Acronyms and Abbreviations 6C-v

1 Introduction 6C-1-1

2 Description of Major Facilities 6C-2-1
2.1 Dams 6C-2-1
2.1.1 Intermediate Dam 6C-2-1
2.1.2 Cross Valley Dam 6C-2-2
2.1.3 Emergency Spillways at the Intermediate and Cross Valley Dams 6C-2-2
2.1.4 Secondary Dam 6C-2-3
2.1.5 Rose Creek Diversion 6C-2-3
2.1.6 Little Creek Dam 6C-2-4
2.2 Open Pits 6C-2-5
2.2.1 Faro Pit 6C-2-5
2.2.2 Grum Pit 6C-2-5
2.2.3 Vangorda Pit 6C-2-6
2.3 Waste Dumps 6C-2-6
2.3.1 Faro Waste Dumps 6C-2-6
2.3.2 Vangorda Waste Dump 6C-2-8
2.3.3 Grum Waste Dumps 6C-2-9
2.4 Haul Road 6C-2-9

3 Interim Closure Criteria 6C-3-1
3.1 Dams 6C-3-1
3.1.1 Hazard Classification 6C-3-1
3.1.2 Design Criteria for Spillway Capacity and Earthquake Loading 6C-3-3

4 Loading Conditions 6C-4-1
4.1 Hydrotechnical 6C-4-1
4.1.1 Previous Hydrologic Studies 6C-4-1
4.1.2 Flood Hydrograph Development 6C-4-3
4.2 Seismic 6C-4-3

5 Stability Evaluation of Major Physical Structures 6C-5-1
5.1 Dams 6C-5-1
5.1.1 Adequacy of Conveyance Structures to Withstand Hydraulic Loading 6C-5-1
5.1.2 Structural Stability of Dams 6C-5-5
5.2 Open Pits 6C-5-9
5.2.1 Faro Pit 6C-5-9
5.2.2 Grum Pit 6C-5-10
5.2.3 Vangorda Pit 6C-5-11
5.3 Waste Dumps 6C-5-11
5.3.1 Faro Waste Dumps 6C-5-11
5.3.2 Vangorda and Grum Waste Dumps 6C-5-11
5.4 Haul Road 6C-5-12
5.4.1 North Fork Rock Drain 6C-5-12

6 Summary and Conclusions 6C-6-1
6.1 Dam Stability during the Interim Period 6C-6-1
6.2 Recommended Interim Hydraulic Upgrades 6C-6-1

6.2.1 ID Spillway 6C-6-1
6.2.2 Rose Creek Diversion Dike 6C-6-2
6.2.3 Embankment Haul Road and North Fork Rock Drain 6C-6-2

7 Works Cited 6C-7-1

Attachment

SECTION 1

Introduction

The Faro Mine Complex (FMC) is located near the Town of Faro (Faro) in Yukon. The complex consists of two separate sites: the Faro Mine Area, located approximately 15 kilometres (km) north of Faro, and the Vangorda/ Grum Area approximately 9 km northeast of Faro (Figure 6C-1). The Faro Mine Area (Figure 6C-2) includes the Faro Pit and Waste Dumps, Mill facilities, and a series of tailings impoundments. The Vangorda/Grum Area (Figure 6C-3) includes the Vangorda Pit and Waste Dumps, the Grum Pit and Waste Dumps, as well as treatment facilities. The two sites are connected via a Haul Road.

This appendix describes the current condition of the major civil structures or facilities at the FMC and includes a description of interim measures that are proposed to reduce risks.

The appendix outline is as follows:

1. Description of the major civil structures/facilities. The facilities described in this appendix can be divided in the following categories: (1) dams, (2) open pits, (3) waste dumps, and (4) the Haul Road, including the North Fork Rock Drain (NFRD). Because of the interconnection between the Rose Creek Diversion (RCD) and the tailings dams, the RCD is also discussed in this document. The other clean water diversions, including the Faro Creek and Vangorda Creek Diversions, are discussed in *Hydraulics Characterization of Existing Facilities, Faro Mine Interim Works* (CH2M HILL, 2014b). The emphasis will be on the dams, since the consequence of dam failure is significantly larger than the consequence of failure of the other facilities, and therefore warrants greater attention for the Interim Works period.
2. Design criteria. This will include discussion of the design criteria for the final closure plan as well as for the interim period.
3. Loading conditions. This includes hydrological (flood) loading and seismic loading.
4. Stability evaluation of the major facilities under the various loading conditions.
5. Summary and Conclusions, including description of proposed interim upgrades
6. Works cited in developing this appendix.

To prepare this appendix, the following tasks were performed:

1. Review and extract information from past reports to evaluate the stability of the major structures.
2. Perform stability analyses including seismic analyses (liquefaction and slope stability) of the East Limb of the Secondary Dam (SD), and stability evaluations for the NFRD. These analyses were performed to address gaps from historical reports.

SECTION 2

Description of Major Facilities

2.1 Dams

Most of the dams in the FMC are associated with the Rose Creek Tailings Area (RCTA). These are also the largest dams at the FMC.

Approximately 28.6 million cubic metres (m^3) of flotation-derived process tailings were deposited in the RCTA between 1969 and 1998 (CH2M HILL Canada Limited [CH2M HILL], 2012). The tailings are contained by a series of three dams (Original dam, SD, and Intermediate Dam [ID]) constructed across the Rose Creek Valley, as shown on Figure 6C-4. The Original dam is completely enclosed by tailings on both sides, so it is no longer functioning as a dam structure.

The Cross Valley Dam (CVD) Pond, downstream of the tailings impoundment dams, serves as a polishing pond for the treated effluent from the existing Faro Mill Water Treatment Plant. The ID is the major tailings impoundment structure that also contains flood waters entering the Intermediate Impoundment from a small residual catchment area. Any floodwater routed through the ID spillway would flow into the CVD Pond, and once the storage capacity of the CVD Pond is exceeded, water would flow through the CVD spillway down into the Rose Creek Valley, where it would flow into Rose Creek. However, this water routing is not part of day-to-day operations and has never been used to route flood waters to-date. Upstream flows are currently routed around the tailings facility in the RCD and onsite water management activities convey water from the ID to the water treatment circuit.

The tailings vary in thickness upstream to downstream and across the valley, with an estimated thickness of 5 to 10 metres (m) at the edges of the valley, maximum thickness of more than 25 m upstream of the SD, and maximum thickness of 20 to 25 m upstream of the ID (SRK Consulting Canada Inc. [SRK], 2006). The maximum thickness of the original tailings is also estimated to be 20 to 25 m.

Analyses of Faro Mill production records and assays indicate that the tailings have an average concentration of lead, zinc, and copper of approximately 0.8 percent, 1.3 percent, and 0.12 percent, respectively (Curragh Resources Limited, 1993). Oxidation of the sulphides results in production of low pH (acidic) water with elevated concentrations of sulphate, zinc, and other metals (Robertson GeoConsultants [RGC], 1996). These metals are toxic to aquatic and terrestrial life.

2.1.1 Intermediate Dam

In 1981, the ID was constructed across the Rose Creek Valley to contain supernatant water and tailings solids. It was raised in 1988, 1989, and 1991 to a final crest elevation of 1,049.8 m, a maximum height of about 32 m above the old Rose Creek channel. A typical section through the dam is shown on Figure 6C-5. There is an emergency spillway channel on the right (north) abutment, constructed as a rock-lined channel in natural overburden material.

Based on available drawings, the ID is a zoned earthfill embankment with a sloping upstream low-permeability core and a downstream random fill shell. Granular filter zones were constructed on both sides of the core. The initial construction in 1981 made use of natural terrace material present across the valley. A drainage blanket was placed over this footprint downstream from the core and filter zone, extending to the toe of the planned final dam construction.

Upstream and downstream slopes are at 2H:1V. A 20-m-wide berm was constructed on the downstream slope at about 1,034 mamsl, approximately adjacent to the polishing pond; therefore, the overall downstream slope is at 2.1H:1V. It is assumed that the purpose of the berm is to provide access to the blanket drain exit and to provide stability against drawdown loading from the CVD Pond.

Although there is a cut-off of limited depth (estimated 3-m deep) beneath the core of the dam to reduce seepage through the uppermost natural soils, no deep foundation cut-off is present to reduce seepage through the permeable foundation soils. However, the tailings on the upstream slope and deposited in the area upstream of the dam have small particle sizes that reduce seepage rates to an acceptable level; the hydraulic gradient is reduced because of the longer seepage path through relatively thick layers of fine-grained tailings.

The drains on the dam section are set to just above the design level of the polishing pond. When the polishing pond is full, and there is minimal differential pressure between the groundwater pressure in the dam and the hydrostatic pressure in the polishing pond, the absence of drains and filters in the lower part of the dam is not a major concern. However, if the polishing pond is drained, the absence of drains in the lower half of the dam may become more problematic because of the potential for seepage daylighting on the downstream face. Under such a scenario, some sloughing of the slope may occur, but the potential for backward erosion and piping is considered low because the material below the blanket drain consists of sand and gravel, which would not sustain a roof.

2.1.2 Cross Valley Dam

The CVD was constructed as part of the Down Valley Project in the early 1980s, a project to expand the tailings disposal capacity in the Rose Creek Valley. The CVD retains a polishing pond downstream from the ID. Based on available drawings, the embankment is a zoned dam with core and filters, constructed as a conventional water-retaining dam with no retained tailings. Figure 6C-6 shows the design section of the CVD without the seepage berm at the downstream toe. The seepage berm was constructed at a later date (after the original construction was completed) to collect and monitor seepage that appeared near the toe of the dam.

The crest of the dam is at elevation 1,034 mamsl and the downstream toe is at elevation 1,016 mamsl (nominal). The height of the dam is about 18 m above original grade.

The dam section is a central impervious core, supported by upstream and downstream granular shells at slopes of 2H:1V. The core and downstream shell are separated by a chimney drain that connects to a blanket drain that extends to the toe of the drain. There is also a filter/transition zone on the upstream side of the core that acts as a crack filler. The central impervious core connects to a low-permeability upstream blanket that extends beneath the upstream shell, to 60 m upstream from the toe. A core trench was extended a few metres into existing ground below the stripped grade. This limited depth (estimated 3 m) cut-off and upstream blankets were designed to reduce seepage through the foundation soils. The cut-off and upstream blankets are partially effective, and remaining seepage into the downstream drainage blanket is collected and channeled from the dam in a controlled manner. There are no other cut-offs extended into the pervious Rose Creek sediments.

2.1.3 Emergency Spillways at the Intermediate and Cross Valley Dams

The current spillways at the right (north) abutments of the ID and the CVD are sized to pass runoff from large rainfall events (including the Probable Maximum Precipitation event), where the runoff would only be from the relatively small area of the tailings areas, but would not include any flows from the Rose Creek watershed. Whereas the RCD is designed to approximately pass 1-in-500-year flood flows without overtopping the RCD dike, the current overflow weir configuration would result in overtopping and potential breaching of the weir for much smaller flows (flows of about 70 cubic meters per second). Although the overflow weir has been referred to as a “fuse plug” in previous studies, there is uncertainty whether this structure will breach soon after being overtopped. The existing structure is heavily armoured with large diameter riprap and conveys overflow or breached flows out onto the tailings area through a dedicated relief channel.

The ID spillway only has a capacity equal to about 32 cubic metres per second (m^3/sec) when the pool reaches the top of the core zone, whereas the CVD has a spillway capacity equal to about 300 m^3/sec

(Northwest Hydraulic Consultants Inc. [NHC], 2006). The ID spillway discharges into the CVD Pond. If the CVD Pond fills, additional water would be routed through the CVD spillway down into the Rose Creek Valley, where it would flow into Rose Creek.

Since the existing ID spillway does not have the capacity to safely pass a moderate or major flood event (from Rose Creek catchment area and the surrounding area that drains to the Intermediate Impoundment) without overtopping and potentially breaching the dam, improvements to the spillway and the dam were designed as part of the Down Valley Interim Hydraulic Upgrades as detailed in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a). As part of this work, the hydrology and hydraulics for the RCD was updated, including attenuation of the NFRC flows.

Apart from remediating spill capacity associated with large flood events, an increase in ID spillway capacity would also provide mitigation for other RCD failure mechanisms. These include (1) failure of the RCD dike by piping or slope instability during moderate flood events, (2) landslide or debris flow originating on the mountainous slopes to the south of the RCD that would block the RCD and cause overtopping of the RCD dike, and (3) icing buildup in the RCD resulting in overtopping of the RCD dike.

2.1.4 Secondary Dam

Construction of the SD began in 1974 and was completed in 1975. A failure of the SD occurred in 1975, resulting in more than 200,000 m^3 of decant water and tailings discharged to the Rose Creek Valley. The spill was observed to move downstream several miles from the site (Williams, 1975). A survey conducted almost 30 years later indicated “obvious areas of killed and stressed vegetation” and “many areas of stressed vegetation and dead trees that appear to also have been impacted by the spill” (Gartner Lee Limited, 2004).

The West Limb of the SD is defined as the curved portion of the dam that crosses the Rose Creek Valley in a roughly north–to-south direction. The East Limb is the portion of the SD that is parallel to the south Rose Creek Valley wall. The West Limb of the SD was raised using centerline construction and compacted fill to a maximum height of 27 m. The East Limb is a low retention dike that was constructed of compacted fill. Tailings were deposited behind this dam from 1975 until 1982, and again for approximately 5 months in 1986. When the SD was constructed, Rose Creek was diverted to the Rose Creek Diversion (RCD) that ran parallel to the south Rose Creek Valley wall and emptied into its original channel downstream from the SD. Cross sections and photos of the SD are shown on Figure 6C-7. Elevations shown on figures are in feet relative to the Down Valley Project datum. To convert to mean sea level datum (NAD 27), subtract 106 feet (32.3 m). To convert from feet to m, multiply by 0.3048 m per feet.

2.1.5 Rose Creek Diversion

The RCD, on the south side of the valley, diverts clean water from the North and South Forks of Rose Creek around the RCTA. The RCD was constructed in two stages. An upstream section of the channel was completed in 1974, to carry clean water past the Secondary Impoundment. A longer downstream section was completed in 1981, in preparation for construction of the Intermediate Impoundment downstream (west) of the Secondary Impoundment. This second reach extended the diversion by about 3,800 m, to the location where it discharges back into Rose Creek, downstream from the CVD.

The existing diversion is approximately 4,700 m in total length. Rock weirs were constructed to reduce stream velocities associated with the steep grade of the channel in the lower reaches of the diversion. The weirs were designed on the basis of a 1-in-50-year flood event. The diversion was originally designed to carry a 1-in-50-year flood event (approximately 79 m^3/sec), with 1 m of freeboard. The contingency design capacity, with no freeboard, was such that it would carry a 1-in-500-year flood event of 132 m^3/sec, while spilling a portion of the flow through the overflow weir into the Intermediate Impoundment (assuming that the weir would not breach). Following a review of the RCD capacity in 2003, low sections of crest as a result of settlement were found (BGC Engineering [BGC], 2004), such that the original design flood event would have resulted in overtopping the RCD dike. The low sections were subsequently raised by the required amount (BGC, 2005); after raising these sections, it was concluded that the existing RCD has a flow capacity

(without any freeboard) sufficient to bypass stream flows of 140 m^3/sec, which is slightly more than the previously considered 1-in-500-year flood event (NHC, 2006), when neglecting any flood attenuation by the NFRD. The flow from storm events exceeding the capacity of the RCD will spill through the overflow weir and overtop the RCD dike, such that it will discharge onto the Intermediate Impoundment, flow over the intermediate tailings into the ID Pond, and flow out through the ID spillway into the CVD Pond. A large storm event exceeding the capacity of the RCD will potentially fail the RCD dike. It will most likely do so by overtopping the existing overflow weir location. It is also possible that the dike could fail at other locations by overtopping or fail because of other mechanisms such as piping.

Although hydraulic analyses suggest that the overflow weir should remain stable during the Inflow Design Flood (NHC, 2006), it is uncertain how it was constructed. NHC (2006) noted that the downstream slope is 20 percent with median riprap size of 800 millimetres immediately downstream of the crest of the overflow weir, and a cobble transition zone at 6 percent slope between the structure and the intermediate tailings. It is estimated that about 7 m^3/sec of flow of the 1-in-500-year flood event may occur through the existing overflow weir.

Once the RCD is breached (for example, by overtopping at the overflow weir location or at other locations along the dike) flood water would be conveyed over the intermediate tailings surface and through the ID spillway. This flow could be significantly larger than the capacity of the ID spillway for major floods (> 100-year recurrence interval) resulting in overtopping and breaching of the ID. Even moderate flood events (> 10-year recurrence interval) would overtop and potentially breach the ID if the RCD dike fails by non-overtopping failure modes such as piping. ID failure would result in discharge of a large volume of tailings to the environment. This is because the dynamic flow of a large amount of mobilized tailings is likely to overwhelm the storage of the CVD Pond, such that it would run up and over the crest of the CVD, or would run through the CVD spillway. In both cases, tailings and contaminated water from the Intermediate Pond would then be released into the Rose Creek Valley and Rose Creek downstream of the CVD.

As part of the Down Valley Interim Hydraulic Upgrades as detailed in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a), the hydrology and hydraulics for the RCD was updated, including attenuation of the NFRD flows. The peak un-attenuated inflow at the head of the RCD was calculated as 130 m^3/sec, whereas the attenuated inflow was 111 m^3/sec, i.e., a reduction of about 15 percent due to attenuation. The ID spillway was designed using a 72-hour hydrograph with an attenuated 1-in-500-year peak flow of 121 m^3/sec. This inflow is for the Rose Creek catchment area plus the surrounding area that drains into the Intermediate Impoundment.

2.1.6 Little Creek Dam

The Little Creek Dam (LCD) was completed in 1991, to collect water pumped from the Vangorda Pit and from runoff and seepage at the Vangorda Waste Dump. The location of the dam is shown in Figure 6C-10. The water from the dam was pumped directly to the water treatment plant. Electrical power was supplied by a single line to a transformer located on the dam crest adjacent to the pump house. The pump house, no longer operational, had two 35-horsepower (hp) and one 125-hp pump that were used to pump from the Little Creek Pond to the treatment facilities.

Once mine operation ceased, water management at the site changed. Now only runoff from the Vangorda waste dump collects behind the dam, and this water is pumped in the summer months to the abandoned Vangorda Pit. Water from the Vangorda Pit is now routed directly to the treatment plant. A 30-hp Flyte pump conveys water from the LCD to the Vangorda Pit.

The dam is a homogeneous embankment section of local glacial till, with a cut-off trench and granular drains under the downstream slope (Figure 6C-11). The crest is about 10 m above natural ground, ranging in elevation from 1,114.5 m to 1,120 m. Side slopes are 2H:1V on the downstream side and 2.5H:1V on the upstream side. A zone of permafrost encountered at the south abutment was excavated before till placement.

The dam is inspected daily during the summer months. Instrumentation includes six pneumatic piezometers and three thermistors that are read twice a year, typically in the spring and fall. The site is inspected once a week during the winter months. As described, the pond level is not operated at full supply level. It varies between about elevation 1,108 m and 1,110 m. The crest slopes from north to south with the minimum level at Elevation 1,114.5 m. The minimum freeboard (except for short duration exceedances) is 4.5 m on a 10-m-high dam.

2.2 Open Pits

2.2.1 Faro Pit

Mining from the Faro Pit was conducted from 1969 until 1982, and from 1986 to 1991. The pit is oval in shape with a maximum open length of approximately 1,600 m, and a maximum width of approximately 975 m, measured crest to crest. The major axis of the pit is oriented in a northwest direction. The elevation of the top of the slope at the northwest end of the open pit is approximately 1,320 mamsl, and the elevation of the top of the slope along the east side of the pit is approximately 1,296 mamsl. The bottom of the pit is currently under water, but is estimated to be excavated down to elevation 975 m (RGC, 1996). An aerial photo of Faro Pit is shown in Figure 6C-12.

The Faro Pit was excavated within the Faro Creek Valley. Faro Creek was diverted around the east side of Faro pit into the NFRD. Faro Pit has partially filled with water from surface flow and groundwater sources to an elevation of approximately 1,147.8 m, measured in November 2013. The lowest point around the perimeter of the pit is located at the southeast end of the pit, where an access road enters the pit. The high point on the ramp, or overflow point of the pit, has an invert of approximately 1,175 m. The maximum storage capacity of the pit is about 52.45 million m^3, whereas the volume of the water contained in November 2013 was about 34.54 million m^3.

The exposed materials consist generally of meta-sedimentary rock materials overlain by glacial till. The till generally has a thickness less than a few m, but increases in thickness within the Faro Creek Valley up to approximately 100 m thick.

A smaller pit, referred to as Zone II Pit, was excavated immediately southeast of the Faro Pit. This pit was mined during the initial mine operations up until 1982, and had a depth estimated at 100 m below the original ground surface (RGC, 1996). This pit was entirely backfilled with waste rock in the 1980s.

Underground mining was also conducted through the southwest wall of the Faro Pit, but the extent is not well defined. Approximately 3.4 million m^3 of mine rock were dumped into the Faro Pit from the underground mining operations.

The side slopes are benched where intact, with overall slopes varying between 30 to 45 degrees. The steepest slopes are located around the northwest end of the pit, and the less steep slopes are located along the eastern wall. Many of the benches contain ravelled rock materials; in some cases the benches are completely filled with this material. Pit slope failures have occurred at two separate locations on the eastern pit wall. These failures occurred during mining, and no significant displacements have occurred during the last eight years. Portions of the scarps at the crest of the pit slope failures are retreating from erosion and weathering of the oversteepened slope at a rate of up to 40 centimetres (cm) per year.

2.2.2 Grum Pit

Mining from the Grum Pit was conducted intermittently from 1990 to 1998. The pit is oval in shape, oriented with the long axis in a north to south direction. The pit is approximately 1000 m in length (north to south), and 625 m wide (west to east), measured crest to crest. The elevation of the top of the pit slopes is 1,300 m, except for the southern end of the pit, where an access ramp enters the pit. The access ramp crests at an elevation of 1,232 m. The bottom of the pit is currently underwater, but a bathymetry survey conducted in 2009 by Laberge Environmental Services reported a minimum elevation of 1,134 m. An aerial photo of Grum Pit is shown in Figure 6C-13.

The side slopes are benched, where the rock is of good quality, with overall slopes varying between 33 to 42 degrees. The steepest slopes are located around the west edge, and the northeast portion of the pit. The majority of the eastern slope has failed in till, resulting in very hummocky terrain and variable slopes within the overburden materials. The existing till material at the upper scarp of the failed slope is standing at an approximate angle of 46 degrees in many locations.

The exposure on the east wall reveals a deposit of glacial till materials with an estimated thickness of at least 100 m. Within the overburden, confined layers of cleaner sand and gravel materials have been encountered within soil borings. Rock materials beneath the overburden generally consist of phyllite with some sulphides.

