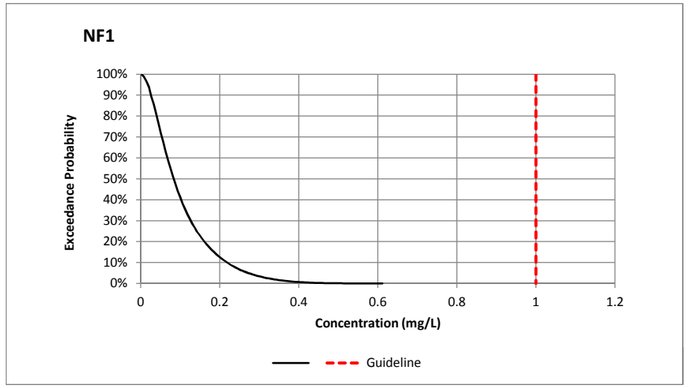
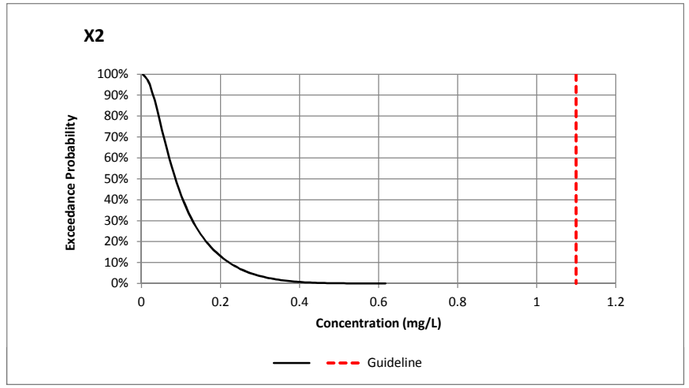
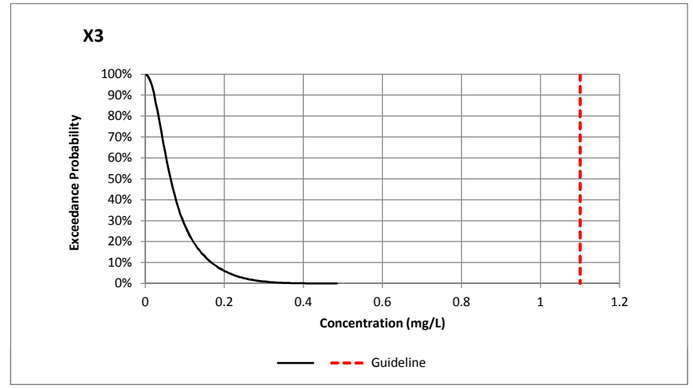
3.2.4.2 Mode of Toxicity



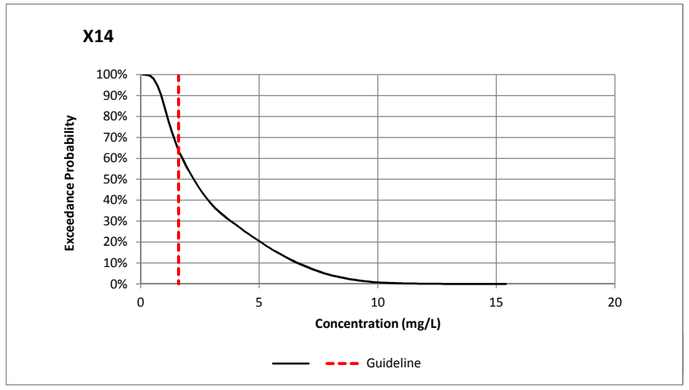
Manganese is an essential nutrient for optimal cellular function (Lasier et al. 2000; Strydom et al. 2006). Relative to many other metals it is considered only slightly to moderately toxic to aquatic organisms, and its presence often ameliorates the effects of other metals (Nagpal 2001). Soluble manganese species, which are readily available for biological reactions, are considered to be the most toxic (Nagpal 2001), but as noted above, most manganese in aerobic freshwater forms insoluble oxide precipitates or is bound to particulates. Consequently, the British Columbia water quality guideline recommends interpretation relative to the dissolved metal fraction in circumstances when elevated levels are associated with high particulate concentrations and there are no obvious concurrent adverse effects (Nagpal 2001). Information on the specific mode of toxicity to aquatic organisms is lacking, presumably because it is considered relatively non-toxic and it tends to precipitate to sediments in most aerobic receiving waters. In mammals manganese is known to cause neurotoxicity by increasing oxidative stress and also disturbing neurotransmitter metabolism (Erikson et al. 2004). As Mn(II), manganese has a relatively high affinity for sulphur and nitrogen in functional groups of proteins and other molecules, which enables Mn to interfere in a wide spectrum of biological processes (Simkiss 1979).