The mining of Grum Pit was shut down during the winter/spring of 1996/1997. Dewatering was discontinued during this time, allowing the rise of subsurface groundwater levels within the till materials. During this time period, a failure of the upper eastern pit wall occurred likely because of the increase of pore pressures within the overburden material.

The Grum Pit is located near a drainage divide, and the catchment area of the pit is approximately 1.5 square km (km^2). Approximately one-third of the surface drainage above the Grum Pit is directed around the east side of the pit within the Grum Interceptor Ditch into the Vangorda Creek drainage, and the remainder of the drainage enters the pit (RGC, 1996) Since the mine operations were shut down, the water level in the Grum Pit has been steadily rising from an elevation of 1,185 m in 2003, to 1,207 m in 2010. The current water elevation measured in October 2013 was 1,215.7 m.

2.2.3 Vangorda Pit

Mining in the Vangorda Pit was conducted intermittently from 1990 to 1998. The pit has a maximum open length of approximately 1,150 m (550 m for the main pit plus a 600 m long slot), and a maximum width of approximately 375 m, measured crest to crest. The major axis of the pit is oriented in a northwest to southeast direction. The elevation of the top of the pit slope varies from 1,140 m along the southwest edge, to approximately 1,170 m along the southeast edge. The bottom of the pit is currently underwater, but is estimated to be excavated down to an elevation of 1,023 m (RGC, 1996). An aerial photo of Vangorda Pit is shown in Figure 6C-14.

The Vangorda Pit was excavated within the Vangorda Creek drainage, and Vangorda Creek was diverted around the west side of the pit, crossing beneath the Haul Road before rejoining the original creek alignment. Water accumulates in the Vangorda Pit, which also serves as a reservoir for storage of contaminated water from the LCD. Seasonal water treatment at the Vangorda Water Treatment Plant (WTP) Sludge Pond is used to manage water levels at safe elevations. The October 2013 water level in the Vangorda Pit was 1,084.7 m. The lowest point around the perimeter of the Vangorda Pit is at the location of the original Vangorda Creek at the west side of the pit. The elevation at the low point is approximately 1,130 m, or approximately 55 feet above the current water level within the pit. The access ramp is a switchback that enters the pit from the southeast side, dropping from an elevation of 1,141 m, down into the pit.

The exposed materials consist generally of phyllite and sulphide rock materials overlain by a veneer of glacial till. Sulphides are prevalent on the northeast pit wall. Several faults intersecting the Vangorda Pit have contributed to some localized pit wall instability (Golder, 2013).

2.3 Waste Dumps

2.3.1 Faro Waste Dumps

2.3.1.1 History and Description of Dumps

The history of development of the Faro Waste Dumps are described in detail in the Integrated and Comprehensive Abandonment Plan (ICAP) report (RGC, 1996), and the following descriptions are summaries from the ICAP report.

The main dumps at the Faro Mine Area are as follow (Figure 6C-15):

- Northwest Dump
- Faro Valley Dump
- Main and Intermediate Dumps
- Northeast Dumps
- Zone II Dumps
- "Near Pit" Dumps
- Low-Grade Stockpiles

The dumps were developed during the period of mining of the Faro Pits, with waste rock being deposited at several dumps over the same time period. The Faro Valley and the Northwest Dumps were the first to be developed, from 1968 to the early 1970s, by receiving waste from early stripping and mining from Faro Main Pit (Zone I Pit). The other rock piles developed during this period were marginal ore or low-grade stockpiles.

The **Northwest Dumps** are located to the west of the main pit, and north of the plant site area. The dumps were constructed primarily by end-dumping, with three major lifts to the dump, namely the Upper, Middle, and Lower Northwest Dumps. These dumps cover a total area of about 393,000 square metres (m^2), with an average height of 21 m.

The **Faro Valley Dump** is located to the north of the open pit, in the original channel of the Faro Creek. Faro Creek was diverted around the pit (this became the Faro Creek Diversion) to the northeast to allow mining of the pit. The dump fills the original creek channel and is, in part, draped over the edge of the pit resulting in a variable dump height, with a maximum waste rock thickness of 23 m and an average thickness of 11 m. The Faro Valley Dump can be divided into two sections: the larger Faro Valley North Dump covering an area of about 360,000 m^2 and a smaller Faro Valley South Dump with an area of about 32,600 m^2. Together they contained a total of about 4.1 million tonnes of waste rock.

The two largest dumps at the Faro Mine Area, the Main and Intermediate Dumps, were also started during the 1970s. These dumps are the largest Waste Dumps and are located to the south and southwest of the Faro open pit, covering a total area of about 1.1 km^2. The two dumps represent over half of the total waste rock onsite at a total of 145 million tonnes.

These dumps continued to be used until 1990, when mining at Faro was nearing completion.

The Northeast Dumps were built in the 1970s, primarily with waste from the Zone I and Zone II Pits. The **Northeast Dumps** can be divided into three areas: the Outer Northeast Dump, the Upper Northeast Dump, and the Lower Northeast Dump. These dumps are located to the northeast of the Zone II Dumps, but are to the southeast of the Main Pit. The Upper and Lower Dumps are relatively large, containing a total of 38.3 million tonnes of waste rock. The western portion of the Upper and Lower Dumps infill the Zone II Pit. Since they are located within the pit, the dumps are high, averaging 31 and 39 m, respectively.

The Parking Lot Dumps were also built in the mid-1970s. These are smaller dumps located immediately north of the mill site, and southwest from the Northwest Dumps.

Dump construction in the early 1980s was primarily in the **Zone II Dumps,** which are located mostly within the old Zone II Pit, to the southeast of the Main Pit. The dumps were built as the pit was mined, with the Zone II East Dump built first. The Zone II East Dump has a maximum height of 137 m and average height of 65 m, compared to values of 67 m and 34 m, respectively for the Zone II West Dump.

Several smaller dumps were built (less than 10,000 tonnes) in the later 1980s. The majority of the waste was deposited in the Outer Haul Road West Dump, with continued deposition on the Main and Intermediate Dumps.

In the 1990s, deposition continued on the Main and Intermediate Dumps, and on the low-grade stockpiles. In addition, waste was also placed on some of the smaller dumps, which were started in the late 1980s.

The "**Near Pit" Dumps** include the Ramp Zone Dump, the Ranch Dump, and the Southwest Pit Wall Dump. These dumps are located immediately to the south and southwest of the pit, and just north of the Main and Intermediate Dumps. Even though they are relatively small dumps with about 4.3 million tonnes of rock, the dumps are quite high with a maximum height of 60 m.

The main **Low-grade Stockpiles** are called Stockpile "A" and "C". These stockpiles were built from 1987 to 1990 with low-grade ore from Zone III of the Faro Main Pit. With regard to geotechnical properties, the low-grade ore is not significantly different from the waste rock.

In general, all the dumps on the site were constructed at their angles of repose on moderately sloping well-drained terrain. The physical stability of the dumps during the interim period is discussed in Section 5.

2.3.1.2 Rock Type Composition

The ICAP report (RGC, 1996) provides estimates of the dump composition; these estimates were based on the understanding of the pit geology, the pit development, and on observations of the dumps. The geochemistry of each of the dumps was considered with reference to the size and the composition of the dumps. Results of geochemical testing were used to estimate the range of acid generation and acid neutralization potential.

The report also provides estimates of contained "soluble load" for each dump, which were estimated from the results of extraction tests, for each rock type, and for both "old" and "young" dumps. These values were then used as a basis for evaluating the comparative environmental concerns associated with each.

2.3.1.3 Dump Hydrology and Drainage

Over the last 20 years, considerable effort has been made to detect and monitor water quality from the dumps. Seep surveys are conducted annually around the site, with emphasis on the waste dumps to identify and sample drainage from the dumps. Sampling and monitoring included digging of test pits immediately downstream of dump toes, water samples taken from shallow piezometers placed in the backfilled pits, and drilling and installation of piezometers and monitoring wells. Appendix 6A describes the geochemistry of waste dumps.

The ICAP report describes the evaluation of the water seepage through the dumps. To evaluate the effect of the seepage on the receiving water hydrology, the original ground topography was reviewed to identify surface water divides, and compared with the current configuration of the dumps. It was concluded that while waste rock placement has significantly changed the surface topography in the area, placement of the dump material did not significantly change the drainage pattern.

2.3.2 Vangorda Waste Dump

The Vangorda Waste Dumps were constructed, beginning in May 1990, to contain mined waste rock from the Vangorda Pit. The dump contains about 16 million tonnes of material and covers about 40 hectares as shown in Figure 6C-16. The two main rock types that were mined from the Vangorda Pit include sulphides and phyllites. Geochemical analyses performed on the rock indicated that both rock types have the potential to generate acid rock drainage. The sulphide rock has a much higher potential for acid generation than the phyllite and therefore the original design called for the construction of separate cells to accommodate the two different rock types.

On the northeastern side of the dump there is an area where baritic fines have been stockpiled in an area of about 11,400 m2. The concept in the SRK Closure Plan (2010a) is that these fines will be covered with a very low infiltration cover, which must be completed prior to regrading the waste rock.

Seepage from the Vangorda Waste Dump is currently collected and treated at the Vangorda WTP Sludge Pond.

The physical stability of the dumps during the interim period is discussed in Section 5.

2.3.3 Grum Waste Dumps

There are three Grum Waste Dumps: the Overburden Dump, the Southwest Dump and the Main Dump. The Grum Overburden Dump (also called Till Dump) contains an estimated 24 million tonnes of glacial till that was stripped from the buried valley in the northeast part of the pit.

The Grum Rock Waste Dumps (i.e., the Southwest Dump and the Main Dump) contains about 28 million tonnes of material and covers about 148 hectares as shown in Figure 6C-16. The Southwest Dump consists mainly of calcerous phyllite of the Vangorda Formation with about one third of the dump being non-calcerous phyllite. The Main Dump is the largest and includes a sulphide cell where most of the Grum sulphide waste was placed. The sulphide cell in the Grum Waste Dump contains strong acid-generating material, but the remainder of the Grum Waste Dump contains only pockets of acid-generating material. The sulphide cell in the main dump has been covered and revegetated at this time.

The dump was built on the moderate northwest slope of the Vangorda Creek Valley, generally dipping 6 to 10 degrees southeast to south, with local areas as steep as 12 degrees and also some flat areas.

Sulphide waste rock was segregated in the Grum Pit and placed in two sulphide waste rock cells or lifts encapsulated by phyllite waste rock in the Main Dump, as a condition of the Water License. The need for internal till layers was abandoned in favor of a final 3-metre till cover.

2.4 Haul Road

The Haul Road was developed for use by heavy duty off-road trucks hauling ore from the Ore Transfer Pad to the Faro Mill, a distance of 13 km (Figure 6C-17). The road extends an additional 3 km past the transfer pad along the south side of the Grum Pit to the pit entrance on the south side of the Vangorda Pit. The road was built by Curragh Resources starting in October 1986 and was completed in 1989. The road surface is approximately 30 m wide and there is a 2 m high safety berm on each side of the road; significant upgrading of the road surface has been done over the years.

The road was mainly built as a fill road; there are two minor cut areas, one on the east side of the West Fork of Vangorda and the other on the west side of the South Fork of Rose Creek. The road was built largely from mine waste rock selected for non-acid generating characteristics. The central 2 km of the road was built from locally borrowed surficial deposits. Most of the rock on the Faro side of the Haul Road (8 km) is schist with lesser calcium-silicate and minor intrusive, all from the Faro Pit. The rock on the Vangorda Plateau side is calcareous phyllite from the Grum Pit.

The Haul Road crosses several major streams including the north and south forks of the Rose Creek, as well as the West Fork and main stem of Vangorda Creek. The NFRD crossing is a rock drain and is discussed in detail under the dam sections. A second, smaller rock drain crosses Reservoir Creek, whereas the other crossings are corrugated metal pipes of 600 to 1600 millimetres (mm) diameter, with 600 mm culverts at most crossings. Culvert crossings were sized for a 1-in-25-year flood event and were not designed to allow for fish passage. Side slopes of the road embankment are generally 2H:1V for sections built from overburden and 1.5H:1V for sections built from pit rock.

2.4.1.1 North Fork Rock Drain

Although the Haul Road embankment, including the NFRD, was not designed or intended to impound water, it may temporarily retain a significant pool of water during very large flood events. As part of the design of the Down Valley Interim Hydraulic Upgrades (CH2M HILL, 2014a) breach analyses of the NFRD were performed to gain an understanding of the consequences of failure in the case the NFRD would be to fail under the inflow design flood (500-year recurrence interval). The consequences of NFRD breach will vary depending on the volume of water retained at the time of breach. This volume depends on the assumed flow rates through the NFRD; these flow rates are uncertain and difficult to evaluate or estimate. For a high flow-through capacity, the volume of water impounded behind the rock drain would be significantly less than the volume of water that would be stored if a lower flow-through capacity is assumed.

Breach analyses were performed for the medium and low flow-through assumptions, as well as a low flow-through condition assuming a 25 percent reduction in flow-through capacity (possibly because of debris blockage). Since it was found that, for all three cases, the rock drain would not be overtopped, it was assumed that other failure modes would initiate a breach. However, overtopping may be possible in conjunction with a ravelling failure, wherein material is removed from the downstream face of the embankment, resulting in an oversteepened slope that could lead to slope failure, lowering of the crest, and overtopping. For the purpose of the breach analyses it was assumed that a piping failure is more likely than an overtopping failure. The potential piping failure modes for the Haul Road embankment include (1) wash-out of finer particles within the schistose fill material leaving concentrated flow paths that could result in piping and (2) piping through the foundation.

It was found that a breach of the NFRD, assuming a low flow-through condition or a low flow-through condition with 25-percent reduction in capacity because of debris blockage could lead to overtopping of the ID crest. Under these scenarios, the flood wave resulting from the breach would exceed the RCD capacity, resulting in overtopping and breach of the overflow weir and the RCD dike, such that the flood wave would spill into the Intermediate Impoundment. Assuming that all the flow will go into the Intermediate Impoundment, the flow would fill the ID Pond and exceed the capacity of the modified ID spillway and overtop the ID.

For the medium flow-through scenario, the flow from the NFRD breach may result in overtopping and breach of the RCD dike, but the flow through the Intermediate Impoundment would spill through the modified ID spillway without overtopping the ID. For this scenario, the potential for loss of life, impacts to infrastructure and economics, and impacts to the environmental and cultural values in the area are relatively low.

SECTION 3

Interim Closure Criteria

3.1 Dams

3.1.1 Hazard Classification

Different dams on the site pose different levels of hazard; the RCTA dams are considered the most hazardous.

3.1.1.1 Intermediate Dam

The most severe consequence of a dam breach are associated with the ID, which contains more than 11.9 million m^3 of copper, lead, and zinc-laden tailings that are toxic to aquatic and terrestrial life. The total tailings volume of all three impoundments (original, secondary, and intermediate) is 28.6 million m^3 (RGC, 1996). Failure of the ID could result in a significant or major loss or deterioration of critical fish or wildlife habitat downstream of the FMC within Rose Creek, Anvil Creek, and possible extending to the Pelly River.

KCB (2008) estimated that the ID has a "High" risk classification, but it is noted that this estimate was made in the absence of a formal dam breach and inundation study. Government of Yukon (YG) will be conducting dam breach and inundation studies for the ID and the CVD in conjunction with the 2014 dam safety evaluation. These studies will assess downstream consequences of dam failure and may result in a modification of the hazard classifications for these facilities. Considering the Canadian Dam Association (CDA) dam safety guidelines as shown in Table 6C-1 (CDA, 2007), and noting that a large spill would likely make restoration or compensation impractical or impossible, it is quite likely that the hazard classification may change once these updated studies have been completed.

The ID (and CVD) needs to accommodate hydraulic loading from Rose Creek, as well as seismic loading. Rose Creek flows would overtop into the Intermediate Impoundment in case the capacity of the RCD is exceeded during severe flooding, or during moderate flooding when the diversion is blocked due to icing, debris flow/landslide, or woody debris. Rose Creek flows would also enter the RCTA in case the RCD dike would breach as a result of slope stability failure or piping.

TABLE 6C-1
Dam Classification – CDA 2007
Faro Mine Interim Works

Dam Class	Population at Risk [a]	Incremental losses		
		Loss of Life [b]	Environmental and Cultural Values	Infrastructure and Economics
Low	None	0	Minimal short-term loss No long-term loss	Low economic losses; area contains limited infrastructure or services
Significant	Temporary only	Unspecified	No significant loss or deterioration of fish or wildlife habitat Loss of marginal habitat only Restoration or compensation in kind highly possible	Losses to recreational facilities, seasonal workplaces, and infrequently used transportation routes
High	Permanent	10 people or fewer	Significant loss or deterioration of *important* fish or wildlife habitat Restoration or compensation in kind highly possible	High economic loses affecting infrastructure, public transportation, and commercial facilities

TABLE 6C-1
Dam Classification – CDA 2007
Faro Mine Interim Works

Dam Class	Population at Risk [a]	Incremental losses		
		Loss of Life [b]	Environmental and Cultural Values	Infrastructure and Economics
Very high	Permanent	100 people or fewer	Significant loss or deterioration of *critical* fish or wildlife habitat Restoration or compensation in kind possible but impractical	Very high economic losses affecting important infrastructure or services (e.g., highway, industrial facility, storage facilities for dangerous substances)
Extreme	Permanent	More than 100 people	Major loss of *critical* fish or wildlife habitat Restoration or compensation in kind impossible	Extreme losses affecting critical infrastructure or services (e.g., hospital, major industrial complex, major storage facilities for dangerous substances)

Notes:

[a] Definitions for population at risk:

None = There is no identifiable population at risk, so there is no possibility of loss of life other than through unforeseeable misadventure.

Temporary = People are only temporarily in the dam-breach inundation zone (e.g., seasonal cottage use, passing through on transportation routes, participating in recreational activities).

Permanent = The population at risk is ordinarily located in the dam-breach inundation zone (e.g., as permanent residents); three consequence classes (high, very high, extreme) are proposed to allow for more-detailed estimates of potential loss of life (to assist in decision making if the appropriate analysis is carried out).

[b] Implications for loss of life:

Unspecified = The appropriate level of safety required at a dam where people are temporarily at risk depends on the number of people, the exposure time, the nature of their activity, and other conditions. A higher class could be appropriate, depending on the requirements. However, the design flood requirements, for example, might not be higher if the temporary population is not likely to be present during the flood season.

3.1.1.2 Cross Valley Dam

The CVD has the same hazard classification as the ID. The main hazard from a CVD breach is not only the uncontrolled release of water from the CVD Pond, but sudden release of the polishing pond could also cause significant danger to the ID. The ID does not have filter and drainage systems in the lower part of the embankment below the downstream bench, and it depends on the polishing pond to provide a counterbalancing hydrostatic head to reduce seepage and the need for filtering. A sudden drawdown of the pond is likely to result in significant seepage from the saturated ID downstream slope, which in turn could lead to progressive sloughing, even more seepage, possibly backward erosion, and eventually could result in piping or loss of the crest from larger slope stability failures. Based on this potential impact to the ID, the CVD is considered to have the same potential hazard classification as the ID, i.e. a classification of 'High" risk, as estimated by KCB (2008). As for the ID, it is possible that the hazard classification of the CVD may change once a formal dam breach and inundation study is performed.

3.1.1.3 Secondary Dam

A breach of the SD could also lead to a loss of tailings into the environment, but the magnitude of such a tailings loss would be much smaller and more contained than the tailings loss associated with an ID breach. Whereas the ID and CVD need to accommodate hydraulic (flood) loading from Rose Creek, as well as seismic loading, the SD only needs to be designed for seismic loading. The SD does not need to be designed for hydraulic loading because its associated tailings area are elevated high above the RCD, and the only runoff it needs to contain or pass is the surface water associated with the surface area of the tailings itself. Under

severe flood loading conditions, the floodwater in the upper regions of the RCD will be against the downstream slope of the East Limb of the SD, however, the velocities will be too low to cause significant scour of the embankment during the anticipated duration of such an event (see hydraulic calculations in Down Valley Interim Hydraulic Upgrades Design [CH2M HILL, 2014a]).

Seismic loading could cause liquefaction of the dam foundation, and specifically at the locations where Rose Creek sediments occur beneath the dam. At the West Limb, which is the curved portion of the SD that crosses the valley roughly north to south, there are intermediate tailings on the downstream toe of the SD. These intermediate tailings would prevent failure of the dam during seismic loading even if the foundation soils liquefy. Even if some tailings loss would occur along this portion, the tailings are likely to be contained within the Intermediate Impoundment.

A breach of the East Limb of the SD, which is the portion of the SD that is parallel to the RCD and where there are no tailings at the toe, could result in tailings flowing into the RCD. It is noted that the likelihood of tailings loss is low even when losing a portion of the East Limb crest; given that the upper layers of the secondary tailings are not saturated and given the relatively small height of about 4.6 m. KCB (2008) did not estimate the risk classification for this dam, but since a breach of the East Limb of the SD could result in tailings loss into the RCD and from there into the areas downstream of the tailings areas, it can be conservatively assumed that the SD has the same risk classification as the ID, which is “High.”

3.1.1.4 Little Creek Dam

The LCD is typically not operated at full supply level. Since the dam contains a small volume of potential water release, KCB (2008) assigned a “Low” risk classification, based on the fact that (1) there would be relatively small economic loss, (2) there is limited Infrastructure or services downstream, and (3) there would be loss of marginal habitat only and/or restoration or compensation in kind would be highly possible.

3.1.2 Design Criteria for Spillway Capacity and Earthquake Loading

Table 6C-1 provides the CDA-recommended guidelines (CDA, 2007) for required spillway capacity and stability under earthquake conditions based on the dam risk classification. According to these guidelines, dams with a “High” risk classification should be designed to pass an IDF of 1/3rd, between a 1,000-year flood and a PMF, and be able to withstand an earthquake with a 2,500-year recurrence interval.

Since it may take several years (approximately 10 years) to prepare for and initiate construction of the final closure plan for the FMC, it is necessary to provide adequate levels of security of the dams and to implement interim works activities necessary to manage potential risks to human health and safety, and to the environment. Until the closure conveyance strategy and structures are agreed upon and implemented, the existing conveyance structures are to be capable of safely conveying the 1-in-500-year flood as required in the conditions of the expired water license (Water Use License QZ03-059), in which it is stated:

> *40. The Rose Creek Diversion shall have a capacity to carry a 1:500 year design flow.*
>
> *41. The spillways on the Intermediate Dam and the Cross Valley Dam shall have a capacity to carry a 1:500 year design flow of Rose Creek.*
>
> *42. The overflow structure on the Rose Creek Diversion shall be maintained to ensure that peak flows can freely pass through it.*

To evaluate whether this criteria is reasonable, the likelihood of a 1-in-500-year flood event during an interim period of 10 years can be compared with the likelihood of exceeding the design flows for typical design diversion schemes when constructing high hazard dams; typically, these schemes are designed for a 10- to 20-year flood event with the diversion in place for 2 to 3 years. The likelihood that a 10-year flood or greater could occur during a 2-year construction period is 18 percent, whereas the likelihood that a 1-in-500-year flood or greater could occur during a 10-year period is 2 percent. If it is assumed that the PMF would have a recurrence interval of 10,000 years, the likelihood that it could occur during a 100-year period is about 1 percent. It seems appropriate that the tailings dams be designed to a flood event with a much

lower annual probability of occurrence than for a temporary diversion scheme, given that the consequence of failure for the tailings dams could be significantly higher than consequence of failure of typical diversion works. On the other hand, it also seems reasonable to design it to a flood event with a higher annual probability of occurrence than that of the permanent dam.

The expired water license (Water Use License QZ03-059), also provided criteria for seismic loading for the interim period. Under Part D, Modification and Construction, it is stated:

33. All dams and diversions shall be designed to withstand the 1:475 year return period.

Until the closure concepts are agreed upon and implemented, the existing dams shall therefore be capable of withstanding the 1-in-500-year earthquake event.

The final closure concepts for the CVD have not been determined at this time, but it is unlikely to continue to function as a polishing pond. In the future it is likely to be operated in a dewatered state and will only contain significant amounts of liquid when needed for emergency storage. Since it will generally be empty, it is not considered necessary to design the dam for the maximum credible earthquake, but to design it to withstand the 1-in-500-year earthquake. Considering hydraulic loading, however, it is recommended that the CVD be required to pass the PMF, since it would contain a significant pool during flood loading conditions. In addition, the CVD is the last dam in a series of dams, where the upstream dams (SD and ID) will be required to pass the PMF.

The LCD is typically not operated at full supply level. Since the dam contains a small volume (about 120.0 m^3) of potential water release, KCB (2008) estimated that it has a “Low” risk classification. According to the CDA guidelines (CDA, 2007), dams with a “Low” risk classification should be designed to pass a 1 in 100-year flood and to withstand an earthquake with a recurrence interval of 500 years (Table 6C-2).

TABLE 6C-2
CDA Dam Safety Guidelines – Suggested Design Flood and Earthquake Levels (for Use in Deterministic Assessments)
Faro Mine Interim Works

	Annual Exceedance Probability (AEP)	
Dam Class [a]	**Inflow Design Flood [b]**	**Earthquake Design Ground Motion (EDGM) [c]**
Low	1/100	1/500
Significant	Between 1/100 and 1/1,000 [d]	1/1,000
High	1/3 between 1/1,000 and PMF [e]	1/2,500 [f]
Very high	2/3 between 1/1,000 and PMF [e]	1/5,000 [f]
Extreme	PMF [e]	1/10,000

Notes:

[a] As defined in Table E4-1 Dam Classification – CDA 2007.

[b] Extrapolation of flood statistics beyond 1/1000-year flood (10^{-3} AEP) is discouraged.

[c] AEP levels for EDGM are to be used for mean rather than median estimates of the hazard.

[d] Selected on the basis of incremental flood analysis, exposure, and consequences of failure.

[e] PMF has no associated AEP. The flood defined as “1/3 between 1/1000 year and PMF” or “2/3 between 1/1000 year and PMF” has no defined AEP.

[f] The EDGM value must be justified to demonstrate conformance to societal norms of acceptable risk. Justification can be provided with the help of failure modes analysis focused on the particular modes that can contribute to failure initiated by a seismic event. If the justification cannot be provided, the EDGM should be 1/10,000.

SECTION 4

Loading Conditions

4.1 Hydrotechnical

Since the existing ID spillway does not have the capacity to safely pass a moderate or major flood event (from Rose Creek catchment area and the surrounding area that drains to the Intermediate Impoundment) without overtopping and potentially breaching the dam, improvements to the spillway and the dam were designed as part of the Down Valley Interim Hydraulic Upgrades as detailed in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a). As part of this work, the hydrology and hydraulics for the RCD was updated, including attenuation of the NFRC flows. This section provides some of the results of those analyses, but more details can be found in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a).

4.1.1 Previous Hydrologic Studies

Previous hydrologic studies for the FMC have generally focused on determining instantaneous peak flows for a range of recurrence interval events. The studies have relied on regional analyses to determine discharge yield based on catchment area for a range of flood events. Regional analyses involve the use of runoff records from gauges in a geographic region that are expected to be hydrologically similar to catchments in the FMC. The recurrence interval events for the gauges containing longer periods of record are typically fit with a curve relating drainage area to peak flow rate. These curves are then used to predict recurrence interval flood events for the site of interest (Faro mine catchments) based on known drainage areas for various locations.

NHC (2001) conducted a regional analysis based on data obtained from seven regional gauges. At the time of the study, the period of record represented by the gauges ranged from 14 years to 37 years. The catchment areas for the gauges ranged from 91 square kilometres (km^2) to 7,250 km^2. Instantaneous peak discharges were estimated for the 1-in-2-, 1-in-50-, 1-in-100-, 1-in-200-, and 1-in-500-year return period flood events. NHC and BGC (2004) updated the return period flood estimates from NHC (2001) using additional stream gage observations. As part of the study, they also added an estimate of the mean annual flood and the 1-in-1,000-year return period flood.

Another regional study was conducted by Hydrotechnical Consulting (2006) to determine average daily flows for the 1-in-2-, 1-in-100-, 1-in-200-, 1-in-500-, and 1-in-1,000-year flood events. The recurrence interval floods were determined for flow durations ranging from 1 to 365 days. Using plots of peak discharge vs. catchment area, a relatively constant discharge per square kilometer was observed for flow records representing catchment areas ranging from 13.7 km^2 to 7,250 km^2. This observation led to the conclusion that catchment response to floods could be estimated by using recurrence interval estimates from a single gauge with the most extensive period of record (because catchment unit discharge during recurrence interval events appeared to be independent of total catchment area).

SRK Consulting (SRK) performed a regional analysis to estimate instantaneous peak on Vangorda Creek, as part of a draft design report for the Vangorda Creek Diversion (SRK, 2010b). Relationships between catchment area and peak instantaneous flood discharge were developed for the 1-in-2-, 1-in-100-, 1-in-500-, and 1-in-1,000-year flood events. Upper envelope and best-guess equations were developed for the 1-in-500-year flood event.

A PMF analysis was conducted by Water Management Consultants (2006) for the Rose Creek watershed. The PMF study applied the 24-hour probable maximum precipitation (Taylor and Hale, 2006) to the Rose Creek catchment. The antecedent conditions assumed saturated soil conditions and a shallow snowpack across the entire Rose Creek catchment. The Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS) software was used to simulate the rainfall-runoff processes occurring during the probable

maximum precipitation event. Outflow hydrographs at the NFRD, South Fork Rose Creek (SFRC) outlet, and lower end of the diversion channel (assumed to be near gauge X14) indicate that the PMF response to the probable maximum precipitation occurs over a period of approximately 2 to 3 days. Peak flows occur between 16 and 17 hours after the initiation of the probable maximum precipitation event for all catchments. The analysis assumed that the NFRD would not be in place during the PMF, and therefore no attenuation was modelled through the NFRD. Peak flood discharges in the NFRD and SFRC were estimated to be approximately 384 and 300 m^3/sec, respectively. Peak flood discharge at the lower end of the diversion channel was estimated to be approximately 692 m^3/sec.

The regional analyses conducted for either instantaneous or sustained (i.e. daily or 7-day) periods were used to select design discharges at various locations within the FMC. The locations were selected to define design flows at strategic locations within the FMC for hydraulic analyses of structures. Instantaneous peak discharges can be used for design of channels and conveyance elements where peak discharge is the only parameter that affects sizing of such elements. Hydrographs detailing flows during the duration of the design flood are required for design when flow attenuation and routing effects need to be taken into account.

Table 6C-3 summarizes the FMC locations and associated design peak discharges during the 1-in-50, 1-in-100-year, 1-in-500-year, 1-in-1000-year, and PMF events.

TABLE 6C-3
Summary of Peak Discharge Hydrology
Faro Mine Interim Works

Location	Drainage Area (km^2)	Instantaneous Design Peak Discharge (m^3/sec)				
		1-in-50 year	1-in-100 year	1-in-500 year	1-in-1000 year	PMF
R7 gauge	99	37	42	63	77	*Not Reported*
NFRD	118	44	49	72	93	384
SFRC	73	29	33	49	61	300
RCD (Head of diversion)	203	71	75	111	150	*674*
X14 gauge	229	79	83	122	167	692

The Inflow Design Flood for the interim period is the 1-in-500-year flood event. Table 6C-4 summarizes peak unattenuated discharges during the 1-in-500-year flood event for all catchments upstream of the ID spillway.

TABLE 6C-4
Down Valley Interim Hydraulic Upgrades 1-in-500-year Design Peak Discharge
Faro Mine Interim Works

Location	Drainage Area (km^2)	1-in-500-year peak discharge (m^3/sec)
NFRD	118	72
Downstream of NFRD	1.24	1.9
SFRC	73	49
South Slope adjacent to RCD, discharging to head of RCD	6.8	7.5
South Slope adjacent to RCD, discharging to RCD downstream of overflow weir	4.5	5.4
North Slope and Tailings area, discharging to ID Pond	9.1	9.4

4.1.2 Flood Hydrograph Development

Flood hydrographs were developed for the PMF event (Water Management Consultants, 2006) since rainfall-runoff characteristics were explicitly modeled using the HEC-HMS software. No flood hydrographs representative of the 1-in-50-year, 1-in-100-year, 1-in-500-year, and 1-in-1000-year were available for the NFRD, SFRC, or RCD from previous studies since regional analyses do not account for the hydrological conditions that would produce the estimated instantaneous peak discharges. Flood hydrographs at various recurrence interval events are necessary in order to determine routing characteristics and response of FMC elements to incoming flow rates and volume. In the absence of hydrological modeling to estimate flood hydrographs for recurrence interval events, flood hydrographs were constructed using predicted instantaneous peak discharge estimates (Section 4.1.1) and a non-dimensional hydrograph developed from an observed flood on Vangorda Creek in 1993 (NHC, 2001).

1-in-500-year design flow hydrographs were developed for the NFRD, SFRC, additional NFRD downstream, South Slope catchment draining to the head of the RCD, South Slope catchment draining to the RCD downstream of the overflow weir, and the Intermediate Impoundment using the non-dimensional hydrograph proposed by NHC (2001).The instantaneous peak discharge from each catchment was constrained to match the instantaneous peak discharge as reported in Table 6C-4.

The shape, duration, and timing of the developed hydrographs for NFRD, SFRC, South Slope, and Intermediate Impoundment catchments are expected to represent the potential runoff response during a 1-in-500-year event. The predicted volume of the runoff hydrographs were compared to regional precipitation data and determined to be feasible for larger basins such as the NFRC and SFRC basins (i.e., flood hydrograph volumetric yield is reasonable compared to available annual precipitation during a year in which the 1-in-500-year flood may occur). Hydrograph volumes for smaller basins are conservative, meaning that during a 1-in-500-year flood event, the actual volume would likely be less than what is predicted by applying the non-dimensional hydrograph from NHC (2001). However, the overall volume contribution from smaller drainage basins is small compared to the contribution from the larger NFRC and SFRC basins so the level of conservatism is assumed to be acceptable. Figure 6C-18 shows the design flood hydrographs.

4.2 Seismic

The seismic hazard assessment for the site was updated in 2013 by Atkinson and Assatourians (2013), resulting in significantly lower estimated ground surface motions associated with local seismic conditions than those presented by Atkinson's previous seismic hazard assessment (2004). The main reason for this re-evaluation of ground motions at Faro is due to the insights gained in several studies performed since 2004.

A significant study involved the evaluation of the tectonic setting of the Tintina Fault, considered to be the controlling fault for the site. In a report by CH2M HILL Canada Limited (CH2M HILL, 2013), the most recent interpretation of the 30-km wide fault zone is that it no longer accommodates significant seismic deformation. The fault is currently characterized by low slip rates and activity rates. Also, it was concluded that the fault is structured more as aerial source zone comprised of several faults, rather than a distinct linear active fault.

The most important factor warranting a re-evaluation is the improvement of ground motion prediction equations (GMPE). GMPEs provide an estimate of ground shaking based upon earthquake magnitude, distance from site, and site conditions. The databases used to compile GMPEs are actively growing, promoting continual refinement to the models. Following the recommendations by Atkinson and Adams (2013) for the 2015 NBCC National Seismic Hazard Maps, the GMPEs were developed for the site, based upon B/C site conditions ("Site Class B/C" denotes the boundary between rock and soil materials and is defined as material with average shear wave velocity of 760 metres per second [m/s] in upper 30 m of soil profile). Amplification factors converting spectral accelerations from Site Class B/C to other site classes, such as Site Class C (450 m/s), can be applied to account for change in ground motions due to softer soil conditions.

Based upon the recent studies, the ground motions were reduced significantly for the site, particularly for an earthquake with a 10,000-year return period, which can be considered as the MCE for the site. Atkinson and Assatourians (2013) reduced the MCE peak ground acceleration (PGA) for the site from 0.5 g (mean value from Atkinson, 2004) to 0.25 g at the B/C boundary, a 50-percent reduction, where "g" is the acceleration because of gravity equal to 9.81 metres per square seconds.

Ground motions were also evaluated for the subduction zone bordering Alaska. Although the subduction zone is located approximately 500 km from the site, a magnitude M9 subduction event is capable of producing high ground motions at low frequencies, affecting structures with larger periods.

In Table 6C-4, the spectral accelerations (in centimetres per seconds square [cm/s^2]) are provided for return periods of 500, 1,000, 2,500, 5000, and 10,000 years for frequencies between 0.1 to 20 Hertz (Hz), in addition to PGA and PGV. Ground motions, as determined from the deterministic evaluation of a magnitude M9 subduction zone earthquake along the Alaska border, are also provided. The spectral accelerations are provided in Figures 6C-19 and 6C-20 at the B/C boundary and Site Class C conditions, respectively.

UHS = Uniform Hazard Spectra
PSA = Peak Spectral Acceleration
PGA = Peak Ground Acceleration
PGV = Peak Ground Velocity

SECTION 5

Stability Evaluation of Major Physical Structures

5.1 Dams

Evaluation of dam stability includes two components: (1) the adequacy of the associated conveyance structures (such as spillways and diversions) to pass the IDF, and (2) the structural stability of the dams under normal, flood loading, and earthquake loading conditions. For this Interim Works Project Proposal, the evaluations were limited to dam stability for the interim period.

5.1.1 Adequacy of Conveyance Structures to Withstand Hydraulic Loading

The following specific major conveyance structures were considered (upstream to downstream) in this evaluation:

- RCD
- Overflow Weir in RCD Dike
- ID Spillway
- CVD Spillway

The general approach to assess the adequacy of the existing dams to withstand the design hydraulic loads for each conveyance structure during this interim period was as follows:

1. Assemble the 1-in-500-year IDF estimates for each conveyance structure based on routing scenarios and area-based hydrologic estimates.
2. Compare the existing capacity of the specific conveyance structure with the IDF. The existing capacity is determined by hydraulic modeling and the development of rating curves for the structures.
3. Identify required modifications to address insufficient conveyance capacity.

5.1.1.1 Inflow Design Floods

Section 4.1 summarizes the development of design flood hydrographs used to evaluate the adequacy of the major conveyance structures. The routing of these design hydrographs to evaluate interaction of flood flows and various conveyance structures was completed using hydraulic models as described in the following sections.

5.1.1.2 Capacity of Conveyance Structures

Using topographic and bathymetric data available for the FMC, RCD, and proposed improvements, CH2M HILL prepared one-dimensional (1D) and two-dimensional (2D) hydraulic models to evaluate hydraulic conditions for design flood flow rates with a recurrence interval of 500 years. The 1D hydraulic model was used to route flood hydrographs from the NFRC and SFRC to the upstream end of the RCD. The rock drain and upstream impoundment were included in the 1D model to estimate attenuation characteristics of the rock drain during flood events.

The 2D hydraulic model was used to route flood hydrographs from the upstream end of the RCD through the RCD, spilling over the overflow weir into the Intermediate Impoundment, and through the ID spillway.

5.1.1.2.1 Attenuation in the North Fork Rock Drain

Similar to the methodology followed by BGC (2006), stage-discharge relationships for the rock drain were estimated by assuming a range of possible parameters to represent the flowthrough area and characteristics of the rockfill within the drain. Assumptions were also made about the extent and behavior of the calcium-silicate and schistose rock zones. Using a range of discharge and attenuation values results in potential high, moderate, and low discharge scenarios for flow through the rock drain. Low flow-through scenarios further assumed various degrees of debris blockage (25-, 50-, and 75-percent). Estimating upper and lower limits for flowthrough provides a range of potential scenarios that may occur during the 1-in-500-year flood event. Each scenario is briefly summarized as follows:

- **High-Flow Scenario**: The high-flow scenario is similar to the scenario presented by BGC (2006). The dominant rock size for the entire embankment is assumed to be 0.25 m. The void ratio for both calcium-silicate and schistose rock is assumed to be approximately 0.4. While it is possible that the void ratio of certain portions or pockets of the schistose rock may change as some particles breakdown, if there is not significant settlement the overall void ratio of the schistose rock may not be changed significantly. A high void ratio of 0.4 was selected for the schistose rock to obtain higher flow-through capacities including a higher upper bound estimate for high flow-through (i.e., a higher upper bound value for flow-through capacity). Since a zero flow was assumed for the schistose rock in the low-flow scenario, this facilitates consideration of a wider range in flow-through capacities. It was assumed that both the schistose and calcium-silicate areas would be available for flow-through.
- **Medium-Flow Scenario**: The medium-flow scenario assumes that the dominant rock size for the calcium-silicate zone is approximately 0. 25 m. The dominant rock size for the schistose is assumed to be 0.05 m. The void ratio for both rock types is again assumed to be approximately 0.4. It was assumed that both the schistose and calcium-silicate areas would be available for flow-through, but the smaller dominant diameter for the schistose rock would reduce flows through this zone compared with the calcium-silicate zone.
- **Low-Flow Scenario**: The low-flow scenario assumes that there is no flow through the schistose rock. All flow through the NFRD is conveyed through the calcium-silicate zone, which is assumed to have a dominant rock size of 0.25 m. The void ratio for the calcium-silicate rock is assumed to be approximately 0.4.
- **Low-Flow Scenario plus 25-Percent Reduction in Flow-Through Capacity:** The low-flow plus 25-percent reduction in flow-through capacity scenario assumes the same parameters as the low-flow scenario, but imposes a 25-percent reduction in flow-through capacity. This capacity reduction is intended to represent a minor blockage resulting from conditions such as debris racking on the NFRD face or plugging of interstitial spaces within the NFRD by soil or other material.
- **Low-Flow Scenario plus 50-Percent Reduction in Flow-Through Capacity:** The low-flow plus 50-percent reduction in flow-through capacity scenario assumes the same parameters as the low-flow scenario, but imposes a 50-percent reduction in flow-through capacity. This capacity reduction is intended to represent a mid-range blockage resulting from conditions such as debris racking on the NFRD face or plugging of interstitial spaces within the NFRD by soil or other material
- **Low-Flow Scenario plus 75-Percent Reduction in Flow-Through Capacity:** The low-flow plus 75-percent reduction in flow-through capacity scenario assumes the same parameters as the low-flow scenario, but imposes a 75-percent reduction in flow-through capacity. This capacity reduction is intended to represent a major blockage resulting from conditions such as debris racking on the NFRD face or plugging of interstitial spaces within the NFRD by soil or other material.

To route flood hydrographs through the NFRD and downstream in NFRC and also from the SFRC to the upstream end of the RCD, CH2M HILL used Hydrologic Engineering Center–River Analysis System (HEC-RAS) version 4.1.0, a 1D hydraulic model developed by the U.S. Army Corps of Engineers. The HEC-RAS model was created using HEC-GeoRAS version 10, which allows HEC-RAS geometry elements to be defined in a Geographic Information System environment and results in a georeferenced, spatially consistent hydraulic model. The topography of the NFRC and SFRC catchments results in flowpaths that are more easily defined than for the RCD and tailings area. The less complex flowpaths, lack of off-channel storage elements, and relatively short distance between the NFRD and the head of the RCD result in a model geometry that is well-represented by a 1D modelling tool. Since 1D and 2D modelling tools provide equally suitable results under these conditions, the 1D hydraulic model was considered a reasonable means for routing flood hydrographs to the upstream end of the RCD.

The flowthrough scenarios predict varying attenuation of flows ranging from 18- to 38-percent through the NFRD during the 1-in-500-year flood under unblocked conditions. A potential reduction in flow-through capacity, which would occur when there is significant woody debris blockage of the upstream face, would cause further attenuation of peak flows. A 75-percent reduction in flow capacity of the low-flow scenario is estimated to attenuate the peak flow for the 1-in-500-year flood by approximately 68 percent.

5.1.1.2.2 Rose Creek Diversion

A 2D model to describe existing conditions was prepared to simulate flow and estimate capacity in the RCD. Hydraulic modeling results predict that the existing configuration of the RCD does not provide adequate capacity to convey the 1-in-50-year flood flow of 71 m^3/sec before overtopping the overflow weir.

To evaluate the effectiveness of vegetation removal in the RCD, the existing conditions 2D model was re-run with revised roughness mapping to represent the channel cleared of vegetation on the right bank only, and then on both the left and right banks. Model input requires an evaluation of flow resistance expressed as Manning's roughness coefficient, *n*. Vegetation characteristics are commonly represented with the roughness coefficient. Areas mapped as large and small vegetation were revised to represent the same channel area without vegetation. For example, areas classified as large vegetation (n = 0.12) were revised to bare rock (n = 0.047) or bare soil (n = 0.03).

To compute the required increase in capacity for the RCD to convey the 1-in-500-year flood, the existing conditions model described in the previous section was modified in the location of the overflow weir to raise the elevation of the overflow weir to the modeled water surface elevation during the 1-in-500-year flood. The elevation of the overflow weir was set to elevation 1,058 m. This elevation provides zero freeboard at the overflow weir during the 1-in-500-year flood event. Other locations along the dike were modelled assuming a minimum freeboard requirement of 0.5 m.