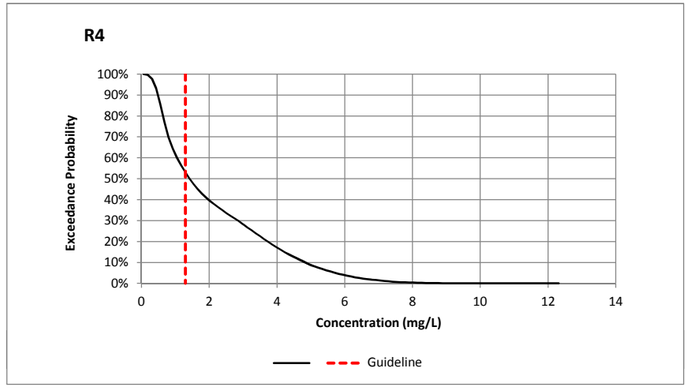
Manganese toxicity decreases as water hardness increases, so the water quality guideline varies depending on water hardness (Nagpal 2001).



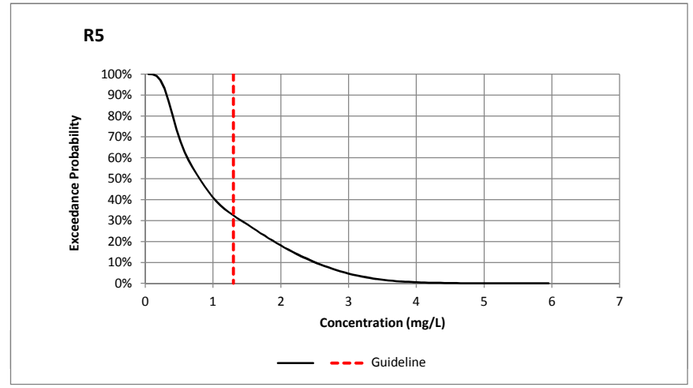
3.2.4.3 Predicted Concentrations and Effects

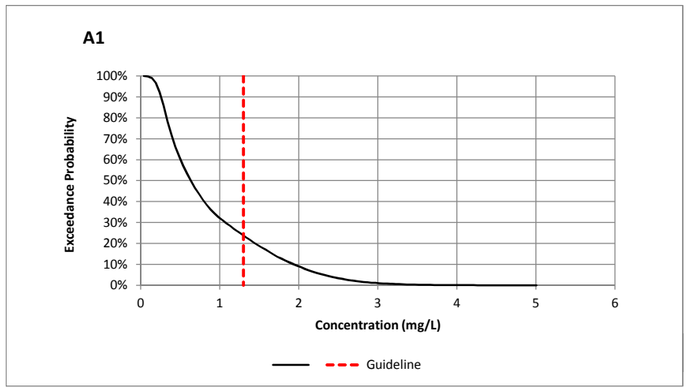


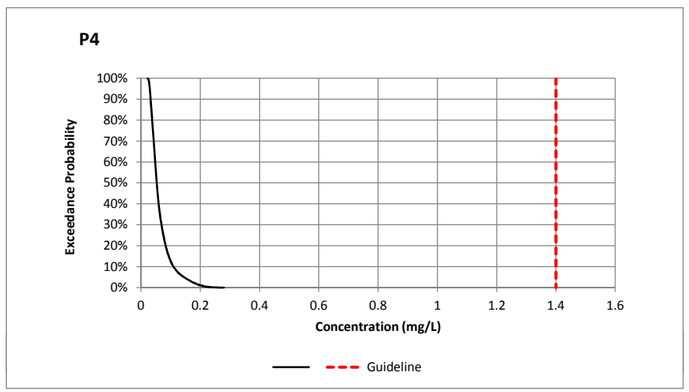
For the normal operating scenario, manganese concentrations are not predicted to change substantially from baseline conditions, except that concentrations may decrease slightly in winter months and increase slightly in other months at Rose Creek stations at, and downstream from, X14 (Table 7C-4). There is no federal water quality guideline for manganese, but British Columbia has established a guideline that varies based on water hardness (Table 7C-5). Manganese concentrations are predicted to be above the hardness-adjusted guidelines in a substantial percentage of months at X14 (65 percent) and in an increasingly lower percentage of months at stations increasing farther downstream (Figure 7C-7).



Toxicity data for manganese, particularly for long-term exposures, are sparse and there are no data for the specific fish species found near the FMC (Table 7C-5). The available data suggest that aquatic toxicity could occur at the manganese concentrations predicted at X14 (median 2.4 to 4.2 mg/L). However, winter manganese concentrations at X14







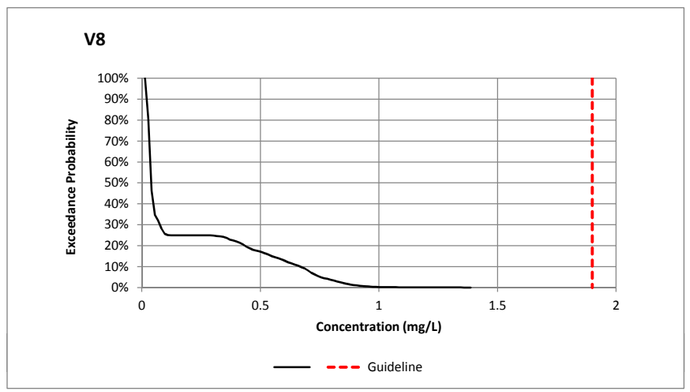


Figure 7C-7: Percentage of months when water concentrations of manganese are expected to be above the water quality guideline.

averaged 3.9 mg/L over the baseline period (Table 7C-4) and baseline biological studies concluded that mine-related effects on aquatic biota (e.g., benthic invertebrate surveys) were undetectable or relatively minor at X14/R2 (Minnow 2014). Also, the predicted median concentrations at X14 are unlikely to cause acute lethality to fish (Table 7C-5).