The 2D model was used to evaluate the effectiveness of interim measures. Model simulations with the 1-in-500-year flow rate predict the following:

- 1-in-500-year flow at upstream end of RCD = 111 m^3/sec
- 1-in-500-year flow in RCD downstream of the overflow weir = 116 m^3/sec
- 1-in-500-year flow in the Intermediate Impoundment assuming failure of the overflow weir (or of the RCD dike), and zero flow in the RCD = 121 m^3/sec

5.1.1.2.3 Intermediate Dam Spillway

The existing ID spillway does not have the capacity to safely pass a moderate or major flood event without overtopping and potentially failing the dam and releasing tailings to the downstream environment. NHC (2006) determined that the ID spillway capacity is 32 m^3/sec if the top of flood water surface elevation is limited to the top of the dam core estimated at elevation 1,048.5 m. The capacity is 63 m^3/sec if the flood water surface is allowed to rise to the dam crest (approximately elevation 1,049.0 m).

5.1.1.2.4 Cross Valley Dam Spillway

According to NHC (2006), the CVD spillway has a capacity of 300 m^3/sec, which is enough capacity to convey the IDF.

5.1.1.3 Interim Modifications

5.1.1.3.1 Rose Creek Diversion

Design criteria dictate that the RCD maintain 0.5 m freeboard at the 1-in-500-year flow. Table 6C-5 summarizes results of 2D modeling, existing elevation of the right bank of the RCD, and the additional embankment fill placement required to meet minimum freeboard requirements.

TABLE 6C-5
Summary of 2D Model Results in the RCD and Elevation of Right Bank

5+200	1052.75	1053.25	0.24

[a] RCD station as indicated for interim improvements.

In addition to raising the crest of the RCD dike to meet freeboard criteria, vegetation needs to be removed from the dike and riprap, and slope sloughing needs to be repaired at some locations as needed. Reasons for vegetation removal includes the following: (a) allow proper inspection, surveillance, and monitoring for seepage, cracking, displacement, and any other signs of distress in the dike; (b) allow access for Operations and Maintenance activities; and (c) limit those habitat characteristics that encourage the creation of animal burrows.

Interim measures specify that the elevation of the overflow weir be raised to elevation 1,058.2 m, which corresponds to the water surface elevation that is predicted for conveyance of the 1-in-500-year flowrate

(elevation 1,058.0 m) plus a 200 mm-thick layer of native sand and gravel covering the crest to provide a road surface (i.e., the structure will have a freeboard of 0.2 m).

5.1.1.3.2 Intermediate Dam Spillway

The improvements at the ID spillway consist of excavating the existing channel by a maximum of about 2 m, and placing a 0.45-m-thick gabion mattress on the excavated surface and side slopes of the channel. The proposed channel will follow the same footprint of the existing channel, so there will not be any significant widening of the channel. Gabion cells that are 0.9 m by 0.9 m in cross section will be used on the sides of the channel, with a geotextile between the gabions and the excavated soil surface. Waste rock was considered as a potential material for the gabion structures. However, given the irregular shape of the calcium-silicate waste rock, high sulfate content, and the fact that borrow material in the Rose Creek Borrow Area will already be processed to generate other materials needed for this project, only the Rose Creek Borrow Area is considered a cost-effective and suitable source of cobbles for the gabions.

To raise the effective ID crest, a geomembrane will be installed vertically in a trench between the dam core and the crest surface, and a single row of 0.9-m by 0.9-m gabions will be placed along this line to further raise the effective crest to an estimated elevation of 1,049.6 m. The gabions will be partially embedded (depth of about 0.2 m) in the upper portion of the excavated trench on top of the compacted backfill. It is noted that the ID crest is at an average elevation of about 1,048.9 m, and, based on the test pit exploration results, the top of the dam core at the center of the dam crest varies with a low elevation of about 1,048.3 m. To tie the geomembrane into the existing core, the upstream edge of the installation trench will be located 1 m from the top of the upstream slope, with a depth of 1.5 m. Low-permeability glacial till material will be imported from a nearby borrow area and will be placed in the lower 0.5 m of the installation trench. The material excavated from the trench would be used for backfill in the upper 1.0 m. The crest surfacing will be reinstated as shown on the drawings, by placing a 0.2-m-thick layer of gravel and sand at the crest.

The 2D model was used to evaluate some proposed improvements to the ID spillway capacity. Model simulations assume that the overflow weir has blown out with subsequent erosion of the right bank levee at that location, resulting in the entire design flow conveyed onto the tailings. Model simulations were run with the 1-in-500-year design hydrograph accounting for attenuation of flow through the NFRD. The peak flowrate in the Intermediate Impoundment is approximately 117 m^3/sec. At the start of the model simulations, the water surface elevation in the Intermediate Impoundment is assumed to be 1,046.5 m corresponding to the ID spillway invert elevation. As the simulation runs, water is first conveyed down the RCD, then out the overflow weir opening, across the tailings, and through the spillway. Spillway discharge is a function of the headwater depth that builds behind the ID. The 2D modelling takes the storage of the Intermediate Impoundment into account while routing the 1-in-500-year design hydrograph through the ID spillway with the result that the peak ID spillway discharge is less than the peak inflow rate into the Intermediate Impoundment.

Model simulations with the 1-in-500-year flow rate routed down the RCD, discharged into the Intermediate Impoundment, assuming that the overflow weir and/or the RCD dike would breach such that all the RCD flow will be conveyed over the tailings predict the following:

- Flow over the ID spillway = 115 m^3/sec
- Headwater elevation = 1048.6 m
- Freeboard at ID = 1.0 m

5.1.2 Structural Stability of Dams

Stability of the following dams was evaluated:

- ID
- CVD
- SD
- LCD

Numerous studies have been undertaken by different consultants over the last 10 years to assess the stability of the dams. Many of these evaluations were seismic stability assessments by Golder (2004) and Klohn Crippen Consultants [KCC] (later KCB) for the tailings dams and the CVD; other studies (NHC, 2006, etc.) were performed to assess the flood vulnerability of the ID and CVD. The results of these studies formed the basis for evaluating the embankment slope stability under static and seismic loading conditions, for the interim period.

To evaluate the potential for other failure mechanisms, including the potential for excessive seepage, internal erosion and piping, we have relied upon the results of periodic dam safety reviews and annual dam safety inspections that were performed and documented by various consultants (KCB, Golder, SRK, and BGC) over the last 10 to 15 years. Periodic dam safety reviews are performed every 5 to 7 years, and typically include a review of all the potential failure modes. The first dam safety review by KCC (2002) triggered a number of the seismic and flood studies referenced above. The 2002 report also reviewed the safety of the Fresh Water Dam on the south fork of Rose Creek upstream of the tailings area. In 2003 that dam was breached to release the pond so it was no longer a hazard to the downstream environment and facilities.

A subsequent dam safety review was performed in 2007 by KCB (2008) for the ID, CVD and channels at the Faro Mine Site. The report presented information on dam classification and methods to improve the dam safety program at the Faro Mine. Additional studies were performed since that time including:

1. BGC (2008a) wrote an Emergency Response Plan (ERP) for potential failure of the dams at the FMC.
2. BGC (2008b), with input from SRK, prepared an Operations, Maintenance, and Surveillance manual for the dams at the FMC (including LCD near the Vangorda/Grum Area)
3. Golder (2009) reported on the performance of the stability of the soil slope between the Faro Pit and the Faro Creek Diversion Canal
4. BGC (2009) wrote a report that updated recommendations on a rapid drawdown for the ID and CVD Ponds.

Other sources for condition assessment of the dams were associated with annual dam safety inspections, such as the dam safety inspections performed by KCB, BGC, and SRK. Evaluation of the stability of the dams also includes the results of seismic slope stability analyses of the East Limb of the SD performed by CH2M HILL. Analyses were previously performed to evaluate the seismic stability at this location, and it was concluded that the dam had insufficient margin of safety against slope failure as a result of foundation liquefaction, and will require seismic mitigation to meet the long-term design criteria. These analyses were performed for a 10,000-year earthquake event, which is the criterion for final closure (long term). To assess the seismic stability of the embankment for the interim period of 10 to 15 years, analyses were performed for a seismic event with a recurrence interval of 500 years, with the analyses also incorporating the updated seismicity for the site (Atkinson and Assatourians, 2013).

5.1.2.1 Intermediate Dam

Extensive seismic stability assessments were performed to determine the liquefaction potential in the ID foundations and to evaluate seismic slope stability (KCB, 2006a; KCB, 2006b). The evaluations included a geotechnical exploration program using the Becker Penetration Testing (BPT). A plan showing the BPT locations are provided in Figure 6C-21. BPT was used because the methods traditionally used for liquefaction assessment, the Standard Penetration Test (SPT) and the Cone Penetration Test could not be used because of the known presence of gravel and larger particle sizes in the natural foundation soils. All the liquefaction potential evaluations were performed assuming MCE ground motions.

The BPT results showed that the terrace or glaciofluvial deposits which form most of the uppermost foundation soils of the ID (Figure 6C-22), the northern foundation of the East Limb of the SD, and most of the foundation of the East Limb of the SD are not liquefiable.

However, it was found that the recent Rose Creek sediments were generally liquefiable under MCE loading (for example, beneath the West Limb of the SD and the southeast corner of the East Limb). The only exception where the recent Rose Creek alluvial sediments were found to be not liquefiable was beneath the maximum section of the ID. KCB (2006b) noted that "*to check this apparently contradictory result, two more BPTs and SPTs/LPTs were*

conducted at the Intermediate Dam with the same result. The Recent Rose Creek alluvial sediments at the Intermediate Dam are not liquefiable so remediation is not necessary for present conditions."

KCB (2006a) described post-seismic stability analyses performed for the ID. In these analyses it was assumed that the tailings would liquefy completely, but that no liquefaction would occur in the dam foundation or in the embankment. It was shown that the dam would be stable with a factor of safety of more than 1.5 for all failure surfaces through the crest and foundation of the dam, but with factors of safety slightly less than 1.5 for shallower failure surfaces. From these results, it can be concluded that the dam also has ample margins of safety under static (normal) loading conditions. It is noted that no shaking (seismic coefficient) is applied when performing post-seismic stability analyses.

In addition, Newmark sliding block type of analyses were carried out to estimate the permanent seismic displacements of the ID. Calculated displacements varied from 13 cm for the Makdisi and Seed (1978) method to 55 cm for the Hynes and Franklin (1984) method.

Since the design earthquake for the interim period only has a recurrence interval of 500 years, with ground motions much smaller than the MCE motions (1-in-10,000-year motions), the ID should be stable for this level of shaking, and permanent seismic displacements should be small. Also note that all the evaluations described used the ground motions from the Atkinson (2004) study, which are significantly higher than the ground motions of the recent updates to the seismic hazard assessment (Atkinson and Assatourians, 2013). Therefore, the actual margins of safety would be even larger than suggested by the analysis results presented.

Based on the historical performance of the dam and the observations from periodic dam safety reviews and the annual dam safety inspections, stability concerns pertaining to seepage and/or piping have not been identified. KCB (2008) noted that there is no evidence of seepage along the downstream berm, which implies that the phreatic surface is below the ground surface and apparently lower than the horizontal drain, so that groundwater seepage bypasses the drain and discharges into the polishing pond below the water surface elevation of the polishing pond. There is thus no observed water seepage at an exit face that can lead to backward erosion and piping.

KCB (2008) further noted that some riprap benching (forming of small bench at stable water line by long term wave action) is evident on the upstream slope, but stated that the riprap is generally in good condition, but will require periodic maintenance as was done in 2007.

5.1.2.1.1 Recommended Maintenance Activities for Intermediate Dam

BGC (2010) documented their 2009 Annual Geotechnical Evaluation and Instrumentation review and noted some items for maintenance. The latest Annual Geotechnical Review was performed by Klohn Crippen Berger in 2011 (KCB, 2012) and they also made recommendations for ongoing maintenance. A summary of potential maintenance items are as follow:

- The downstream face experienced rill erosion and some slumping. BGC (2010) noted that this has occurred on the face of the dam over the last four or five years, ever since sand and gravel was applied to the face of the dam. The rill erosion and slumping occurs within this surfacing material. KCB (2012) recommended that the ongoing rill development and related longitudinal cracking and slope slumps should be monitored. KCB (2012) also suggested that experimenting with potential remedial measures, such as grass planting or placement of riprap, should be considered.
- Monitor sediment deposition over the discharge face of the drainage zone above the downstream berm face (KCB, 2012). This sediment tends to collect on the road surface as it is eroded down the face of the dam. BGC (2010) noted that it would be advisable to extend the gravel drain onto the prepared surface of the road, to prevent blockage of the drain by future erosion on the face of the dam.
- Continue to monitor the upstream slope wave erosion zone because the ID Pond has been drawn to below the riprap protection zone since 2010. KCB (2012) suggested that remedial measures, such as replacement of riprap, may be required if excessive erosion is observed. Remedial measures must take into consideration the works required for permanent closure of the pond.

- Repair shoulder erosions of the downstream berm (KCB, 2012).
- Check piezometric data to check potential blockage of drains (KCB, 2012).

5.1.2.2 Cross Valley Dam

Final closure concepts for the CVD have not been developed at this stage. Initial concepts are that the CVD will be retained for the following: (1) provide emergency storage; (2) allow a facility for sedimentation of tailings that may erode during extreme runoff events; and (3) capture any contaminated water that may surface downstream of the ID. Under this scenario, the CVD Pond will be drained and maintained in a dry condition, i.e., effectively decommissioned, which will require installation of a low-level outlet. KCB (2006b) had showed that the dam in its present configuration would not be stable if subjected to the design earthquake event (MCE with 10,000-year return interval); however, as discussed in Section 3.1.2.2, the design earthquake for the interim period has a recurrence interval of 500 years.

KCB (2007) also performed seismic stability analyses of the dam for the 1-in-500-year earthquake. Ground motions from the Atkinson (2004) study were used for those analyses. The results of the analyses showed that the foundation soils do not liquefy under the 1-in-500-year motions, and that the dam would be able to withstand the 1-in-500-year earthquake. KCB (2007) noted that there will still be seismic deformations of the dam during an earthquake event of this magnitude. Such movements will be permanent but should be small and would not lead to release of the reservoir, provided the freeboard is more than 1.5 m.

Since the analyses performed in 2007 (KCB, 2007) used the ground motions from the Atkinson (2004) study, which are significantly higher than the ground motions of the recent updates to the seismic hazard assessment (Atkinson and Assatourians, 2013), it is concluded that the CVD is stable under the design seismic loading for the interim period. Therefore, CH2M HILL has concluded that the dam would have a significant margin of safety for the 1-in-500-year seismic loading.

Results from a Dam Safety Assessment by Klohn Crippen Consultants (2002) indicate that the CVD also met static stability criteria.

5.1.2.3 Secondary Dam

As for the ID, seismic stability assessments for the SD included BPT, liquefaction potential evaluations, and seismic slope stability computations (KCC, 2006a; KCC, 2006b). All the liquefaction potential evaluations were performed assuming MCE ground motions as determined by Atkinson (2004).

The BPT results showed that the recent Rose Creek sediments beneath the West Limb of the SD and the southeast corner of the East Limb (see Figure 6C-23) are liquefiable under MCE seismic loading. Using liquefied strengths in the foundation soil and the retained tailings, KCB (2006a, 2006b) found that the southeast section of the East Limb of the SD will not be stable for long-term design criteria, i.e., the factor of safety against flow sliding was less than 1.0. The southeast section is where the embankment is underlain by the recent Rose Creek alluvial sediments.

Because of the stabilizing force provided by the intermediate tailings at its downstream toe, it was found that the West Limb of the SD was stable, even at the locations where the foundation consists of liquefiable Rose Creek sediments.

Because the evaluations discussed were performed for 1-in-10,000-year motions, and since the design earthquake for the interim period has a recurrence interval of 500 years, additional analyses were performed by CH2M HILL to assess its stability and need for seismic mitigation for the interim period. The analyses and its results are documented in Attachment 6C-1. Analysis results showed no liquefaction in the foundation soils (including the recent Rose Creek sediments) for a 1-in-500-year seismic event. It also showed that the dam will be stable with factors of safety of 1.5 or greater under all considered load cases, including static, pseudo-static and post-seismic loading. It is anticipated that small deformations will occur and such deformations would be tolerable; the dam will not breach and no tailings would be released.

5.1.2.4 Little Creek Dam

Based on the observations from periodic dam safety reviews and the annual dam safety inspections, the dam appears to be stable. KCB (2008) noted that the upstream slope of the dam showed no evidence of slumping or erosion on the upstream slope and that the crest was also in good shape. Although there is no riprap on the upstream slope, the fetch of the reservoir is too small to generate waves that can cause wave erosion.

However, KCB (2008) reported some erosion and sloughing on the downstream slope of the dam which would require repair. Because the downstream slope is glacial till it is subject to freeze-thaw softening, and rainfall then tends to erode gullies into the loose surficial slope material. Gully-forming can only be rectified by placing a suitable frost protection fill (sand and gravel layer) on the slope, with a thickness that is more than the frost depth. Alternatively, any damage can be controlled by performing annual inspections and to implement maintenance measures as needed.

Instrumentation in the dam includes six pneumatic piezometers and three thermistors. KCB (2008) noted that from 1994 to middle of 2006 the piezometer readings are very uniform, but in the middle of 2006 there was a rise in the levels of two of the piezometers that could not be explained. It was hypothesized that downstream slope erosion may be blocking drainage on the downstream slope of the dam and foundation slope beyond the toe of the dam. It is concluded that the static safety of the dam is acceptable, and that gully erosion can be managed by inspections, monitoring and maintenance repairs in the interim period. In the long term, and especially if it is desirable to limit maintenance, it would be desirable to remediate the slope by placing frost protection on the downstream slope.

5.2 Open Pits

5.2.1 Faro Pit

Two slope failures have been identified along the east slope of the Faro Pit, referred to as the North and South Instability Zones (Golder, 2013). These instabilities have resulted from planar, westerly dipping rock structures that intersected the slope of the open pit as it was excavated. The North Instability Zone includes overburden material above the rock slope, while the South Instability Zone is entirely within rock. The slope displacements occurred progressively over an extended time during active mining within the pit. Catastrophic failures were not observed. Overall, the slopes within the instability zones have become relatively stable, with only localized sloughing or raveling occurring in the oversteepened head scarp areas within the overburden.

For the interim period, catastrophic failure of the slopes of the Faro Pit is a low risk. The greatest risk to the existing infrastructure is posed by the progressive raveling, erosion, and sloughing of the steep head scarp area of the North Instability Zone. The exposed overburden soils become weathered over time from repeated wetting, drying, and freezing, causing a loss of cohesion and sloughing down the slope. The newly exposed fresh till material then becomes weathered, leading to a progressive retreat of the crest of the slope. This progressive loss of soil could reach the Faro Creek Diversion and access road that run along the top of the East slope of the Faro Pit over time. A more detailed description of the slope instability zones can be reviewed in the FMC annual pit slope stability inspection report (Golder, 2013).

The Faro Pit instability zones are currently being monitored on a periodic basis. Measurements of displacements are being made around the crest of the East Pit slope. A total of nine survey prism posts and six measurement bars have been installed. Also, visual inspections are made to identify any changes in conditions observed between the inspections. The instability zones have not shown significant displacement since the time that observations were started in 2002. The rate of crest retreat is anticipated to continue similar to the rates observed during the last few years. Only localized erosion, sloughing, and raveling have been observed, but these processes could eventually undermine the Faro Creek Diversion and access road in the long term. The periodic observations and surveys should continue through the interim period on an annual basis in order to evaluate trends and give advance warning of potential safety hazards.

No changes to the current monitoring observations and surveying are necessary during the interim period given the slow rate of crest retreat and absence of movement within the slide area. For the long term, an evaluation of

the estimated maximum area that could be affected above the slope instabilities should be performed. This should be completed for cross sections through both the north and south instabilities. The maximum retreat of the top of the pit slope will provide an idea of which sections of the Faro Creek Diversion and access road is at greatest risk of being affected, assuming the angle of repose is reached for the overburden and rock failure area. A plan to stabilize these sections could be developed for the overall closure plan where the Faro Creek Diversion and access road are at risk in the long term.

Drainage from the access road above the East pit slope is currently discharged into the east slope of the pit in a few areas. Erosion is occurring, and the water appears to be infiltrating the materials at the top of the slope. As part of the overall closure activities, this drainage should be regraded and be controlled and directed away from the slope to limit long-term erosion losses and saturation of the pit slope.

5.2.2 Grum Pit

Slope failure has been observed on the East wall of the Grum Pit within the glacial till materials overlying rock (Golder, 2013). A large portion of the East pit slope, approximately 300-m wide, initially failed during a temporary shutdown of the mine operations and a stop in dewatering in winter/spring of 1996/1997. It is unknown whether the failure was entirely within overburden soils or whether the failure extended into underlying rock. Based on visual observations over the last ten years, the slope failure has increased in size, with a current width of approximately 350 m. Multiple tension cracks have been observed around the perimeter crest of the East pit wall showing horizontal displacement up to 30 cm, and vertical displacement up to 60 cm. It is unknown how long the various cracks have existed. Slumping of existing slide debris appears to be occurring within the landslide over the last few years (Golder, 2013). Additional smaller failures around the perimeter and within the existing landslide area are imminent based on existing tension cracks and oversteepened slope configurations.

The Grum Interceptor Ditch and electrical substation could be affected by slope instability on the East pit slope, but whether these could be affected within the interim period is not clear with the available data. Based on visual observations, continuing displacement is occurring within the instability zone, but the rate and magnitude of these displacements are unknown. If displacement is occurring within the lower portions of the slide area, this will affect the rate of progression of instability of the upper head scarp. In order to quantify these movements during the interim period, monitoring points should be installed within the slide area and around the perimeter above the slope. A total of 14 points were recommended by Golder (2010). Four of these have been installed during 2013, and the remainder will be installed in 2014.

During the interim period, smaller progressive failures within and around the existing failure may occur. It is possible that the blocks of soil hanging at the top of the slope could break free at any time. Monitoring pins have been installed to track crest movement at two locations (Golder, 2013). In addition, survey points will be installed within the landslide area to track further displacement of the slide. Recommendations for measurement and monitoring of these features are presented by Golder (2013). The recommended monitoring is important to protect the safety of workers entering the pits during the interim period. Additional observations should be made immediately before entering the eastern side of the Grum Pit as recommended by Golder (2013). After enough data points are available to evaluate trends of movement, the frequency of measurement can be decreased to a frequency relevant to the initially collected data.

For the overall closure, stability analyses should be performed to evaluate the potential extents of further slope displacements during the long term. To begin, a back calculation of the shear strength of the till material should be performed based on the original pit slopes before failure, along with soil laboratory testing. This information can be used to evaluate the stability of the existing pit slope configuration, and to make a determination of whether actions need to be taken to protect the Grum Interceptor Ditch and electrical substation. As recommended by Golder (2013), the effect of water levels on the pit slopes should be evaluated. As part of the stability analyses, the potential for slide movement to affect water storage volume within the pit, or to cause a wave that overtops the access road invert, should be evaluated.