As noted in Section 3.2.4.1, manganese (like iron, Section 3.1.1, and cobalt, Section 3.2.3) tends to partition to particulate phases of freshwater aquatic systems. Therefore, although manganese is released at X14 largely in the dissolved form, highest concentrations in areas farther downstream tend to be increasingly associated with suspended solids and less in dissolved form (Figure 7C-6). Metals tend to be more bioavailable to interact with aquatic organisms in the free ion form than when complexed or speciated with other components in water (Luoma 1983, Morel 1983, Pagenkopf 1983, DiToro et al. 2001, Luoma and Rainbow 2008). Consequently, any effects associated with manganese are expected to be limited to the area immediately downstream of X14, with gradual reduction of bioavailable manganese farther downstream as a result of partitioning to suspended and bottom sediments.

Overall, the data indicate that aquatic effects, if any, of manganese in surface waters around the FMC would be limited to Rose Creek in the vicinity of X14 (i.e., within the LSA) and would likely be minor in magnitude.

3.2.5 Zinc

3.2.5.1 Aquatic Chemistry

Zinc ranks as the 24th most abundant element in the earth's crust, with an average concentration of 70 mg/kg (CCREM 1987). Zinc concentrations in uncontaminated freshwater are usually ≤ 10 µg/L (USEPA 1987). Zinc occurs in many forms in surface waters, including suspended and dissolved forms. Complexes of zinc with the common ligands of surface waters are soluble in neutral and acidic solutions, so it is readily transported and considered one of the most mobile of the heavy metals (USEPA 1987). Aqueous pH is an important factor influencing zinc speciation (Heijerick et al. 2002b and 2003; Wilde et al. 2006). In freshwater with pH around 6.0, the dominant inorganic forms are the free ion (98 percent) and zinc sulphate (2 percent), whereas at pH of 9.0, the dominant forms are the monohydroxide ion (78 percent), zinc carbonate (16 percent), and the free ion (6 percent) (Turner et al. 1981). Decreasing alkalinity and pH both favour the free metal ion (CCME 1999), which is considered to be the form responsible for aquatic toxicity (Heijerick et al. 2002a, De Shamphelaere et al. 2005).

In the presence of dissolved organic materials, much of the dissolved zinc may be in the form of zinc-organic complexes (Lu and Chen 1977; De Schamphelaere et al 2005), but some studies have shown that only a small proportion of zinc was complexed by organic ligands (CCME 1999; De Shampheleare and Janssen 2004). As with inorganic zinc speciation, formation of organo-zinc complexes is probably at least partially pH-dependent. Greater zinc sorption to dissolved organic carbon likely occurs at higher pH and higher concentrations of dissolved organic matter relative to the amount of zinc present (USEPA 1987; CCME 1999; Heijerick et al. 2003; De Shamphelaere et al. 2005).

Thus, zinc speciation is controlled by pH, alkalinity, and the concentrations of various other inorganic and organic ligands (CCME 1999). Most the zinc introduced to aquatic environments is eventually partitioned into sediment by sorption onto hydrous iron and manganese oxides, clay minerals, and organic materials (USEPA 1987).

3.2.5.2 Mode of Toxicity

Zinc is an essential micronutrient for all living organisms, being involved in nucleic acid synthesis and occurring in many enzymes (CCME 1999). Aquatic toxicity of zinc is primarily attributable to waterborne exposure to the free ion (Zn^{2+}) (Heijerick et al. 2002a, De Shamphelaere et al. 2005), although aquatic invertebrates and some fish may also be affected by ingestion of suspended, particulate, or colloidal zinc. Consequently, zinc toxicity is influenced by the factors affecting zinc speciation. Also, although most studies have focused on the toxic effects of water-borne zinc exposures, dietary exposure to zinc may play a significant role in zinc toxicity to aquatic biota. Reproductive effects on *Daphnia magna* were observed after feeding on algae that had been exposed to 28 µg/L Zn, (De Shamphaleare et al. 2004), whereas daphnid toxicity occurred at concentrations of >100 µg/L in water-only tests conducted at the same laboratory (Heijerick et al. 2005b).

At extremely high waterborne levels, zinc causes gross morphological alterations at the teleost gill (Skidmore and Tovell 1972) and fish usually die within a few hours as a result of tissue hypoxia from impaired gas exchange (Lappivaara et al. 1995). At lower waterborne concentrations that more realistically reflect contaminated environments, zinc (Zn^{2+}) disrupts calcium uptake by chloride cells of the gills (Spry and Wood 1985, Heijerick et al. 2002b, Hogstrand et al. 1995 and 1996). Calcium and zinc appear to compete for binding sites at the channels that regulate calcium uptake, such that while elevated levels of zinc inhibit calcium uptake, the converse is also true (Santore et al. 2002). Inhibition of calcium uptake leads to hypocalcemia, which may culminate in the death of the fish within a few days, depending on the zinc concentration. Survival of fish is equally or more sensitive than other endpoints in chronic exposures to zinc (De Shampheleare and

Janssen 2004). Swim-up alevins or young juveniles appear to be more sensitive to zinc than either younger or older life stages (Buhl and Hamilton 1990).

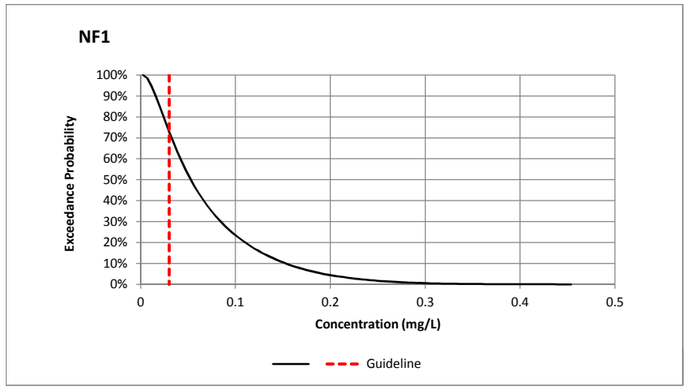
As with fish, it appears that zinc toxicity to aquatic invertebrates (Heijerick et al. 2005b; Muyssen et al. 2006) and algae (Wilde et al. 2006) may occur through disruption of calcium regulation by chloride cells. However, there may be differences in the specific mechanisms controlling acute versus chronic toxicity, at least for some invertebrates (Pauluskis and Winner 1988; Heijerick et al. 2005b).

The aquatic toxicity of zinc is influenced by a number of chemical factors including pH, hardness and the presence of other inorganic or organic ligands (USEPA 1987, CCME 1999). These affect zinc toxicity either by influencing the speciation of zinc or by influencing the sorption or binding of available zinc to biological tissues (e.g., competition for binding sites at gills).

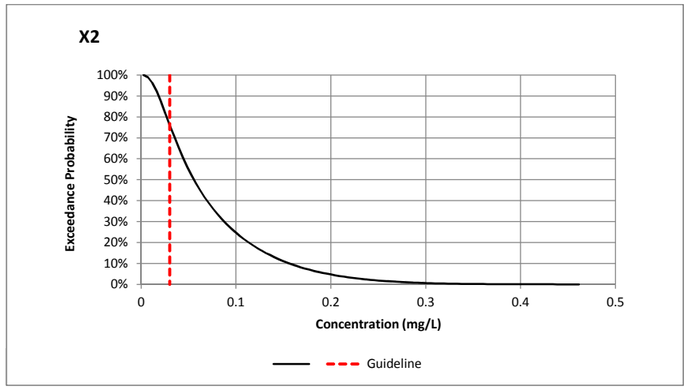
As noted above, aqueous pH influences zinc speciation, which in turn influences zinc toxicity to aquatic biota. Toxicity test results expressed on the basis of total zinc concentrations often show a pattern of reduced toxicity at basic, as compared to neutral, pH because formation of hydroxides at elevated pH reduce the quantities of available Zn^{2+} ion (Heijerick et al. 2002b, Santore et al. 2002). However, the toxicity of the free ion (Zn^{2+}) is decreased at lower pH as a result of increased competition between H^{+} and Zn^{2+} for binding sites on biotic ligands, particularly at pH <7 (Santore et al. 2002; Heijerick et al. 2002a, 2003, and 2005b; De Shampheleare and Janssen 2004; Wilde et al. 2006). The effects of pH on zinc toxicity to algae may be quite large, while pH effects on toxicity to invertebrates and fish are modest (Minnow 2008). Aqueous pH appears to also affect the number and/or characteristics of binding sites of algae, whereas the binding characteristics for higher organisms is believed to be independent of the test medium characteristics (Heijerick et al. 2002a).

Hardness is probably the strongest single water quality factor influencing acute and chronic zinc toxicity to aquatic biota, with the calcium component of hardness being particularly effective in protecting fish from zinc toxicity (Santore et al. 2002). Magnesium appears to be as, or more, effective than calcium in reducing zinc toxicity to invertebrates and algae (Heijerick et al. 2002a; Niyogi and Wood 2004).

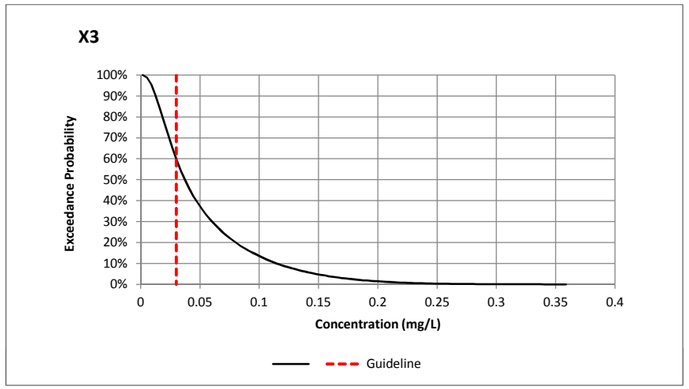
Dissolved organic carbon (DOC) plays a varying role in mitigating zinc toxicity to aquatic biota, with the magnitude of influence dependent on factors such as the quantity and type of DOC present (e.g., humic versus fulvic acids), aqueous pH (affecting Zn sorption to DOC) (Heijerick et al. 2003; De Shamphelaere et al. 2005), and the relative