The ground surface above the east pit wall is poorly drained in some areas, resulting in ponded water (Golder, 2013). These areas should be graded for the overall closure to limit the amount of water that infiltrates into the east pit wall soil material or that flows over the pit wall.

5.2.3 Vangorda Pit

Pit wall failures occurred within the north-west end of the pit during mining where there are several faults (RGC, 1996). This area appears to be stable for overall slope failure for the existing pit slope configuration. However, localized sloughing from the sheared fault zones continues to occur over time (Golder, 2013).

Within the overburden of glacial till along the southwest pit wall, there is evidence of slope movement, and signs of instability including arc-shaped oversteepened head scarps and tension cracks within the safety berm along the Haul Road. Failures within the southwest pit wall could undermine the Haul Road and water conveyance piping running between the Haul Road and the Vangorda Pit. The tension cracks should be monitored by installing extensometers and/or displacement monitoring pins. The cracks should be monitored initially at a minimum of twice per year to determine whether there is active movement and to track any trends in rate of movement. A stability analysis should be performed to identify the extents of the Haul Road that could be affected by progressive slope failure.

The rock within the northwest portion of the Vangorda Pit is generally weak and altered, and the bench crests have raveled and filled lower benches in many places, creating talus slopes from crest to toe (Golder, 2013). These slopes are sometimes interrupted by narrow bench crests that have remained intact. The risk of large-scale failure within the northwest portion of the pit is considered low.

The rock slopes within the northeast portion of the pit are more competent, but the benches are almost full of debris from interbench sloughing failures. In some areas, bench failures have occurred along large-scale joints parallel to the slope face. The upper portion of the northeast pit slopes consist of overburden that is irregular because of erosion and sloughing. However, no facilities above this area of the pit are at risk of being affected by the overburden instability in this area.

There is a high risk of rockfall along the access road slopes, as identified by Golder (2013). Unprotected work in this area should be restricted unless safety catch berms are constructed to protect workers from rock falls.

5.3 Waste Dumps

5.3.1 Faro Waste Dumps

Most of the Faro Waste Dumps were constructed at the waste rock material's angle of repose on moderately sloping, well-drained terrain. The dumps have been stable since construction (over 40 years ago) and there are no signs of any significant instability. Over time, as the surficial rock weathers, some shallow slope creep and slumping of the surficial layers on the relatively steep dump faces may occur.

An exception is the Faro Valley Waste Dumps, which are located on the deep Faro Valley alluvium and immediately adjacent to the Faro Pit, which impounds a shallow water pool on the upstream side. Stability of the southern slopes of the dump is dependent on the stability of the north wall of Faro Pit. The valley alluvium is an aquifer and has a relatively high water table which is drawn down as seepage occurs into the Faro Pit. Over time, the alluvium has slumped and ravelled into the pit and this should be expected to continue.

Other than the periodic site inspections, no specific measures to address the physical stability of the dumps are recommended for the interim period.

5.3.2 Vangorda and Grum Waste Dumps

As for the Faro Waste Dumps, the Vangorda and Grum Waste Dumps have been stable since construction, with no signs of significant instability. Shallow slope creep and slumping of surficial layers on the dump faces may occur as surficial rock weathers. Other than the periodic site inspections, no specific measures to address the physical stability of the dumps are recommended for the interim period.

5.4 Haul Road

The Haul Road embankments have been stable since construction, including the embankments where several major streams including the north and south forks of the Rose Creek, and the west fork and main stem of Vangorda Creek. With the exception of the crossing of the NFRC, which is the location of the NFRD, the consequences of failure of any of these crossings are relatively minor. Risks associated with the performance of the NFRD during large flood events are discussed in the next subsection.

5.4.1 North Fork Rock Drain

Under normal flow conditions, the NFRD does not retain much water. It is only during large flood events when more significant ponding will occur that the structure will be subjected to significant water head. As detailed in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a), the risk posed by excessive ponding behind the NFRD during very large floods were considered by (1) evaluating the consequence if the NFRD was to fail, and (2) evaluating the likelihood of NFRD failure. These two aspects are discussed in the following sections.

5.4.1.1 Consequence of NFRD Failure

Stability of the Haul Road embankment, including the NFRD, must be considered in the context of the objective of the Down Valley Interim Hydraulic Upgrades, which is primarily to protect the ID until implementation of the final closure plan. If a 1-in-500-year flood is likely to result in failure of the Haul Road embankment, the objective of the Down Valley Interim Hydraulic Upgrades could be compromised. To evaluate the consequences of failure under the 1-in-500-year flood event, breach analyses of the Haul Road embankment were performed. Since there is much uncertainty in the flow-through capacity of the NFRD (which includes seepage through the adjacent schistose rockfill zones), the analyses were performed for the following different flow-through scenarios: (1) a best estimate flow-through scenario, (2) a low flow-through scenario, and (3) a low flow-through with 25-percent reduction in capacity scenario.

A 2D hydraulic model was used to route the breach flood hydrographs from the upstream end of the RCD through the RCD, resulting in overtopping and breach of the overflow weir or the RDC dike, and spilling into the Intermediate Impoundment and through the ID spillway. All breach scenarios assumed that, once the RCD dike is breached, 100 percent of the 1-in-500-year flood event and breach flood wave flow would be conveyed into the Intermediate Impoundment.

Table 6C-6 summarizes the key information associated with each model simulation. As shown in the table, the low-flow condition and low-flow condition with 25-percent blockage result in overtopping of the ID. Overtopping because of a breach of the NFRD under the low-flow condition is minor, with a maximum predicted water surface elevation of 1,049.9 m and duration of overtopping of less than 1 hour. This is considered to be the threshold case.

TABLE 6C-6
Summary of Breach Simulations
Faro Mine Interim Works

NFRD Flow-through Condition	Blockage	Peak Flow (m^3/sec)	Maximum WSEL (m)	Overtopping at ID
Medium	zero	640	1049.3	No
Low	zero	1,262	1,049.9	Yes[a]
Low	25%	1,669	1,050.1	Yes

[a] Minimal overtopping of ID crest occurs for breach scenario assuming low flow-through condition and no blockage. This is considered the threshold case.

Based on this analysis, overtopping is expected for any breach scenario with a peak flow discharge greater than approximately 1,200 m^3/sec. This estimate of the overtopping flow is dependent on the following conditions occurring concomitantly.

- Initial conditions assume that the ID Pond is at full pool elevation of 1046.5 m. This assumption limits storage in the ID Pond and subsequently reduces potential attenuation of the peak discharge.
- In the model simulation, the RCD is blocked off at the overflow weir so that flow is not conveyed down the RCD once the flood is directed onto the Intermediate Impoundment. Model simulations that provide for conveyance down the RCD result in an approximate decrease of 0.3 m in water surface elevations at the ID.
- A low flow-through condition was assumed at the NFRD, the most conservative estimate of flow-through capacity.
- Blockage (25 percent) of flow was assumed at the NFRD which reduces capacity further and results in greater impounded volume at the NFRD.

5.4.1.2 Likelihood of NFRD Failure

There is successful precedent in Canada, and elsewhere, to use flow-through rockfill in mine rock waste dumps, which has saved the cost of culverts or diversion works around the waste dumps (Minalta and Piteau, 1999). The precedent, however, does not include reliance of the mine waste dumps as water-retaining dams, but perhaps as temporary non-engineered pervious barriers to flow-through.

Comparing the construction of the NFRD with the general recommendations provided in the British Columbia Rock Drain Research Program report, *Mined Rock and Overburden Piles* (Minalta and Piteau, 1999), it was concluded that the Haul Road embankment does not include elements that should be included where rock drains could become water retaining structures. These elements are discussed in detail in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a) and include (1) limited foundation preparation, (2) absence of filter layer (such as gravel or small size rockfill) between foundation soils and rockfill embankment material, and (3) absence of filters/drains for the lower permeability schistose material zones adjacent to the calcium-silicate rock.

BGC (2006) identifies evidence of sediment and wood debris accumulation at the entrance to the NFRD. The scope of BGC's work included an assessment of natural hazards of the terrain in the NFRC Basin and the natural slopes above the RCD Canal. However, it did not include potential hazards from man-made structures (such as those from the waste rock dumps). These hazards add to the uncertainties in assessing the reliability of the Haul Road embankment and NFRD.

The potential blockage of debris on the NFRD face and plugging of the interstitial space within the NFRD by soil or other material arising from man-made activities had not been examined by BGC (2006), nor assessed during this study. Effects of sediment produced by erosion of the Faro Waste Dump and the upper (predominantly sand and gravel) part of the embankment are examples of this type of contamination.

Ravelling and slope stability evaluations were performed to gain an understanding of the embankment stability. However, there are other potential failure modes that could be more critical but do not readily lend themselves to quantitative analyses. One such failure mode is wash-out of finer particles in the schistose rockfill resulting in preferential seepage paths and eventual piping of the embankment. Another such failure mode is piping through the foundation under significant flood pool conditions. Because only two out of numerous potential failure modes were considered in analyses, the results of these analyses could not be considered a complete measure of the stability of the rock drain.

The two potential failure modes considered under estimated flood pool conditions include the following:

- Ravelling failure initiated by high discharge velocities exiting the downstream toe
- Slope stability failure with high phreatic surfaces in the embankment

The analyses and results are provided in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a).

Results from the ravelling analysis suggest that there should be an adequate margin of safety against slope ravelling under high flow-through conditions. By inspection, the reported as-constructed D_{50} diameter of the NFRD (1 m) is more than 3 times as large as the critical D_{50} diameter for the worst-case 1-in-500-year flood event flow.

The factors of safety developed for all slope stability cases analyzed meet the recommended minimum criteria, indicating that deep-seated slope stability issues should not be a major issue for the embankment. It should be noted that, during the life of the structure, shallow surface sloughing is a likely occurrence on the upstream or downstream face. While this sloughing is not considered to be critical to overall stability of the embankment, the effects of the sloughing could have other impacts on conditions near the toe of the embankment, particularly if left unchecked. For example, sloughing of finer material onto the NFRD slope surface could impair the flow-through. Signs of sloughing need to be monitored and maintenance performed as needed.

5.4.1.3 Conclusions

The objective of the interim improvements is to prevent an environmentally damaging discharge of metals-laden tailings to the Rose Creek Valley and downstream creeks and rivers. This objective will be met by preventing overtopping of the ID during the 1-in-500-year flood. Breach analysis results indicate that overtopping of the ID would occur for any NFRD breach with a peak flow discharge greater than approximately 1,200 m^3/sec. During a 1-in-500-year flood event, such a discharge is predicted for an NFRD breach when assuming a low-flow-through capacity in the NFRD.

Based on a review of the design and construction records of the NFRD, the objective of ID protection cannot be met with a high degree of confidence by relying on the haul road embankment to act safely and reliably as a flood retarding structure. To achieve a high confidence level in its performance, more positive measures would need to be implemented to pass large flood events safely at the Haul Road embankment and NFRD to prevent formation of large flood pools against the Haul Road embankment. One such measure might include installation of culverts or tunnels under the embankment.

In the absence of such measures, a significant flood pool may form against the Haul Road embankment and NFRD. A risk analysis would be helpful in determining acceptability of the Haul Road embankment and NFRD in the interim period. Since the probability of a 1-in-500-year flood occurring within a 10-year interim period is 2 percent, and the conditional probability of failure of the Haul Road embankment given this flood event is less than 1, the probability of failure of the Haul Road embankment would be less than 2 percent over a 10-year period. A risk analyses would not only consider the 1-in-500-year flood, but would combine the probability of failures during the interim period with the consequence of failure for the full range of flood loading up to the 1-in-500-year event.

Monitoring of the Haul Road embankment and NFRD should continue and maintenance measures should include prevention of blockage of the inlet to the NFRD by removing any buildup of debris.

SECTION 6

Summary and Conclusions

From the evaluation of the different types of structures on the site, it was concluded that most of the major existing facilities can be considered physically stable for the interim period. However, it was found that some of the existing flood conveyance structures are undersized and inadequate to convey the IDF for the interim period (500-year return period flood event). Interim measures will be implemented to upgrade the capacity of the structures as discussed in this section.

6.1 Dam Stability during the Interim Period

Evaluation of dam stability included the adequacy of the associated conveyance structures (such as spillways and diversions) to pass the IDF, as well as the structural stability of the dams under normal, flood loading, and earthquake loading conditions.

It was concluded that the dams meet the design criteria for earthquake and flood loading for the interim period. The loading for the interim period is significant smaller than the loading for the long term. Some maintenance needs to occur during the interim period to maintain the stability of the dams.

It was found that some of the existing flood conveyance structures are undersized and inadequate to convey the IDF for the interim period (500-year return period flood event). Interim measures will be implemented to upgrade the capacity of the structures as discussed in the following section.

6.2 Recommended Interim Hydraulic Upgrades

6.2.1 ID Spillway

The most severe deficiency is for the ID Spillway. In the case of a breach of the overflow weir or at another location along the RCD dike, the existing ID spillway does not have the capacity to safely pass a moderate or major Rose Creek flood event without overtopping and potentially failing the ID and releasing tailings to the downstream environment. NHC (2006) determined that the existing ID spillway capacity is only 32 m^3/sec if the top of flood water surface elevation is limited to the top of the core. The capacity is 63 m^3/sec if the flood water surface is allowed to rise to the dam crest (approximately elevation 1,048.9 feet). Because of this deficiency, modifications to the spillway are proposed and currently under design.

A freeboard analysis was performed in accordance with technical guidelines from CDA (2007) to determine minimum and normal freeboard requirements. The minimum required crest elevation to provide suitable freeboard was determined to be approximately 1,047.4 m for the normal freeboard case and 1,049.3 m for the minimum freeboard case. The design crest elevation of 1,049.6 m provides suitable freeboard under both conditions. Additional information regarding the wind analysis and freeboard calculations can be found in Down Valley Interim Hydraulic Upgrades Design (CH2M HILL, 2014a).

Apart from remediating spill capacity associated with large flood events, an increase in ID spillway capacity would also provide mitigation for other RCD failure mechanisms. These include (1) failure of the RCD dike by piping or slope instability during moderate flood events, (2) landslide or debris flow originating on the mountainous slopes to the south of the RCD that would block the RCD and cause overtopping of the RCD dike, and (3) icing buildup in the RCD resulting in overtopping of the RCD dike.

The improvements at the ID spillway will consist of excavating the existing channel by about 2 m, and placing a 0.45-m-thick gabion mattress on the excavated surface of the channel. The proposed channel will follow the same footprint of the existing channel, so there will not be significant widening of the channel. Three layers of gabion cells 0.9 m by 0.9 m in cross section will be used on the sides of the excavation. Geotextile will be placed between the gabion mattress and the excavated soil surface. It is assumed that calcite waste rock could be used as material to fill the gabion mattress and gabion cells.

To raise the effective crest ID crest, a geomembrane will be installed vertically in a trench between the dam core and the crest surface, and concrete traffic barriers will be placed along this line to further raise the effective crest to an estimated elevation of 1,049.6 m. The gabions will be partially embedded (depth of about 0.2 m) in the upper portion of the excavated trench on top of the compacted backfill. It is noted that the ID crest is at an average elevation of about 1,048.9 m and based on the test pit exploration results the top of the dam core at the center of the dam crest varies with a low elevation of about 1,048.3 m. It is assumed that the material excavated from the trench would be used for backfill again. The gravel and sand crest surfacing will be reinstated.

6.2.2 Rose Creek Diversion Dike

Hydraulic modelling results indicate that the existing crest elevation is deficient to contain the predicted 1-in-500-year flood event flows. Over some portions of the dike, it would overtop and at other locations there would not be adequate freeboard. To mitigate this deficiency, the dike crest needs to be raised over some sections of the dike.

The crest elevation of the overflow weir will be raised to elevation 1058.2 m, which corresponds to the water surface elevation predicted for the 1-in-500-year flood event flow rate (elevation 1,058.0 m) plus a 200 mm-thick layer of native sand and gravel covering the crest to provide a road surface, i.e., the structure will have a freeboard of 0.2 m. This implies that the overflow weir will have to be raised by about 0.95 m.

Apart from the required raise of the dike crest and overflow weir, it is also proposed to remove woody vegetation from the dike and to perform some repairs of slope sloughing and riprap, and to add riprap where slopes are unprotected.

6.2.3 Embankment Haul Road and North Fork Rock Drain

Results of breach analyses of the NFRD indicate that overtopping of the ID would occur during a 1-in-500-year flood event when assuming a low-flow-through capacity in the NFRD. Based on review of the design and construction records of the NFRD and the embankment haul road, the Main Haul Road Embankment and NFRD cannot be relied upon to serve as a reliable attenuation barrier and provide protection to the ID.

To achieve a high confidence level, more positive measures would need to be implemented to pass large flood events safely and prevent formation of large flood pools against the Haul Road embankment. One such measure might include installation of culverts or tunnels under the embankment. In the absence of such measures, a risk analysis might be helpful in determining acceptability in the interim period. Monitoring of the Haul Road embankment and NFRD should continue and maintenance measures should include removing buildup of debris upstream of NFRD.

Attachment 6C-1
Seismic Stability Preliminary Analysis
Secondary Dam, East Limb

Seismic Stability Analysis, Secondary Dam - East Limb Faro Mine Complex

PREPARED BY: Michael Eller/CVO

DATE: October 25, 2013

PROJECT NUMBER: 472645.08.PT.EA.01

Introduction

This technical memorandum details the evaluation of liquefaction potential and slope stability of the East Limb of the Secondary Dam (SD). Ground motions associated with a 500-year seismic event were considered in the analysis.

The East Limb of the SD runs parallel with the Rose Creek Diversion and has a maximum height of approximately 5 metres (m). The dam was constructed with compacted tailings sand, and capped with a granular outer shell along the downstream slope. The downstream slope is 2H:1V. Figure 6C-1-1 shows the location of the SD.

Background

Seismicity

In 2013, Atkinson and Assatourians updated the seismic hazard assessment for the Faro Mine Complex (FMC) (Atkinson and Assatourians, 2013), resulting in significantly lower motions than those presented by Atkinson's previous seismic hazard assessment (2004). The main reasons for this re-evaluation of ground motions were insights gained during studies performed since 2004.

A significant study evaluated the tectonic setting of the Tintina Fault, the controlling fault for the FMC. In a report by CH2M HILL Canada Limited (CH2M HILL, 2013), the most recent interpretation of the 30-kilometre (km)-wide fault zone is that it no longer accommodates significant seismic deformation as once thought. The fault is currently characterized by low slip rates and activity rates. The report concluded the fault is structured more as aerial source zone comprising several faults than a distinct linear active fault.

The most significant study warranting a re-evaluation is the improvement of ground motion prediction equations (GMPEs). GMPEs estimate ground shaking based on an earthquake's magnitude, its distance from site, and site conditions. The databases that house GMPEs are actively growing, promoting continual refinement to the models.

GMPEs were developed for the FMC based upon Site Class B/C site conditions ("Site Class B/C" denotes the boundary between rock and soil materials and is defined as material with average shear wave velocity of 760 metres per second [m/s] in upper 30 m of soil profile). This follows the recommendations by Atkinson and Adams (2013) for the 2015 National Building Code of Canada (NBCC) National Seismic Hazard Maps. Amplification factors that convert spectral accelerations from Site Class B/C to other site classes, such as Site Class C (450 m/s), can be applied to account for change in ground motions due to softer soil conditions.

Based on these studies, the ground motions are reduced significantly for the FMC, particularly for the design maximum credible earthquake (MCE) for the 10,000-year return period. Atkinson and Assatourians (2013) reduce the peak ground acceleration (PGA) for the FMC from 0.5 g (mean value from Atkinson, 2004) to 0.25 g at the B/C boundary, a 50 percent reduction.

Ground motions were also evaluated for the subduction zone bordering Alaska. Although the subduction zone is located approximately 500 km from the FMC, a magnitude M9 subduction event can produce high ground motions at low frequencies, affecting structures with larger natural periods.

The seismic hazard assessment for the FMC was originally prepared by Atkinson (2004). This report presented site-specific seismic hazards, identifying an MCE with a moment magnitude (Mw) of 7.0, a return period of 10,000 years, and that could produce a mean PGA at a rock site (Site Class B/C boundary) of 0.5 g.

For a 500-year recurrence interval (the return period of interest for this analysis), the mean PGAs at the Site Class B/C boundary and at Site Class C are 0.043 g and 0.052 g, respectively. A Site Class amplification factor of 1.21 is applied to the PGA, to convert soil conditions from Site Class B/C to Site Class C.

Previous Geotechnical Work

In earlier phases of the FMC closure process, the following stability evaluations took place for the East Limb of the SD, as well as several other dams across the FMC.

Golder Associates

Golder Associates (Golder) (2004) evaluated the liquefaction potential in the tailings across the FMC, including those behind the East Limb of the SD. Using CPT soundings and laboratory testing, Golder (2004) identified the tailings sand and slimes to be potentially liquefiable for the Atkinson (2004) MCE event. Residual strengths for the tailings sand and slime were determined using the methods by Idriss (2004) and Olson and Stark (2002), respectively.

Klohn Crippen Berger

Klohn Crippen Consultants (KCC) (2006a) performed a seismic stability analysis for the East Limb of the SD based on a 10,000 year seismic event, the MCE for the FMC. According to the analysis, the foundation soils of the SD, particularly along the eastern section near Rose Creek, consisted of liquefiable sands and silts for the given ground motions of the MCE. The residual strength of these soils was estimated based on standard penetration test (SPT) $(N_1)_{60}$ values converted from Becker hammer penetration tests (BPT) using the Sy (1993) method. The liquefaction potential was evaluated based on the simplified method by Youd et al. (2001). Following this method, the ground motions for determining the cyclic stress ratio (CSR) were established using a site-specific response analysis from the time histories Atkinson recommended (2004). After the analysis, several layers were identified as potentially liquefiable between elevations of 1,049.5 m and 1,053.0 m, and 1,042.0 m and 1,046.0 m (KCC, 2006b). This corresponded to layers with BPT-converted SPT $(N_1)_{60}$ values less than 10.

The residual strength of the liquefied sands was determined using methods by Idriss (2004). A slope stability evaluation accounting for the strength loss within these soils resulted in a post-seismic failure along the downstream slope in the SD, releasing tailings downstream. The post-liquefaction slope stability was evaluated using GeoStudio's Slope/W (2004) computer program, following the Morgenstern and Price (1967) method. The post-liquefaction factor of safety was 0.78. Slope deformation estimates were performed using Newmark (1965), Makdisi and Seed (1978), and Hynes and Franklin (1984) methods. However, Golder did not report displacements in the text of the report.

In their analysis, KCC carried Golder's (2004) conclusion that the tailings would liquefy. KCC (2006a) provided a conceptual remediation design to the SD that involved vibro-replacement to densify the loose sands.