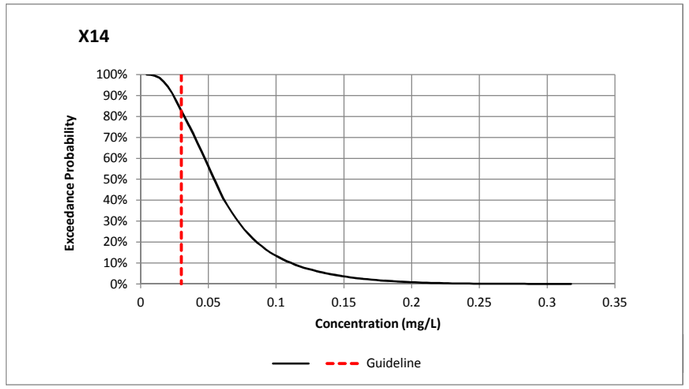
concentrations of zinc and other ions (e.g., calcium and magnesium) (Paulauskis and Winner 1988). The protective effect of DOC is probably greater in soft than hard water (Paulauskis and Winner 1988, Vignault et al. 2004)



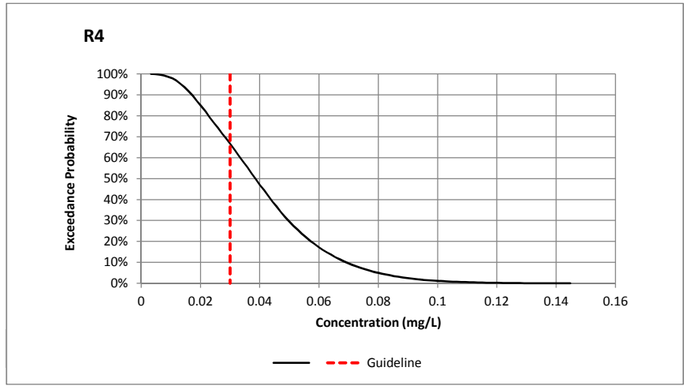
Numerous studies have shown that acclimation of aquatic organisms to low (non-toxic) levels of zinc results in greater tolerance to toxic zinc concentrations (Bradley et al. 1985, Hobson and Birge 1989; Hogstrand and Wood 1995, Anadu et al. 1989, Muyssen et al. 2002, Muyssen and Janssen 2005). This response happens and is lost quickly (i.e., within a few days of zinc exposure) (Bradley et al. 1985; Anadu et al. 1989). As a result, acclimated organisms may be able to tolerate lethal concentrations up to 5 times higher than unacclimated organisms (Anadu et al. 1989; Muyssen et al. 2002). In some cases, sublethal, rather than lethal, tolerance may be increased by pre-exposure to zinc (Muyssen and Janssen 2005).



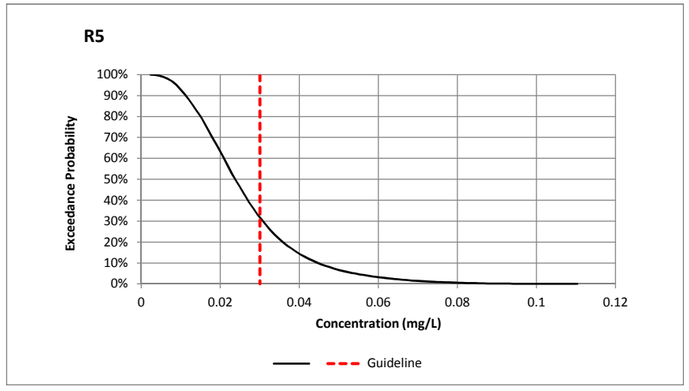
3.2.5.3 Predicted Concentrations and Effects

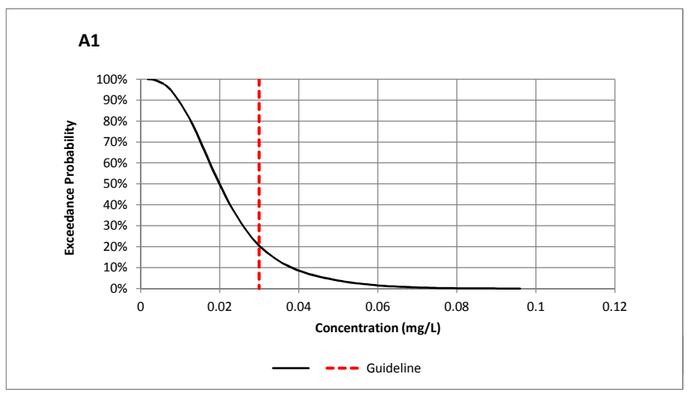


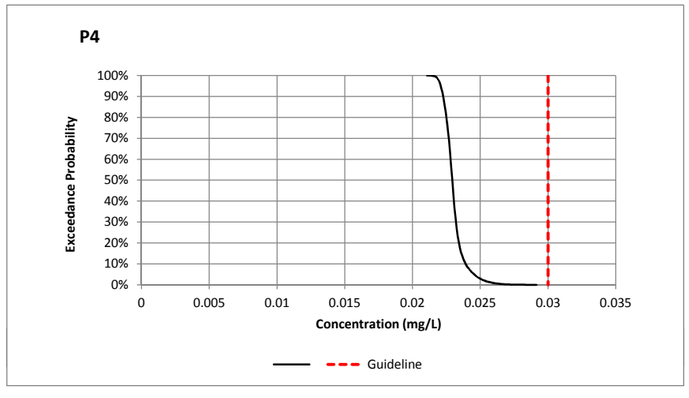
During the baseline period median concentrations of zinc were above the water quality guideline only at X14 (Table 7C-3). However, during the 10-year IW period it is predicted that winter and summer/fall concentrations will sometimes be above guidelines throughout the Rose Creek system downstream of NF1 to the mouth at Anvil Creek (R4). At these stations, probabilities of monthly guideline exceedance range from 60 percent to 80 percent (Figure 7C-8). The exceedance probability declines from 80 percent at X14 to 70 percent at the mouth of Rose Creek (R4) and 30 percent after the confluence of Rose Creek and Anvil Creek (R5), but remains close to 20 percent even at the mouth of Anvil Creek (A1) (Figure 7C-8). Predictions do not assume attenuation with distance downstream and thus may be overly conservative. The water quality guideline for zinc is also expected to be exceeded in approximately 30 percent of months at V8, near the mouth of Vangorda Creek, but will not be exceeded at P4 in the Pelly River downstream of Vangorda Creek and Anvil Creek (Figure 7C-8). These represent predicted “normal” operating conditions at the FMC.



Aquatic toxicity data associated with water hardness around 100 mg/L indicate that toxicity to sensitive aquatic species may occur at zinc concentrations that are only slightly above the water quality guideline of 0.03 mg/L (Table 7C-5). However, winter baseline zinc concentrations at X14 have averaged triple this value at approximately 0.09 mg/L (Table 7C-4) and baseline studies concluded that mine-related effects on biota (e.g., benthic invertebrate surveys) have been undetectable or relatively minor at X14/R2 (Minnow 2014). Although median zinc concentrations are expected to increase at most stations in Rose, Anvil, and Vangorda creeks relative to baseline conditions, they are







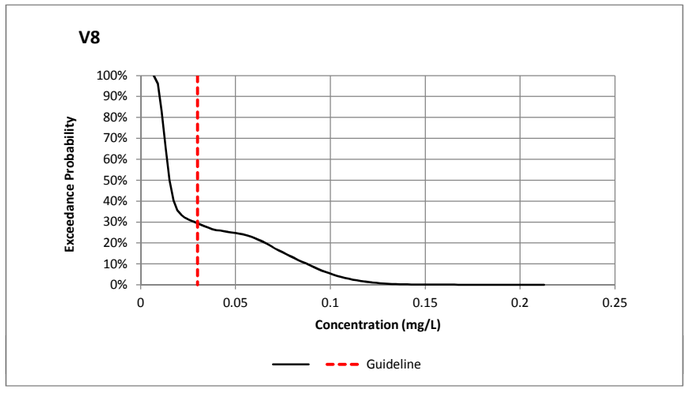


Figure 7C-8: Percentage of months when water concentrations of zinc are expected to be above the water quality guideline.

predicted to be comparable to or less than medians observed at X14 in the period from 2008 to 2012, depending on the season (Table 7C-4). Also, the predicted median concentrations are unlikely to cause acute lethality to fish (Table 7C-5). There is a very small potential for periodic lethal effects to fish in NFRC during winter based on predicted winter 95th percentile concentrations of up to 0.23 mg/L compared to baseline maxima of 0.13 mg/L (Attachment Tables A.10, A.11). Overall, the data indicate that aquatic effects, if any, in surface waters around, and downstream from, the FMC would generally be comparable to those currently observed at X14 (i.e., relatively minor) and aquatic toxicity would be unlikely to occur outside of the LSA.

As noted in Section 3.1.1, there is also potential for new pathways to periodically and unpredictably develop between mine source areas and surface waters over time, particularly via groundwater. These may result in zinc concentrations that temporarily exceed those associated with the "normal" operating scenario described above. Such a condition previously developed south of the Faro waste rock dumps and was detected as a rising trend in winter zinc concentrations in the NFRC that led to installation of the S-wells interception system and subsequent reduction in stream zinc concentrations that is apparent in monitoring results. More recently, a new load source to the NFRC had developed at the Haul Road crossing, which had increased zinc concentrations in the NFRC (NF2, X2) and at X14 such that concentrations in November 2013 (Table 7C-6) were above the maxima predicted for the normal operating scenario (Table 7C-4 and Attachment Tables A.1 to A.4). Average zinc concentrations of 0.2 mg/L or more, such as were observed in November, are in the range for potential lethal effects on biota, including fish. However, a study tracking Arctic grayling around the FMC local and regional study areas using radio telemetry showed two grayling in the RCD on December 10th (EDI 2013), where concentrations in November averaged 0.34 mg/L (at X3A) (Table 7C-6). The literature suggests that concentrations of approximately 0.24 mg/L may be acutely lethal to this species, but the literature also shows that fish can acclimate to low-level zinc exposure levels such that they develop increased tolerance to subsequently elevated zinc exposure concentrations (Bradley et al. 1985, Alsop et al. 1998; Stubblefield et al. 1999).