In a similar study, KCB (2007) evaluated the stability of the Cross Valley Dam for a 500-year event. Based on the seismic loading provided in Atkinson (2004), they concluded the foundation soils would not liquefy and that displacements for such an event will be tolerable.

Liquefaction Evaluation

Based on the updated ground motions provided by Atkinson and Assatourians (2013) for a 500-year event, CH2M HILL Canada Limited (CH2M HILL) re-evaluated the liquefaction potential of the SD, East Limb profile. The following BPTs were evaluated: BPT05-07, BPT04-13, and BPT05-06B. These were the same explorations KCC evaluated in their analysis (2006a). Equivalent BPT-converted SPT $(N_1)_{60}$ values were measured manually from Atkinson and Assatourians (2013). The simplified procedure from Youd et al (2001) was used. The PGA

for rock was modified to account for the Site Class C conditions at the FMC, using a F_a factor of 1.21, as provided by Atkinson and Assatourians (2013). Soil properties, such as unit weight and fines content, were selected based KCC (2006a).

Liquefaction potential is a function of overburden stress. Therefore, profiles at the crest and the toe of the SD were evaluated for each BPT exploration. No liquefaction zones were identified in the six profiles.

Figures 6C-1-2 and 6C-1-3 summarize the results of the analysis, showing the factor of safety against liquefaction (FS_L) with elevations at the crest and toe of the SD, respectively. Tables 6C-1-3 to 6C-1-8 provide complete results of the liquefaction analysis.

Slope Stability Analysis

Following the liquefaction analysis, slope stability evaluations were performed to estimate the factor of safety for the static, pseudo-static, and post-seismic conditions. The computer program SLIDE, Version 6 (RocScience, 2012) was used for the slope stability analysis. The Morgenstern and Price (1967) method was used to calculate the factor of safety for each of the stability analyses.

Although no liquefaction occurred in the profiles for a 500-year event, a post-seismic stability evaluation was performed to assess stability, assuming the retained tailings liquefy. The liquefied tailings would exert lateral pressure on the dam, which would tend to increase sliding potential through a horizontal surface. For the liquefied tailings, the residual strength estimated by Golder (2004) was used. No other reduction in soil strengths are made for this condition.

The cross-section profile used for analysis was that used by KCC (2006a, 2006b), which focuses on the section on the southeast end of the SD near the Rose Creek Drainage (Figure 6C-1-1). Figure 6C-1-4 shows the cross-section used for the analysis.

Soil properties used in the analysis are from KCC (2006a) and Golder (2004), and are summarized in Table 6C-1-1.

Table 6C-1-2 summarizes the results of the slope stability analysis. Based on the analysis, all conditions meet or exceed the minimum required factor of safety of 1.5.

Full results of the slope stability analysis are included in Figure 6C-1-5 for the static analysis, Figure 6C-1-6 for the pseudo-static analysis, and Figure 6C-1-7 for the post-seismic analysis.

Conclusion

For the East Limb of the SD, CH2M HILL reached the following conclusion for a 500-year seismic event:

- No liquefaction was predicted for the foundation soils of the SD.
- The slope on the southeast section of the SD is stable, with factors of safety of 1.5 or greater. Static, pseudo-static, and post-seismic conditions were analyzed, which assumed the retained tailings would liquefy.

For a 500-year seismic event, it is anticipated that small deformations will occur. Such deformations are tolerable; therefore, the SD will not breach and release tailings. This evaluation only applies to the interim period, and it is recommended that detailed analyses be performed for final closure utilizing MCE motions.

TABLE 6C-1-1

Soil Properties used in Post-liquefaction Stability Analyses for the Secondary Dam East Limb Section*

Soil Unit	Unit Weight, (kN/m^3)	Friction Angle (deg)	Cohesion (kPa)	Post-Liquefaction Residual Strength Ratio, s_{ur}/σ'_{vo}
Dam Fill	21	35	0	-
Unsaturated Tailings	19.5	30	0	-
Liquefied Saturated Tailings	24	-	-	0.05
Foundation Sand and Gravel Layer 1 with $(N_1)_{60,cs} > 30$	21	35	0	-
Liquefied Foundation Sand Layer 1 with $(N_1)_{60,cs} \approx 10$	20	-	-	0.10
Foundation Sand Layer 1 with $(N_1)_{60,cs} > 22$	20	35	0	-

Notes

* From KCC (2006a, 2006b)

deg. – degree
kN/m^3 – kilonewton per cubic metre
kPa - kilopascal

TABLE 6C-1-2

Slope Stability Analysis Results for Secondary Dam, East Limb

Analysis Scenario	Factor of Safety
Static	1.60
Pseudo-Static (with $k_h = ½*F_a*PGA_{rock}$)	1.50
Post-Seismic	1.60

Notes:

$k_h = ½*F_a*PGA_{rock}$ – seismic coefficient

Notes:

[1] BPT-converted SPT $(N_1)_{60}$ values are interpreted from Klohn Crippen (2006b) report. It is assumed that the material is very few fines throughout the profile. Therefore, $(N_1)_{60}$ is equal to $(N_1)_{60,cs}$

[2] If BPT-converted SPT $(N_1)_{60}$ values are greater than 30, $CRR_{7.5}$ defaults to 1.0 for calculation.

Notes:

[1] BPT-converted SPT $(N_1)_{60}$ values are interpreted from Klohn Crippen (2006b) report. It is assumed that the material is very few fines throughout the profile. Therefore, $(N_1)_{60}$ is equal to $(N_1)_{60,cs}$

[2] If BPT-converted SPT $(N_1)_{60}$ values are greater than 30, $CRR_{7.5}$ defaults to 1.0 for calculation.

Notes:

[1] BPT-converted SPT $(N_1)_{60}$ values are interpreted from Klohn Crippen (2006b) report. It is assumed that the material is very few fines throughout the profile. Therefore, $(N_1)_{60}$ is equal to $(N_1)_{60,cs}$

[2] If BPT-converted SPT $(N_1)_{60}$ values are greater than 30, $CRR_{7.5}$ defaults to 1.0 for calculation.

Notes:

[1] BPT-converted SPT $(N_1)_{60}$ values are interpreted from Klohn Crippen (2006b) report. It is assumed that the material is very few fines throughout the profile. Therefore, $(N_1)_{60}$ is equal to $(N_1)_{60,cs}$

[2] If BPT-converted SPT $(N_1)_{60}$ values are greater than 30, $CRR_{7.5}$ defaults to 1.0 for calculation.

SECTION 1

Introduction

This report presents a data summary and discussion of recent and historical climatic conditions in the vicinity of the Faro Mine Complex (FMC) to characterize baseline conditions for the Faro Mine Interim Works.

Climate parameters considered in this report include wind speed and directions, temperature, precipitation, humidity, solar radiation, evaporation and evapotranspiration.

The FMC is located in south-central Yukon. It is 22 kilometres (km) northeast of the Town of Faro and about 200 km northeast of the City of Whitehorse. The FMC is located in the Anvil Range Mountains within the Macmillan Highlands of the Yukon North-Plateau Eco region. The Yukon North-Plateau terrain is made up of rolling uplands, small mountain groups, and nearly level table lands dissected by deeply cut, generally broad, U-shaped valleys (Environment Canada, 1996).

The climate near the FMC is characterized as subarctic continental, which is typified by long, usually very cold winters, and short, cool to mild summers (Ritter, 2006). Historical monitoring data indicate a large annual range in temperature and relatively moderate amounts of annual precipitation. The area has strong terrain features that further accentuate the seasonal temperature differences and humidity levels. Winter temperatures can be 10 degrees (°) lower in valley bottoms as compared to higher elevations, because of temperature inversions. During the summer months, temperatures are closer to the environmental lapse rate with valley bottom temperatures higher than upland areas (Janowicz et al., 2005). Additional evaluations of climate data are presented in the Hydrology Baseline Report (CH2M HILL, 2013).

SECTION 2

Meteorological Data Sources

Meteorological monitoring data from Environment Canada's stations located in Faro area and onsite meteorological stations were used to provide the overall state of the regional and site-specific climate.

2.1 Environment Canada Stations

Three Environment Canada stations with hourly monitoring data were identified in Faro area. A summary of the station information is provided in Table 6D-1. The location of the stations are shown in Figure 6D-1. Faro A and Faro AUT Stations are located at the Faro Airport, approximately 145 metres apart. Faro station was located in the Town of Faro approximately 3 km from the other two stations. Considering data completion, data consistency, and length of monitoring periods, the two active Environment Canada stations, i.e. Faro A and Faro AUT Stations, are selected to define baseline regional climate conditions.

TABLE 6D-1
Environment Canada Meteorological Stations
Faro Mine Interim Works

Station Name	Climate ID/ WMO ID	Latitude	Longitude	Elevation (metres)	Hourly Data Available Periods	Parameters Measured
Faro	2100516/NA	62°14'N	133°21'W	694.3	1972 – 1977 04:00 – 22:00, even hours	Temperature, wind direction, wind speed, RH
Faro A	2100517/NA	62°12'25"N	133°22'24"W	716.3	1978 – present 05:00 to 17:00	Temperature, wind direction, wind speed, RH, cloud cover, total (daily) precipitation
Faro AUT	2100518/ 71949	62°12'27"N	133°22'33"W	716.6	1994 – present 00:00 – 23:00	Temperature, wind direction, wind speed, RH

Notes:

Total precipitation: includes total rainfall and total snowfall, reported separately.

AUT = automated
ID = identification
NA = not applicable
RH = Relative Humidity

2.2 Onsite Meteorological Stations

Two onsite meteorological stations were established at the FMC on the Faro Valley and Grum Waste Dump sites in December of 2003. The Faro Valley Dump meteorological station is located on the Faro Valley Waste Dump, at an elevation of 1,200 metres above sea level. The Grum Dump meteorological station was located on the Grum Waste Dump before June 2010 at an elevation of 1,250 metres above sea level. The station was moved on June 21, 2010, to a former gravel pit, located north of Grum overburden vegetation trials to accommodate the Grum sulphide cover project (Denison, 2011). When the Grum meteorological station was moved, efforts were made to verify that the station was installed at a similar location, elevation, and soil type, to where it had been previously. Soil temperature, moisture, and heat flux sensors were reinstalled at the same depths as where they had been. Data from the Grum climate station was reported as one continuous record, with the exception of wind data. A correction factor was applied to wind direction to adjust for the station move, until the wind direction sensor was recalibrated in January 2011. Snow depth sensor installation was evaluated after the move, and, based on preliminary evaluation, no correction factor was required (Denison, 2011). The locations of the onsite meteorological stations are shown in Figure 6D-2.

The Faro Valley Dump and Grum Dump meteorological stations sensors measure the following climate parameters:

- Temperature
- Relative humidity
- Wind speed
- Wind direction
- Soil moisture
- Soil temperature (at two depths)
- Soil heat flux
- Net radiation
- Albedo
- Solar radiation (incoming)
- Snow depth
- Precipitation

Averages of sensor measurements taken every 5 seconds were logged on an hourly basis and meteorological station data were downloaded on a monthly basis.

SECTION 3

Methods and Results

3.1 Temperature

3.1.1 Methods and Data Considerations

Since both Faro A and Faro AUT Stations are located in the Faro Airport at the same elevation and approximately 145 metres apart, consistency in temperature monitoring is expected.

AECOM Canada Ltd. (AECOM) has conducted a comparison between Faro A and Faro AUT Stations and the results show the temperatures at the two stations are generally consistent (AECOM, 2009).

At the completion of each decade, Environment Canada updates its climate normals for as many locations and as many climatic characteristics as possible. Based on data from Faro A Station, Environment Canada published the climate normals, averages, and extremes with at least 15 years of data from 1981 to 2010. These datasets were used to establish the temperature baseline for the region.

Hourly temperature data from the two onsite meteorological data stations were compared with Faro AUT Station data between December 2003 and December 2010. The Faro AUT Station was chosen for this comparison because the hourly records are more complete than the Faro A Station records.

3.1.2 Regional Temperature Normals and Extremes

The temperature normals and extremes published for the Faro A Station are presented in Table 6D-2 and Figure 6D-3. These data show the cold winters and warm summers typically observed in this region.

TABLE 6D-2
Environment Canada Regional Temperatures (1981 – 2010)
Faro Mine Interim Works

	Mean Temperature (°C)											
	Jan	**Feb**	**Mar**	**Apr**	**May**	**Jun**	**Jul**	**Aug**	**Sep**	**Oct**	**Nov**	**Dec**
Daily Mean Temp	-20.1	-15.5	-8.6	0.6	7.5	13.2	15.0	12.4	6.4	-2.0	-14.8	-17.9
Daily Average Min Temp	-24.6	-20.7	-15.0	-5.5	1.2	6.8	8.9	6.3	1.3	-5.7	-18.5	-22.3
Daily Average Max Temp	-16.0	-10.3	-2.1	6.8	13.8	19.6	21.0	18.4	11.5	1.7	-11.1	-13.8

Note:

°C = degrees Celsius

The daily average temperature is lowest in January at -20°C and highest in July at 15°C. This gap is further illustrated by an average daily minimum temperature in January of -24.6°C and an average daily maximum in July of 21.0°C. The average variation of temperature throughout the day is indicated by comparing the normal daily minimum and maximum. The change in temperature throughout the day is slightly more pronounced in the summer with an approximate 12°C difference between the minimum and maximum and less in the winter with an approximate 8°C difference.

A historical daily temperature trend from 1977 to 2011 is provided in Figure 6D-4.

3.1.3 Regional Long Term Temperature Trends

The annual average temperatures from 1981 to 2010 are shown in Figure 6D-5. The figure shows the annual average of daily means, annual average of daily minimum means, and annual average of daily maximum means as well as the extreme minimum and maximum observed each year. A linear regression analysis of the annual average data suggests a warming trend with a 0.7°C, 0.6°C and 1.0°C change in the mean daily maximum, mean

daily, and mean daily minimum, respectively. A warming trend is also observed in the extreme maximum and minimum of 0.3°C and 2.4°C, respectively.

3.1.4 Local Site Temperature Data

The monthly mean temperatures for the two onsite stations are summarized in Table 6D-3. The data indicate that the temperature at the two stations are consistent. The temperature data indicate that annual average temperatures ranged from about 12°C in summer to -16°C in winter.

TABLE 6D-3
Local Site Temperature (Dec 2003 – Dec 2010)
Faro Mine Interim Works

	Mean Temperature (°C)												
Station Name	**Jan**	**Feb**	**Mar**	**Apr**	**May**	**Jun**	**Jul**	**Aug**	**Sep**	**Oct**	**Nov**	**Dec**	**Annual**
Faro Dump Station	-15.6	-12.1	-9.6	-1.1	5.8	11.3	12.3	10.3	4.2	-2.5	-10.7	-13.3	-1.8
Grum Dump Station	-15.5	-12.5	-9.8	-1.2	5.8	11.3	12.1	10.8	3.9	-2.6	-11.3	-12.5	-1.8
Faro AUT	-21.5	-15.8	-9.1	1.2	8.7	14.1	15.0	12.7	6.1	-1.6	-13.4	-18.6	-1.9

A comparison of the monthly average temperatures at the Faro Dump Station with those at the Faro AUT Station are presented in Figure 6D-6, which shows temperatures in the summer are generally cooler at the mine sites, as would be expected given the elevation difference. However, winter temperatures at the Faro AUT Station show a tendency to drop up to 10°C lower than at the Faro Dump Station, because of temperature inversions (Janowicz et al., 2005).

3.1.5 Expected Temperature Conditions at the Faro Mine Complex

While a long-term, complete dataset at the onsite stations does not exist, a strong correlation exists between the temperatures measured at the Faro AUT Station and those measured at the site stations. Plots of the temperatures at the two site stations with those at the Faro AUT Station and the resulting regression analysis and equations are shown in Figure 6D-6. With this correlation, the normals published for the Environment Canada Faro A Station can be adapted to the onsite stations using these equations.

3.2 Precipitation

Precipitation records at the local site stations have a short history (less than 10 years). Detailed discussions of these records can be found in the Hydrology Baseline Report (CH2M HILL, 2013). This section discusses the precipitation characteristics based on Environment Canada's 1981-2010 climate normal for the Faro A Station.

The average monthly precipitation, as recorded at the Faro A Station for 1981-2010, is shown in Figure 6D-7, and the annual total precipitation trend is shown in Figure 6D-8. The mean annual total precipitation ranges from 166 millimetres (mm) (1998) to 355 mm (1990), with an average of 320 mm.

Table 6D-4 summarized the monthly rainfall and snowfall in the same 1981-2010 period. On average, monthly rainfall amounts are higher from May to September. At the Faro A Station, the monthly snowfall amounts are greatest between in October and November, but generally snow covers the ground from October to March.

TABLE 6D-4
Rainfall, Snowfall, and Total Precipitation (1981 – 2010) – Faro A
Faro Mine Interim Works

Component	Monthly Average												Annual Average
	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	
Rainfall (mm)	0	0.01	0.12	2.6	27.3	36.7	56.1	47.5	38.4	9.4	0.16	0.13	218.4
Snowfall (cm)	16.7	14.6	13.1	6.3	0.63	0	0	0.65	2.4	20.4	21.7	17.6	114.0
Total precipitation[a] (mm)	14.6	12.3	12.3	8.7	27.9	36.7	56.1	48.2	41.0	27.3	19.4	15.2	319.7

Note:
cm = centimetre

[a]: Total precipitation is the water equivalent of all types of precipitation, including rainfall, snowfall, drizzle, freezing rain, freezing drizzle and hail.

3.3 Wind

3.3.1 Data Sources and Considerations

Environment Canada's Faro AUT Station and site-specific meteorological stations, as described previously, were used to assess surface winds for the 5-year period between 2006 and 2010. Wind speed, wind class frequency data, and wind direction were assessed and are presented below in a series of wind roses (Figures 6D-9A to 6D-11C).

The seasonal analysis of the wind data is defined as:

- Summer: May, June, July, August, September
- Winter: October, November, December, January, February, March, April

The description of winds has been presented in summary for both total and seasonal wind speed, wind direction and wind class frequency for the Faro AUT Station, Faro Dump Station, and Grum Dump Station in Sections 3.3.2 and 3.3.3.

3.3.2 Total and Seasonal Wind Speed and Frequency

Summaries of the total and seasonal wind speed, and wind class frequency for the Faro AUT Station, Faro Dump Station, and Grum Dump Station are presented in Table 6D-5. Figures 6D-9A, 6D-9B, and 6D-9C are the wind roses that show the total wind speed distribution at the above three stations. Figures 6D-10A, 6D-10B and 6D-10C show the wind rose for summer, and Figures 6D-11A, 6D-11B and 6D-11C for winter for the three stations, respectively.

Total wind speeds average 2.21 metres per second (m/s) for Faro AUT Station, 2.13 m/s for the Faro Dump Station, and 2.49 m/s for the Grum Dump Station. Across data sets, calm winds occur at lower frequencies (Faro AUT <5.5 percent, Faro Dump Station <4 percent, Grum Dump Station <1 percent). Table 6D-5 and Figures 6D-9A, 6D-9B, and 6D-9C also suggest that the data has a higher percentage of wind class frequencies across calmer wind classes (0.5 to 2.1 m/s).

Summer wind speeds average 2.21 m/s for the Faro AUT Station, 2.35 m/s for the Faro Dump Station, and 2.38 m/s for the Grum Dump Station. Winter wind speeds average 2.21 m/s for the Faro AUT Station, 1.96 m/s for the Faro Dump Station, and 2.57 m/s for the Grum Dump Station.

TABLE 6D-5
Wind Class Frequency Distribution
Faro Mine Interim Works

Time Period	Station Name	Wind Class (m/s) 0.5 - 2.1	2.1 - 3.6	3.6 - 5.7	5.7 - 8.8	8.8 -11.1	>= 11.1	Calms	Missing	Total

	Grum Dump Station	47%	23%	23%	2.89%	0.02%	0.00%	1.40%	3%	100%

3.3.3 Total and Seasonal Wind Direction

Summaries of total and seasonal wind direction and frequency distribution for the Faro AUT Station, Faro Dump Station, and Grum Dump Station are presented in Table 6D-6. The wind roses Figures 6D-9A, 9B, 9C, 10A, 10B, 10C, 11A, 11B and 11C also show the total, summer, and winter wind direction distributions for the three stations.

On an annual basis, the winds at Faro AUT Station and Grum Dump are predominantly from the southeast and northwest. Winds at the Faro Dump Station are predominantly from the southeast and northeast.

In summer , all three stations show a predominant wind from the west and northwest, while Faro Valley Dump also shows a smaller northeasterly component.

In winter, all three stations show a strong southeasterly component while Faro AUT shows an easterly component and Grum Dump station shows a strong northeasterly component.

TABLE 6D-6
Wind Direction Frequency Distribution
Faro Mine Interim Works

3.4 Solar Radiation

3.4.1 Data Sources and Considerations

A record of solar radiation is not published for the Environment Canada Faro stations. The meteorological stations at the two onsite stations measure solar radiation and the data were recorded from December 2003 to July 2009. Five complete years of data (2004 to 2008) were used in this analysis. The average daily solar radiation is presented in Figure 6D-12. Table 6D-7 summarizes the monthly data with the calculated monthly average and the average monthly solar radiation is presented in Figure 6D-13.

TABLE 6D-7
Monthly Average Solar Radiation
Faro Mine Interim Works

		Average Daily Solar Radiation (kilowatts)

3.5 Evaporation and Evapotranspiration

Evaporation is measured as the loss of water from free water surfaces and is usually represented as a rate of water loss in monthly or annual mm of depth. Evapotranspiration is the loss of water from land surfaces. It is also normally expressed in terms of monthly or annual mm, and represents a combination of evaporation from the

ground surface and transpiration by vegetation. Estimates of evaporation and evapotranspiration rates for the FMC have been calculated from meteorological data collected at onsite climate stations, and from regional climate stations, using the Environment Canada National Hydrology Research Institute (NHRI) WREVAP Model (NHRI, 1985).

WREVAP is a semi-empirical, semi-physical model that estimates evaporation from meteorological data (humidity, air temperature and sunshine duration or solar radiation). The two onsite dump weather stations monitor the necessary input data for the evaporation model. Accordingly, the WREVAP model was applied by AECOM to the data sets provided by these two stations (AECOM, 2009). The computed mean annual evapotranspiration rates for the Faro Dump and Grum Dump weather stations are 229 mm and 246 mm, respectively. The computed mean annual lake evaporation rates for the Faro Dump and Grum Dump are 472 mm and 484 mm, respectively, or roughly double the corresponding mean annual evapotranspiration rates. The monthly evapotranspiration values for the FMC are shown in Table 6D-8.