Consistent with the AMP, the current situation of elevated zinc in the NFRC and downstream areas is being closely monitored while a remedial solution is concurrently being developed and implemented. During the IW, under this type of scenario, there is increased potential for toxicity to aquatic biota to temporarily occur (estimation of 6 to 8 months), possibly including toxicity to fish (see maximum load predictions in Table 7C-6 compared to guidelines and toxicity data in Table 7C-5), until remediation can be

Table 7C-6: Predicted adverse scenario based on recent observations of new zinc load source to North Fork Rose Creek at Haul Road.

implemented. Thereafter, it is expected that concentrations will return to those associated with the normal operating scenario described previously, with associated recovery of biological communities to conditions typically associated with normal operations.

3.2.6 Summary of Chemical Effects

3.2.6.1 Sulphate, Cd, Co, Pb, Mn During Normal Operations

Neither sulphate nor lead concentrations are expected to exceed water quality guidelines for protection of aquatic life during the IW period. Median concentrations of cadmium will be less than the hardness-adjusted water quality guidelines in all local and regional study areas, but the guidelines may sometimes be exceeded in localized stream reaches within the LSA (e.g., NFRC and in Rose Creek immediately downstream from the Faro Mine Area); however, the predicted concentrations are not expected to be toxic to fish and effects on other aquatic biota are expected to be minimal. Cobalt concentrations are expected to exceed the water quality guideline in Rose Creek at X14 and R4 in approximately 45 percent and 35 percent of months, respectively, particularly during the ice-free seasons; however, predicted concentrations are not expected to be toxic to fish and effects on other aquatic biota are expected to be minimal. Manganese concentrations are not predicted to change substantially from baseline conditions, except that concentrations may decrease slightly in winter months and increase slightly in other months at Rose Creek stations at, and downstream from, X14. Overall, manganese concentrations are predicted to be above the hardness-adjusted guidelines in approximately 65 percent of months at X14 (65 percent) and in an increasingly lower percentage of months at stations farther downstream. The available data indicate that aquatic effects, if any, of manganese in surface waters around the FMC would be limited to the vicinity of X14 (i.e., within the LSA) and would likely be minor in magnitude.

3.2.6.2 Zn During Normal and Operations

During the 10-year IW period it is predicted that, under normal operating conditions, winter and summer/fall zinc concentrations will be above guidelines throughout the Rose Creek system downstream of NF1 to the mouth at Anvil Creek (R4). At these stations, probabilities of monthly guideline exceedance range from 60 percent to 80 percent but declines from 80 percent at X14 to 70 percent at the mouth of Rose Creek (R4), to 30 percent after the confluence of Rose Creek, and to 20 percent at the mouth of Anvil Creek (R5). The water quality guideline for zinc is also expected to be exceeded in approximately 30 percent of months at V8, near the mouth of Vangorda Creek, but will not be exceeded at P4 in the Pelly River downstream of Vangorda Creek and Anvil Creek.

Despite these conditions of elevated zinc, the available data indicate that aquatic effects, if any, in surface waters around the FMC would be comparable to those currently observed at X14. This means that concentrations would rarely exceed fish toxicity thresholds, effects to other aquatic biota would be minor (i.e., affecting only a few sensitive species), and the effects would be limited to the LSA.

3.2.6.3 Zn During Adverse Events

There is potential for periodic, unpredictable, and unpreventable breakthroughs of contamination to surface waters from mine sources via new groundwater pathways, such as is currently occurring in the NFRC. Under such conditions, increased toxicity may temporarily occur (estimation of six to eight months), possibly including toxicity to fish, until remediation can be implemented. Thereafter, it is expected that concentrations will return to those associated with the normal operating scenario described previously, with associated recovery of biological communities to conditions typically associated with normal operations

3.3 Fish and Fish Habitat Effects

Fish habitat includes the physical structure of the areas inhabited by fish, such as stream and bank morphology, substrate and cover characteristics, and water quality, depth and elevation, as well as the aquatic plant and invertebrate communities that contribute to ecosystem function and represent a food source for fish. Potential chemical effects associated with the IW on fish and on the biological components of fish habitat were described in Section 3.2. Potential effects of the IW on physical aspects of fish habitat will be minimal, relating mainly to potential mobilization of particulates into surface waters. Such effects will be mitigated through BMPs for control of erosion and sediment transport (see Section 2.0). Temporary disruption of fish habitat may also occur during the IW if a new road crossing is required to transport site investigation equipment (e.g., drill rigs) to appropriate locations. The effects on fish habitat will be mitigated through control of particulates during associated construction and also adherence to applicable sections of the federal *Fisheries Act.* There are no other aspects of the IW that are expected to affect physical characteristics of fish habitat (e.g., diversions, channel realignment, flow alterations). Therefore, no residual effects are anticipated on physical fish habitat. Proposed monitoring will track the condition of physical and biological aspects of fish habitat during the IW period (Section 3.6).

3.4 Additional Mitigation

No additional, standard mitigation practices are available that could be expected to lessen chemical loads from the FMC to surface waters during the IW. However, an objective of site investigations conducted during the IW will be to identify opportunities for further mitigation or remediation that could be implemented as part of the long-term mine closure plan.

3.5 Significance of Effects

Predicted changes in water quality associated with the IW, described in Section 3.2.6 correspond with significance rankings of low to medium for all relevant chemical variables (sulphate, cadmium, cobalt, lead, manganese, and zinc) and all relevant effect attributes (magnitude, likelihood and duration, geographic extent, and reversibility) as defined in Table 7C-2.

3.6 Monitoring

Monitoring of the aquatic environment will be undertaken to confirm predicted environmental performance and demonstrate compliance with regulatory requirements. Monitoring results will be presented in comprehensive reports that will assess conditions relative to predictions and provide recommendations for future actions allowing for adaptive management of the mine. A brief description of the recommended monitoring is provided below with additional details provided in the Environmental Monitoring, Surveillance and Reporting Plan (Appendix 5E of the IWPP). Detailed monitoring plans will be further developed to address regulatory requirements.

During normal operations of the IW, surface water should be monitored on a monthly basis at representative stations on NFRC (e.g., R9, R10, NF1, NF2, X2), SFRC (R1), RCD (X3), Rose Creek (X14, R4), Anvil Creek (R5, A1), West Vangorda Creek (VW1, VW2, VW3, V5), and Vangorda Creek (V4, V27, VGMAIN, V8). Water data should be assessed on a regular basis relative to baseline conditions and water quality guidelines. Water data should also be regularly evaluated with respect to potential trends or thresholds that may be indicative of non-normal conditions, as outlined in the AMP.

Should water quality monitoring indicate a substantial adverse change in surface water quality that might be associated with a change in toxicity to aquatic biota, samples of surface water should be collected from the affected areas for laboratory toxicity testing. The tests should include a variety of species representing different trophic levels and

effects endpoints. Testing should be repeated if water quality continues to change, but would not need to be repeated if concentrations stabilize.

Benthic invertebrate communities should be assessed every 3 years at all of the water monitoring locations that are accessible to fish. Community characteristics should be compared to those observed during the baseline period and to any other such surveys conducted at the site in the interim. Data should also be evaluated relative to an appropriate suite of synoptically sampled regional reference areas (i.e., having similar habitat characteristics) and should consider any changes in water quality that have been since the last cycle of study.

Monitoring of fish health and population characteristics and fish tissue metal concentrations is not recommended unless specific questions arise that necessitate fish sampling. This is because locally relevant species such as Chinook and grayling can move large distances between winter and summer habitats so the characteristics of individual fish may not reflect conditions in the areas in which they are captured. Also, population densities of these species, and slimy sculpin, are sufficiently low that it is very difficult to obtain sufficient sample sizes in any given area to support statistical comparisons of conditions among reference and mine-exposed areas. Also, lethal sampling should be avoided, if possible, to prevent population impacts that might be associated with the sampling program.

[a] Values adjusted based on hardness using an acute hardness:toxicity slope factor of 0.8473 from USEPA (1987) and the equation: EXP(LN(EFFECT conc)-(0.8473)*(LN(measured water hardness)-LN(desired water hardness))).

Table B.3: Lowest effect endpoint reported for each freshwater species after a long-term exposure to zinc. See Table B.4 for test details and sources.

					Test Reported		Hardness-Adjusted Effect Concentration			
Species Common Name	**Scientific Name**	**Duration**	**Endpoint**	**Observed Effect**	**Hardness (mg/L)**	**Effect Concentration (mg/L)**	**Effect Concentration (mg/L) at 50 mg/L Hardness [a]**	**Effect Concentration (mg/L) at 100 mg/L Hardness [a]**	**Effect Concentration (mg/L) at 200 mg/L Hardness [a]**	**Effect Concentration (mg/L) at 300 mg/L Hardness [a]**

[a] Values adjusted to a hardness of 100 mg/L (as $CaCO_3$) using a hardness:toxicity slope factor of 0.7432 from GEI (2009).

[b] Not provided by GEI (2009).

[c] Data reported as suspect by GEI (2009).

[d] mean hardness of range presented in report.

Table E.3: Detailed chronic toxicity data for manganese. Lowest effect concentration for each species is highlighted (GEI 2009).

Species Common Name	Species Scientific Name	Test Type	Duration	Endpoint	Effect[a]	Effect Concentration (µg Mn/L)	Confidence Interval (ug/L)	Water Hardness (mg/L as $CaCO_3$)	Concentration (ug/L) at 100 mg/L Hardness [b]	Citation
Rainbow trout	*Oncorhynchus mykiss*	Early-life-stage	- [c]	EC10	biomass	1,201	(765-1,887)	29	1,814	Davies and Brinkman (1998) as cited in GEI (2009)