3.6 Relative Humidity

The RH at Faro A Station is generally recorded twice per day in summer months (April through October) at 06:00 and 15:00, and once per day at 15:00 during the rest of the year. The annual average RH, as recorded at 15:00 for 1981-2010, is 62.69 percent. The RH is generally higher in the morning and lower in the afternoon. Table 6D-9 shows the 1981 – 2010 Climate Normal data of RH recorded at Faro A.

SECTION 1

Introduction

Air quality is considered to be an important consideration and a primary goal for the Faro Mine Interim Works (IW) project. Air quality is characterized by ambient concentrations of key air quality indicators including nitrogen oxides (NO_x), sulphur dioxide (SO_2), particulate matter (including metals), carbon monoxide (CO), ozone (O_3), and other pollutants. This document describes the baseline air quality conditions of the area on and around the Faro Mine Complex (FMC) site. The purpose of this baseline air quality analysis is to quantitatively define the existing or baseline ambient air quality conditions near the FMC, which is used in part to assess the air quality effects of the IW project as described in the *Air Quality Effects Report, Faro Mine Interim Works* (CH2M HILL, 2014).

Existing air quality conditions were characterized using recent air quality data obtained from previous onsite monitoring studies, as well as by air quality monitoring data obtained from offsite Environment Canada monitoring stations.

This report summarizes the air quality data used for the baseline assessment and discusses the representativeness of those data used to characterize ambient air concentrations in the vicinity of the project site.

SECTION 2

Methods

This section describes the air quality study area, data sources, and data analysis methods. In general, site monitoring data were used as the primary source of baseline air quality data. For parameters that were not monitored on the site, the nearest National Air Pollution Surveillance (NAPS) monitoring stations operated by Environment Canada were used to obtain representative data. The following sections provide additional details about the study area, data sources, and analysis methods.

2.1 Study Area

The study area for the ambient air quality analysis at the FMC site includes the areal extent of any likely air quality impacts attributable to IW project-related emissions. This area was assumed to be comprised of a 100-kilometre (km) -by-100-km square area approximately centred on the project site. The extent of the study area is considered to be sufficient to assess air quality parameters such as secondary particulate matter formation.

Figure 6E-1 shows the baseline air quality analysis study area.

2.2 Analysis Parameters

Air quality was described by characterizing ambient concentrations of key air quality indicators including NO_x, SO_2, particulate matter, CO, O_3, and particulate based metals. This baseline analysis did not characterize greenhouse gases (GHGs) because the IW is scheduled for completion within 10 years. As a result, the project is not expected to contribute measurably to global climate conditions.

Only those emissions that will be associated with current site operations and proposed IW activities were quantified for the baseline and effects determination, respectively.

2.3 Sources of Data and Information

The following databases and reports were reviewed for use in establishing the baseline ambient air quality for the FMC site:

- Environment Canada NAPS, http://www.ec.gc.ca/rnspa-naps/default.asp?lang=En&n=8BA86647-1, Accessed September 5, 2013 (Environment Canada, 2013)
- Yukon State of the Environment Interim Report, An Update for Environmental Indicators, Government of Yukon (YG), Yukon Environment (YG, 2013)
- AECOM Canada Ltd. (AECOM). 2009. *Faro Mine Closure Complex Closure and Reclamation* – Current Environmental Conditions Supporting Document (AECOM, 2009)
- 2008 Baseline Air Quality Monitoring Assessment – Faro Mine Complex. February 24, 2009. (SENES, 2009)

Results from onsite sampling conducted by SENES Consultants Ltd. (SENES) in 2008 were the data source for contaminants that were measured in that program. Data from the nearest NAPS monitoring stations (Whitehorse in the Yukon Territory [YT] and Norman Wells in the Northwest Territories [NWT]) were used as the primary data source for characterizing ambient air quality for those contaminants that were not monitored at the FMC site.

2.4 Data Analysis Methods

The proposed project activities will result in emissions that have the potential to affect criteria air contaminants as a result of construction and maintenance activities. The effects assessment (CH2M HILL, 2014) required a comprehensive understanding of the current state of air quality in the site area, so that an assessment of effect of the project on baseline air quality could be made.

An evaluation of existing ambient air quality will serve as a benchmark for evaluating effects of project related emissions on existing air quality. Current ongoing projects at the FMC have been considered in characterizing

baseline ambient air quality. The effects primarily result from airborne dust from vehicle traffic on unpaved roads, fugitive emissions from construction and material handling, wind-blown dust emissions from the tailings storage facilities, and the combustion of diesel and other fuels in onsite and mobile equipment.

A review of local air quality literature and information sources shows that only limited ambient air quality monitoring has been performed on or near the FMC site. This includes data from onsite monitoring stations, as well as data from nearby monitoring stations operated by Environment Canada as part of the NAPS network.

2.4.1 Criteria Air Contaminants (Other Than Particulate Matter)

For criteria contaminants other than particulate matter, the ambient air quality characterization relied on Environment Canada NAPS data from the nearest stations. Apart from SO_2, the baseline characterization relied on data collected at Whitehorse, about 200 km from the FMC. Ambient SO_2 was not measured at Whitehorse; therefore, the FMC characterization used data collected at Norman Wells, NWT, approximately 460 km from the FMC, which is the nearest NAPS station measuring SO_2. Although Norman Wells is a significant distance from the FMC, the nature and quantities of SO_2 emissions near the monitor were deemed similar to those expected for the FMC; therefore, these data were used as an SO_2 concentration indicator.

The NAPS network was established in 1969 as a joint program of the federal and provincial governments to monitor and assess ambient air quality in Canadian urban centres. The goal of the NAPS program is to provide accurate and long-term air quality data of a uniform standard across Canada. Air quality data for criteria air pollutants such as SO_2, CO, nitrogen dioxide (NO_2), O_3, and particulate matter are measured at most stations. For smog assessments (ground-level ozone), data for NO_x and volatile organic compounds (VOCs) are being collected at selected stations. Trace contaminants are also monitored at several stations.

NAPS data are validated using automated and manual procedures; data from network agencies are converted to a compatible format and then entered into the NAPS database. Though the NAPS data base is a reliable source for establishing ambient air quality baselines, the monitoring data best indicate pollution levels at sampling sites and may not necessarily represent community-wide air quality. Environment Canada suggests that community-wide comparisons can only be made by using data from all available sampling stations in a region and interpreting them on the basis of specific monitoring site characteristics. The NAPS data are used in this fashion by stating the concentrations from the station along with (1) an accompanying discussion regarding how those values may differ at the FMC and (2) an indication of magnitude of the difference.

The available NAPS hourly monitoring results from Whitehorse and Norman Wells for two recent years (2010 and 2011) for criteria air pollutants (including O_3, SO_2, CO, NO_x, NO_2, and particulate matter with aerodynamic diameter less than 2.5 microns [$PM_{2.5}$]) were downloaded from the NAPS database. In addition, annual mean concentrations for O_3, SO_2, CO, NO_x, NO_2, and $PM_{2.5}$ were obtained from the NAPS database (Environment Canada, 2013).

The Yukon Ambient Air Quality Standards (Yukon Standard) (YG, 2010, and provided in Table 6E-1) were used to select concentration averaging time periods of the applicable air pollutants to establish the ambient air quality baselines for the current air quality analysis. As Yukon does not have a standard for PM_{10}, the BC Ambient Air Quality Objective for PM_{10} was used, as listed in Table 6E-1. These concentrations were also used as background air concentrations in the Air Quality Effects Report (CH2M HILL, 2014).

The United States Environmental Protection Agency (USEPA) provides guidance on which percentile concentrations from a time series of hourly or daily monitored concentrations should be used to characterize ambient air background concentrations when conducting an ambient air quality analysis for permitting purposes. As there is no Canadian guidance available for establishing background concentration from monitoring data sets, the USEPA guidance was followed as a reference. Specifically, maximum, minimum, and average values, as well as 90th, 98th, and 99th percentile values, are presented consistent with that guidance except where noted.

TABLE 6E-1
Yukon Ambient Air Quality Standards

Particulate Matter (PM_{10})[a]			
24-hour average	50		

Notes:

[a] BC Ambient Air Quality Objectives

The above standards are the maximum concentrations of pollutants acceptable in ambient air throughout the Yukon Territory. These standards are used in the effects assessment to help determine the significance of emissions from proposed and existing developments.
µg/m^3 = micrograms per cubic metre
ppm = parts per million
ppbv = parts per billion by volume
All ambient air quality measurements have been referenced to standard conditions of 25 degrees Celsius and 101.3 kilopascals.
Source: Yukon Ambient Air Quality Standards, April 22, 2010

2.4.2 Particulate Matter and Metals

For particulate matter other than $PM_{2.5}$ and metals, the characterization of baseline air quality was based on onsite data. The SENES 2008 monitoring program report indicated the program was successfully completed, with data recovery of TSP samples ranging from 54 percent to 77 percent for 8 of the 9 sampling sites (and 24 percent at the "A1" site near the Faro Pit) and data recovery of PM_{10} samples ranged from 39 percent to 69 percent (SENES, 2009).

AECOM (2009) conducted a further QA/QC analysis on the SENES 2008 sampling results, including (1) a gap analysis to assess the representativeness of results with consideration of the weather conditions during the sampling periods and (2) an additional data recovery analysis following the regulatory sampling procedure outlined by British Columbia, Ontario, and the federal government (NAPS).

Based on these previous assessments by AECOM and SENES, although the SENES 2008 monitoring program had limited results, it did provide representative data that may be used as a primary source to establish a representative ambient air quality baseline for particulate matter and metals. Attachment 6E-1 describes the SENES 2008 program.

SECTION 3

Monitoring Results

3.1 NAPS Monitoring Network

3.1.1 Monitoring Stations

Table 6E-2 lists the NAPS stations that were active in 2010 and 2011 and used in the baseline air quality characterization for the FMC site, including stations in Whitehorse and in Norman Wells, NWT. Figure 6E-2 shows the location of the selected NAPS stations relative to the Faro Mine Area.

3.1.2 Monitoring Results

Hourly concentrations of criteria air contaminants (with exception of SO_2 and PM_{10}) were monitored at the NAPS stations in Whitehorse. Monitoring data from 2010 and 2011 from the NAPS stations in Table 6E-2 were compiled and reviewed and the statistical summary results are provided in Table 6E-3. Please note that NO_x monitoring data were only available for 2011 at station 119004 in Whitehorse.

SO_2 was not monitored at either Yukon NAPS station or in historical ambient air quality monitoring programs conducted onsite, and therefore the monitoring results from the nearest NAPS Station that measured SO_2 (located in Norman Wells, NWT) were used as an ambient concentration representative of the FMC site.

The 2010 and 2011 monitoring results were generally consistent with one another, with only a small variation. The average of the two years of data was used to establish FMC site baseline concentrations. Table 6E-3 shows the contaminants that were used to characterize the baseline concentrations and the station where they were measured (for instance CO concentrations from the Norman Wells station are not shown since the baseline is from the Whitehorse station, which is considered more representative of the FMC).

3.2 Baseline Air Quality Monitoring at Faro Mine

3.2.1 Description of the Monitoring Program

Samples of TSP and respirable PM_{10} were collected by SENES at nine sites in 2008. Eight sites were located on the FMC site and one site was located in the Town of Faro. The locations of the eight environmental effects air monitoring stations at FMC were distributed widely among the three main areas, the Faro Mine Area, the Vangorda/Grum Area, and the Tailings Area.

Five sampling sites were established in the vicinity of the Faro Mine and Tailings areas. Three sampling sites were located in the vicinity of the Vangorda/Grum Area. One site was located in the Town of Faro. Each of these three regions is separated by a minimum of 8 km. The locations of the sampling sites are presented in Figure 6E-3 and described in Table 6E-4.

The monitoring program consisted of thirteen 24-hour sampling periods in July, August, September, and October 2008. The ambient air monitoring program was designed to measure particulate matter and 30 metals contained in the particulate matter.

TABLE 6E-4
Onsite Ambient Air Quality Monitoring Sites
Faro Mine Interim Works

Station	Location	Description
TL1	South of Intermediate Tailings area	Located south of the Intermediate Impoundment, near the unpaved road between the tailings area and Rose Creek, where trace metals concentrations were expected to be elevated.
TL2	South of Intermediate Dam	Located south of the Intermediate Impoundment, near the Intermediate Dam and the unpaved road between the Tailings Area and Rose Creek, where trace metals concentrations were expected to be elevated.
TL3	Mill Area Road	Located southwest of the Mill area, west of the emergency tailing area on a slope beside the main road to the mine administration buildings.
RC1	Rose Creek	Located northwest of the Cross Valley Pond and Existing Emergency Spillways, near Rose Creek, where previous soil sampling indicated the potential for transport of trace metals (Gartner Lee Limited, 2006).
A1	Northwest of Faro Pit	Located northwest of the Faro Pit. The site is beside a road that is no longer in use, in the creek hollow beside an area of exposed soil, and would thus be subject to some potential fugitive dust from the west and southwest.
VG1	Northwest of Ore Transfer Pad and Grum Pit	Located northwest of the Grum Pit beside the Ore Transfer Pad.
VG2	Northwest of Ore Transfer Pad and Grum Pit	Located on the breach dam beside the effluent discharge pond between the Vangorda and Grum pits.
G1	Northwest of Ore Transfer Pad and Grum Pit	Located above and to the east of the Vangorda Pit along a road reported to be used by one family in the Town of Faro, for traditional purposes.

3.2.2 Monitoring Results

A summary of the sampling results for TSP, PM_{10}, and metals (contained in particulate) concentrations are presented in Table 6E-5. Results are grouped into three areas: the Faro Mine and Tailings Area, the Grum and Vangorda Area, and the Town of Faro.

For each parameter, the maximum concentration is in red to highlight the measurement area in which it occurred.
MDL = below Method Detection Limit (MDL) for > 98% of samples.

3.2.3 Analysis of Data Recovery

The acceptability of data recovery for the 2008 air monitoring program was assessed by SENES (2009) and a further analysis by AECOM (2009) using the following sampling procedures:

- British Columbia Field Sampling Manual, HiVol Particulate Sampling Procedure (BC MOE, 2003)
- British Columbia Air Monitoring Guidelines: Volume 1 Particulate Non-Continuous (BC MOE, 1996)
- British Columbia Environmental Laboratory Manual (BC MOE, 2009)
- Operations Manual for Air Quality Monitoring in Ontario (MOE, 2005)
- NAPS network schedule (Environment Canada and Health Canada, 1998, “National Ambient Air Quality Objectives for Particulate Matter”)

SENES concluded that there was a low data recovery rate that may have been as a result of technical issues during the original field surveys and monitoring data periods. The lower data recovery ratio than what is typical of best practices suggested a level of uncertainty in the monitored data. However, despite the data quality issues and concerns, the data do provide an indication of the ambient air quality in the area. As the best available local monitoring data, they were used as primary sources of baseline ambient air pollutant concentrations for this analysis.

3.3 Ambient Air Quality Summary

To select the most representative values for background ambient air concentrations, USEPA guidance for National Ambient Air Quality Standards (NAAQS) compliance was used as a reference for criteria air contaminants. This guidance indicates what percentile concentrations should be used from an ambient air dataset in order to characterize a background value for each contaminant and averaging period. Table 6E-6 summarizes the baseline concentration estimates of criteria air pollutants in the project area. The concentrations shown are consistent with the form of the USEPA standards for each of the Criteria Air Contaminants monitored at NAPS. A 75th percentile of the 24-hour average concentrations of TSP and PM_{10} from the FMC site monitoring program were used as an ambient background concentration for those contaminants. For metals, the maximum observed 24-hour concentration from all nine onsite stations was conservatively used to represent the ambient background of the FMC site.

TABLE 6E-6
Summary of Ambient Air Quality Monitoring Data for the FMC Site Region
Faro Mine Interim Works

Contaminant	Averaging Time	Monitoring Results	Data Description	Station ID	Data Source	AAQS	AAQS Sources
NOx	1-hour	31 (ppb)	98th percentile of 1-hour averages	119004 - Whitehorse	NAPS	213 (ppbv)	Yukon AAQS

SECTION 4

Baseline Ambient Air Quality

Table 6E-7 summarizes the available monitoring data used to represent baseline air quality concentrations of criteria air contaminants and ozone in the study area. The table also shows the Yukon Standard and BC Ambient Air Quality Objectives for applicable contaminants.

Table 6E-8 summarizes the available monitoring data used to represent baseline ambient air quality concentrations for metals. As the Yukon Standard does not include ambient standards for metals, and neither BC nor Alberta has a 24-hour average metal standard or objective, the table provides Ontario Ministry of the Environment (MOE) 24-hour standards or guidelines for metals for comparison. These also help to gauge the magnitude of the concentrations.

Data for many of the contaminants in Table 6E-8 (except PM_{10} and TSP) were derived from the nearest NAPS stations, which were 200 km and 460 km from the site for the Whitehorse and Normal Wells stations, respectively. These stations are in residential or light industrial areas, where there may have been significant anthropogenic contributions to the measured concentrations from sources such as residential wood burning, and combustion gases from nearby traffic arteries and mobile vehicles and equipment. Also, Whitehorse is subject to occasional elevated smog concentrations because of winter inversions, leading to higher concentrations of $PM_{2.5}$, ozone, and nitrogen oxides than would be expected at the FMC site. However, baseline Faro ambient air measurements would be expected to capture emissions from vehicular traffic (tailpipe and road dust re-suspension) and combustion products from heavy equipment, power generation, and heating systems for on-going care and maintenance activities at the FMC site. Therefore, although contaminants other than TSP, PM_{10}, and metals were not measured at the FMC site, conservative estimates can be obtained from NAPS stations where sources that influence the ambient concentrations are likely to be similar in nature and magnitude.

The criteria contaminant concentrations from the NAPS stations are likely higher than those at the FMC site. This is because anthropogenic influence and occasional meteorological effects are more likely to affect measured concentrations in the NAPS station areas than at the FMC site. However, as mentioned, these concentrations are useful for estimating concentration indicators, given the lack of ambient measurements in the FMC site area.

The *Air Quality Effects Report, Faro Mine Interim Works* (CH2M HILL, 2014) quantified the potential effects of IW activities by estimating emissions from those activities and using a comprehensive air dispersion model to estimate the effects. These effects were then added to the background concentrations as determined in this report to determine the effects of IW activities on regional air quality levels. The conservative nature of the background concentrations is expected to lead to conservative conclusions regarding the effects of IW activities on regional air quality.

EXECUTIVE SUMMARY

A baseline air quality monitoring program was conducted at the Faro Mine Complex in the summer of 2008 to establish existing levels of particulate matter and trace heavy metals. A total of nine sampling sites were established in July of 2008 to sample for total suspended particulate (TSP) matter and respirable particulate matter (PM_{10}). Five sites were located in the vicinity of the Faro mine pit and tailings areas, three in the vicinity of the Grum and Vangorda pits, and one site was located in the Town of Faro to provide estimates of background air quality away from the mine site. A dustfall sampling site was also located near the tailings area at the Faro mine site.

TSP and PM_{10} sampling was conducted using battery-operated MiniVol™ samplers during the period July 17th to October 3rd on a 1-in-6 day sampling schedule, for a total of 13 sampling periods (24 hour averages). All TSP and PM_{10} levels were within established ambient air quality objectives defined by Environment Canada or other provincial jurisdictions. The highest and second highest TSP concentrations of 95.5 $\mu g/m^3$ and 70.6 $\mu g/m^3$ were recorded on September 9th near the Grum pit and the Faro mine, respectively. The major elemental constituents of the two TSP samples on that date consisted of aluminium, boron, calcium, chromium, iron, magnesium, phosphorus, potassium and sodium. All other sampling sites had low TSP concentrations (<8 $\mu g/m^3$) on that date. The only other date with TSP concentrations in the range of 35-40 $\mu g/m^3$ occurred on August 4th. One sample was recorded near the Faro mine, while the other two were collected near the Vangorda and Grum pits. The major elemental constituent of one sample was sodium, with smaller concentrations of aluminium, calcium, iron and magnesium in all three samples.

The highest PM_{10} concentration of 24.7 $\mu g/m^3$ was recorded at Rose Creek downwind of the tailings area on July 23rd. All other PM_{10} concentrations were less than 20 $\mu g/m^3$, and there was little difference in PM_{10} concentrations between the mine site and the Town of Faro. The major elemental constituent of the July 23rd sample on Rose Creek was sodium, with smaller quantities of aluminium, calcium, chromium, copper, iron, phosphorus and potassium.

Overall, particulate matter and trace inorganic element concentrations at the Faro Mine Complex were very low, and were often similar to levels recorded in the Town of Faro. Even during the periods with the highest TSP loadings, the composition of the particulate matter was primarily made up of trace elements which either have no ambient air quality criteria or are not of concern for human health exposure. The exception may be chromium which had a relatively high concentration in one sample collected near the Faro pit, but this value is considered anomalous because sample collection did not extend over a full 24-hour period. The 24-hour averaged chromium concentrations in all other samples remained well below any level of concern.

The maximum observed concentrations for inorganic elements with established ambient air quality criteria are listed in Table ES.1 (excluding samples collected near the Faro mine pit which were considered outlier values).

Table ES.1
Comparison of Maximum Observed Elemental Concentrations
And AAQC Values

Element	Maximum Observed Concentration	Sampling Location	PM Size Fraction	Ambient Air Quality Criteria	
	($\mu g/m^3$)			($\mu g/m^3$)	Rationale

Tellurium	0.00185	TL1	PM_{10}	10	health
Tin	0.0108	VG1	TSP	10	health
Titanium	0.0271	TL3	TSP	120	particulate matter
Vanadium	0.00185	TL1	PM_{10}	2	health
Zinc	0.101	TL3	TSP	120	particulate matter

The total dustfall near the tailings area of the Faro mine was very low, with two of the samples (July and September) having dustfall levels at the method detection limit. The maximum total dustfall deposition rate occurred in August with a rate of 0.12 mg/dm^2.day, although July's rate might have been higher if the sample had been collected over the entire month. This maximum deposition rate is an order of magnitude lower than the dustfall criteria adopted by various provinces in Canada, as well as criteria for new mines in Australia and residential areas of the

United Kingdom and the State of New York. The low dustfall levels are consistent with the generally low particulate matter concentrations observed in the TSP and PM_{10} samples.

With respect to elemental composition, most of the trace inorganic constituents were below the method detection limits for all three dustfall samples. The only contaminants that were observed to be higher than the detection limits included arsenic, barium, cadmium, calcium, copper, iron, lead, manganese, molybdenum, silver, strontium, zinc. With the exception of arsenic and zinc, the remainder of these elements were also noted to have somewhat elevated concentrations relative to the Town of Faro in the TSP and PM_{10} samples. This indicates a reasonable degree of consistency between the TSP/PM_{10} samples and the dustfall samples. The highest concentrations of these 12 constituents in dustfall samples occurred either in July or August. All elemental concentrations in the September dustfall sample were lower than in the previous two sampling periods.

Although there were some difficulties with data recovery in the initial part of the sampling program due to operator error on the part of on-site staff, the overall sampling program was successful in establishing baseline levels of particulate matter and trace inorganic elements. It is recommended that the particulate matter sampling program be continued in 2009 with the following changes:

1. The sampling program should be initiated as soon as possible after the loss of snow cover in late May or early June, depending on site conditions. The continuation of the sampling program to the end of September should be reconsidered, with a termination date in early September at the latest.
2. The same nine sampling sites should be retained for 2009, but the sampling periods should be extended to 48 hours in order to obtain higher particle loadings on the filters.
3. It would be preferable to add at least three additional dustfall sampling sites to the program. These could be established at sites Rose Creek (site RC1), the Faro pit (site A1) and between the Vangorda and Grum pits (site VG2).
4. In order to minimize material loss or damage to the filters during handling, it is recommended that a 'clean' room be identified for this purpose. If this cannot be done at the mine administration building, consideration should be given to finding a location in the Town of Faro for that purpose.

1.0 INTRODUCTION

A baseline air quality monitoring program was conducted at the Faro Mine Complex in the summer of 2008 to establish existing levels of particulate matter and trace heavy metals. The Complex is located near the Town of Faro, Yukon Territory, and is the site of a former lead/zinc mine operated by the Anvil Range Mining Corporation. The mine site is being decommissioned, and the objective of the air quality monitoring program in 2008 was to provide baseline exposure data for worker health and safety prior to the start of remediation activity at the mine.

A total of nine sampling sites were established in July of 2008 to sample for total suspended particulate (TSP) matter and respirable particulate matter (PM_{10}). Five sites were located in the vicinity of the Faro mine pit and tailings areas, three in the vicinity of the Grum and Vangorda pits, and one site was located in the Town of Faro to provide estimates of background air quality away from the mine site.

TSP/PM_{10} sampling was commenced on July 17th and conducted on a 1-in-6 day sampling schedule, consistent with the National Air Pollution Surveillance (NAPS) network sampling schedule operated by Environment Canada, until October 3rd. A total of 13 24-hour averaged TSP/PM_{10} samples were collected during this period. In addition, three dustfall samples were collected at one location near the Faro mine tailings area: a partial sample for the latter half of July and full monthly samples for August and September.

All samples were analysed for total mass, as well as for elemental composition of trace heavy metals and inorganic constituents.

2.0 MONITORING PROGRAM

2.1 SAMPLING LOCATIONS

Figure 2.1 shows the location of the nine TSP/PM_{10} sampling sites at the mine complex. Five sites were established in the Faro Mine area (TL1, TL2, TL3, RC1 and A1). Three sampling sites were located in the vicinity of the Vangorda and Grum mine pits (VG1, VG2 and G1). One site was located in the Town of Faro (FA1) away from the mine complex to provide a measure of background concentrations. The latitude/longitude and UTM coordinates of each site is listed in Table 2.1.

Figure 2.1
TSP/PM_{10} Sampling Locations

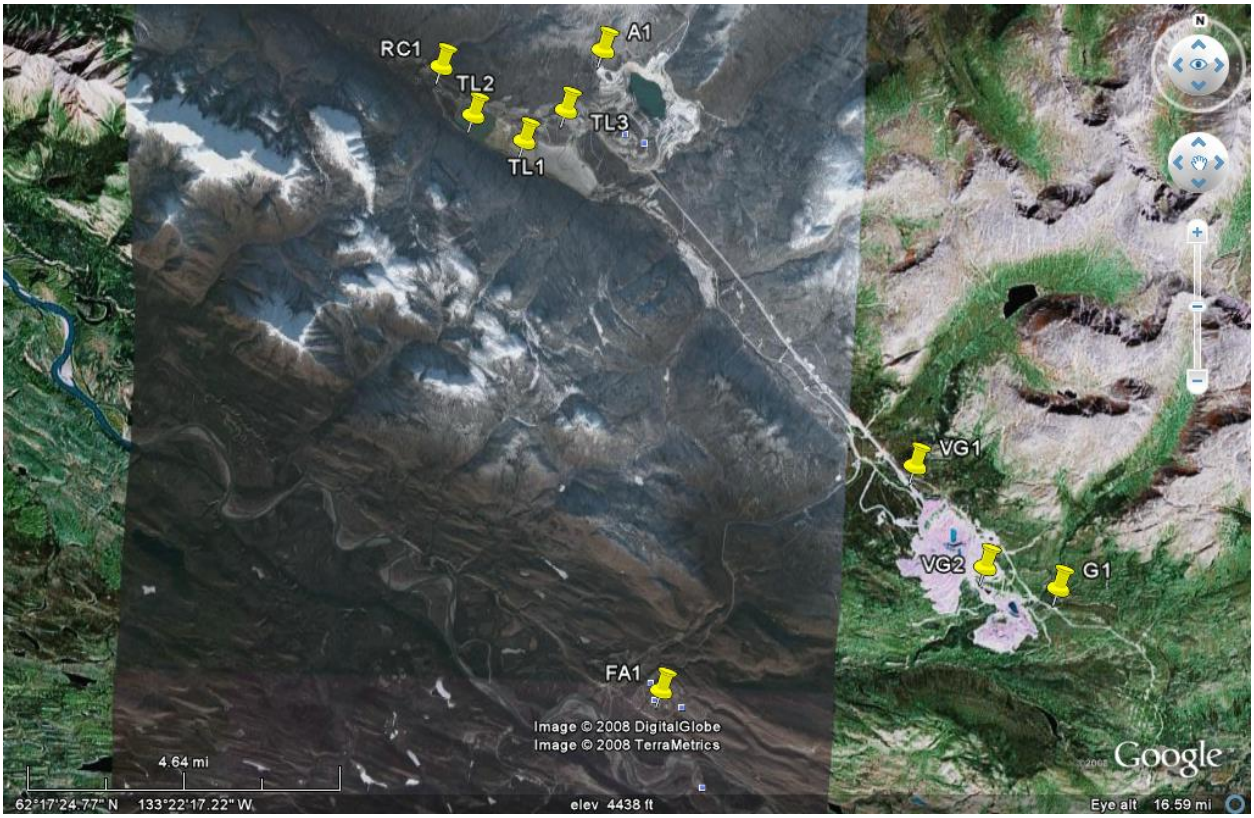

Table 2.1
Sampling Location Coordinates

Site	Latitude N	Longitude W	UTM N (m)	UTM E (m)	Elevation (m)
TL1	62^0 20.566	133^0 25.546	6913359.00	418483.53	1058.6

2.1.1 Faro Mine Site

Figure 2.2 provides an enlarged image of the sampling locations at the Faro mine site. Two sampling sites were located on the southeast side of the tailing area (TL1, TL2) where trace metals concentrations were expected to be elevated. The dustfall sampling site was also located at TL1, along with the meteorological station to record temperature and atmospheric pressure which were used in calculating the TSP/PM_{10} concentrations. Figure 2.3 shows the sampling equipment at TL1, while Figure 2.4 shows the TSP/PM_{10} monitors at TL2. Both Sites are in proximity to the unpaved road running between the tailings areas and Rose Creek.

One sampling site was located at the northwest end of the tailings area beside Rose Creek (RC1) where previous soil sampling had indicate the potential for transport of trace metals along the creek away from the mine complex. The sampling location is shown in Figure 2.5. Although a dirt road runs beside the sampling area, it is seldom used.

One sampling site (TL3) was located below the main mine office complex, between the waste rock dump site to the east and the tailings area. The site is located on the slope beside the main road to the mine administration buildings, and would thus be subject to a fair amount of road dust. The equipment setup at TL3 is depicted in Figure 2.6.

Site A1 is located on the northwest side of the mine pit. The site is beside a road that is no longer in use, in the creek hollow beside an area of exposed soil, and would thus be subject to some potential fugitive dust from the west and southwest. Figure 2.7 shows the equipment set up at the site. The mine pit is located to the left of the samplers in Figure 2.7.

Figure 2.2: Location of Sampling Sites at the Faro Mine Site

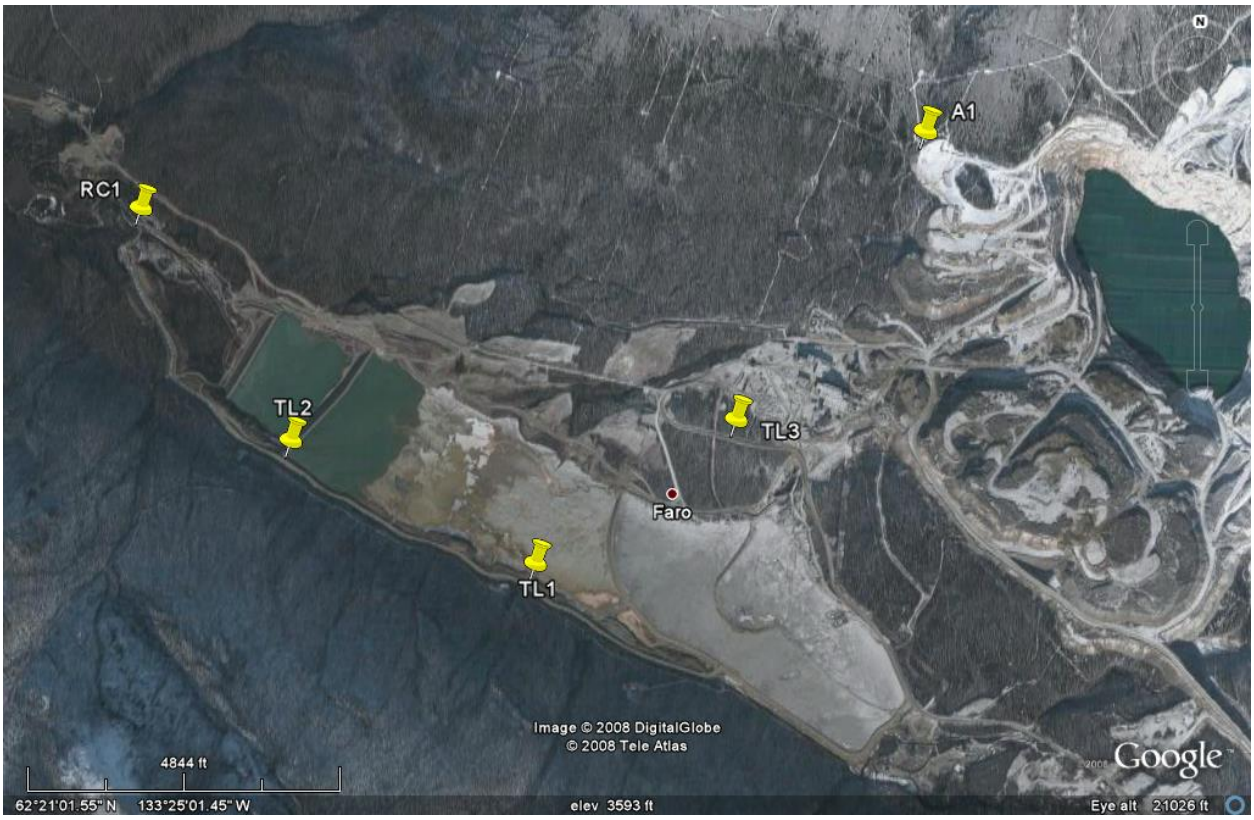

Figure 2.3: TL1 Sampling Site

Figure 2.4: TL2 Sampling Site

Figure 2.5: RC1 Sampling Site

Figure 2.6: TL3 Sampling Site

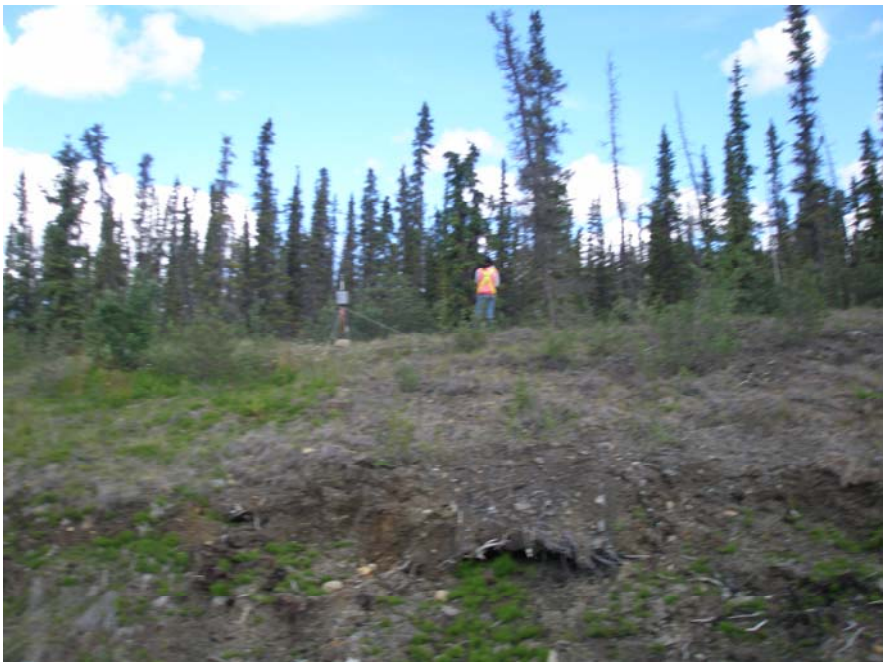

Figure 2.7: A1 Sampling Site

2.1.2 Vangorda and Grum Sites

The three sampling sites near the Vangorda and Grum mine pits were located on the northwest side of the Grum pit (VG1) beside the ore transfer pad, on the breach dam beside the effluent discharge pond between the Vangorda and Grum pits (VG2), and above and to the east of the Vangorda pit (G1) along a road reported to be used by one family in Faro for traditional purposes. All three sites are exposed to fugitive dust from unpaved roads, although VG1 and VG2 would have the greatest potential for exposure to fugitive road dust.

The equipment set up at these three sites is depicted in Figures 2.8, 2.9 and 2.10.

Figure 2.8: VG1 Sampling Site

Figure 2.9: VG2 Sampling Site

Figure 2.10: G1 Sampling Site

2.1.3 Faro Town Site

The background sampling site in the Town of Faro was located on the lawn in front of the medical clinic. The location is depicted in Figure 2.11, while the equipment setup is shown in Figure 2.12. The main source of fugitive dust at this location would be from the unpaved road beside the clinic.

Figure 2.11: Town of Faro Sampling Site

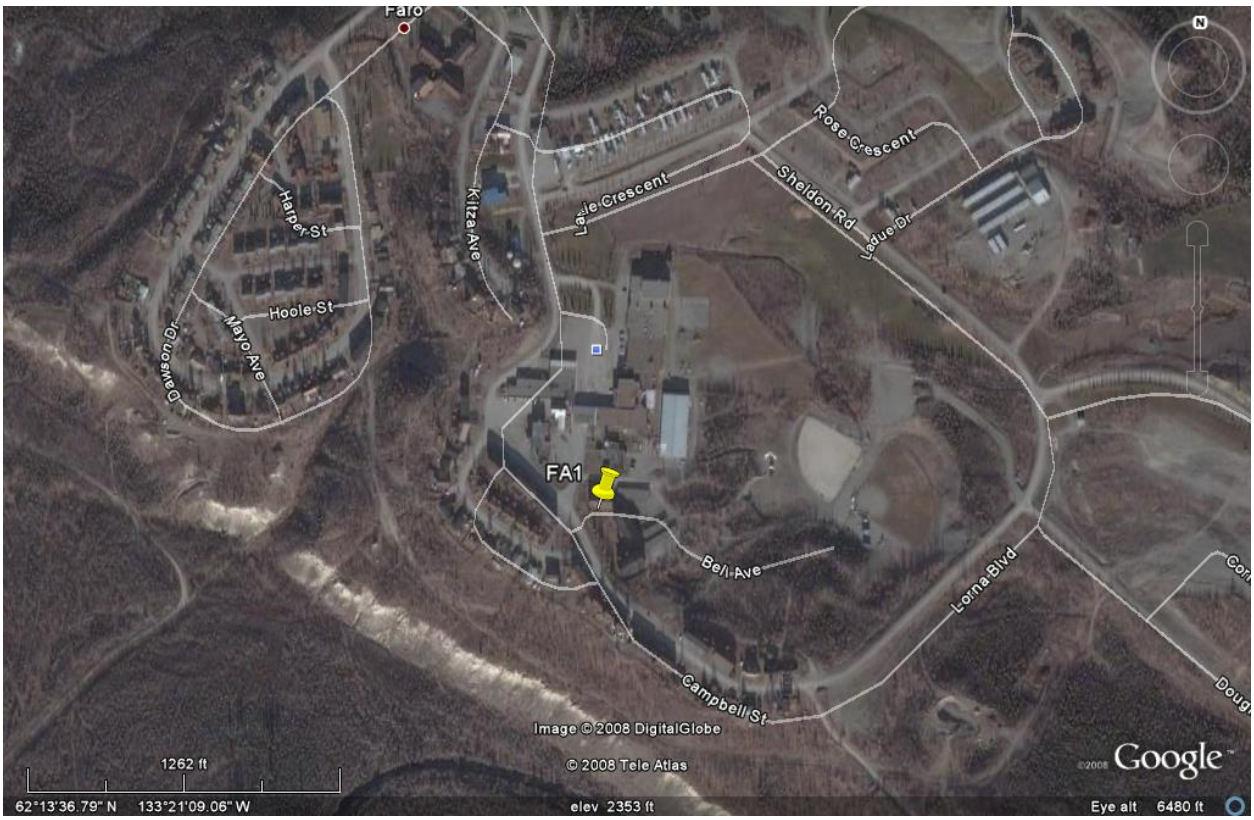

Figure 2.12: FA1 Sampling Site

2.2 SAMPLING METHODOLOGY

2.2.1 TSP/PM_{10} Sampling

The TSP and PM_{10} samples were collected using battery-operated, portable MiniVol™ Tactical Air Samplers (TAS) manufactured by Airmetrics of Eugene, Oregon[1]. The MiniVol™ samplers are designed to operate at a flow rate of 5 litres per minute, and as such provide low volume samples of ambient particulate matter concentrations. While MiniVol™ samplers are not considered a reference sampling method, the mass concentrations derived from MiniVol™ samplers give results that closely agree with reference method concentrations.

Samples were collected on a 1-in-6 day sampling schedule consistent with the National Air Pollution Surveillance (NAPS) particulate matter sampling schedule used by Environment Canada for stations across the country. Appendix A provides details for each set of samples collected during each sampling period.

Samples were collected on 47 mm Teflon filters. Total TSP or PM_{10} concentration was calculated using corrected flow rate (Qact) and the particulate loadings (in mg) on the filters. The following equation to estimate actual flow rate through the filters:

$$Q_{act} = (m_{vol} Q_{ind} + b_{vol}) \times \sqrt{(P_{std}/P_{act}) \times (T_{act}/T_{std})}$$

where

- Q_{act} is the actual flow rate (litres/min)
- Q_{ind} is the rotameter indicated flow rate (litres/min)
- m_{vol} is the slope of the least squares line from the individual sampler calibration report
- b_{vol} is the intercept of the least squares regression line from the individual sampler calibration report
- P_{std} is the standard atmospheric pressure (1013.25 millibars)
- P_{act} is the actual ambient pressure (mbar)
- T_{std} is the standard atmospheric temperature (298^0K)
- T_{act} is the actual ambient temperature (^{0}K)

Total mass of particulate matter on the filters was determined by gravimetric analysis by CANTEST Limited. Elemental composition of the samples was determined by CANTEST using

[1] http://www.airmetrics.com

inductively coupled plasma mass spectrometry (ICP/MS) methods. The method detection limits for the elemental analysis of the filter samples are listed in Table 2.2.

2.2.2 Dustfall Sampling

Two dustfall canisters were established at site TL1 to measure dustfall and the trace inorganic elemental composition of dustfall. Due to concerns about the amount of dustfall that would be present, one canister was used exclusively to analyse for total mass, while the second canister was used to determine chemical composition. Since the sampling program began on July 17th, only a partial month of data was collected for the period July 17th to 31st. Complete monthly samples were collected for both August and September.

The analysis of the dustfall samples was completed by the ASL Laboratory Group using inductively coupled plasma mass spectrometry (ICP/MS) methods as defined by the B.C. Ministry of Environment.

The method detection limits for the analyses are listed in Table 2.3.

2.2.3 Meteorological Sampling

Ambient temperature and barometric pressure were recorded at 5-minute intervals for the duration of the sampling program using a HOBO Micro Station sampler system located at site TL1. The ambient temperature varied from a high of 21.6^0C to a low of -8.6^0C. Barometric pressure varied from a high of 913.4 mbar to low of 864.9 mbar. The data were used in the calculation of daily TSP and PM_{10} concentrations as discussed in Section 2.2.1, above.

3.0 DISCUSSION OF SAMPLING RESULTS

3.1 TSP/PM_{10} SAMPLES

3.1.1 Data Recovery

Table 3.1 provides a summary of the mass concentrations for TSP and PM_{10} at the nine sampling locations. No sampling data (ND) were recovered for 10.8% of the TSP samples and 8.5% of the PM_{10} samples. This was largely due to some early confusion about instrument operation by field staff at the beginning of the sampling program. The lowest data recovery was for TSP at site A1 where the first five sampling periods were missed for TSP. The second lowest data recovery was for TSP at site FA1 in the Town of Faro where three of the 13 sampling periods did not have recoverable data.

Of the recoverable sampling data, 29.5% of the TSP samples and 43% of the PM_{10} samples had low concentrations that were at the method detection limit (MDL - indicated in italics on Table 3.1) of <5 $\mu g/m^3$. The majority of these samples were collected after August 28th. For TSP, six of the 13 samples collected at site TL2 were at the MDL, while five of 13 samples were at the MDL for sites RC1 and A1. In fact, when coupled with the ND samples, only three of 13 samples at site A1 had measurable TSP levels. For PM_{10}, site VG2 had seven of 13 samples at the MDL, with five of the seven occurring after September 3rd. Sites TL1, TL2 and VG1 all had six of 13 samples at the MDL, while sites TL3, RC1 and A1 had five samples at the MDL.

Therefore, the relative fraction of samples recovered in which there were measurable concentrations of TSP or PM_{10} was low for many of the sampling sites. As indicated in Figure 3.1, less than 50% of the PM_{10} samples collected at sites TL1, TL2, TL3, VG1 and VG2 had measurable concentrations. All of the sampling sites except A1 had more than 50% of the samples with measurable TSP concentrations, and the low data recovery at A1 was due to the previously mentioned operator error in running the samplers early on in the program. Therefore, TSP sampling was relatively more successful than the PM_{10} sampling, and this should be borne in mind in the interpretation of the sampling results.

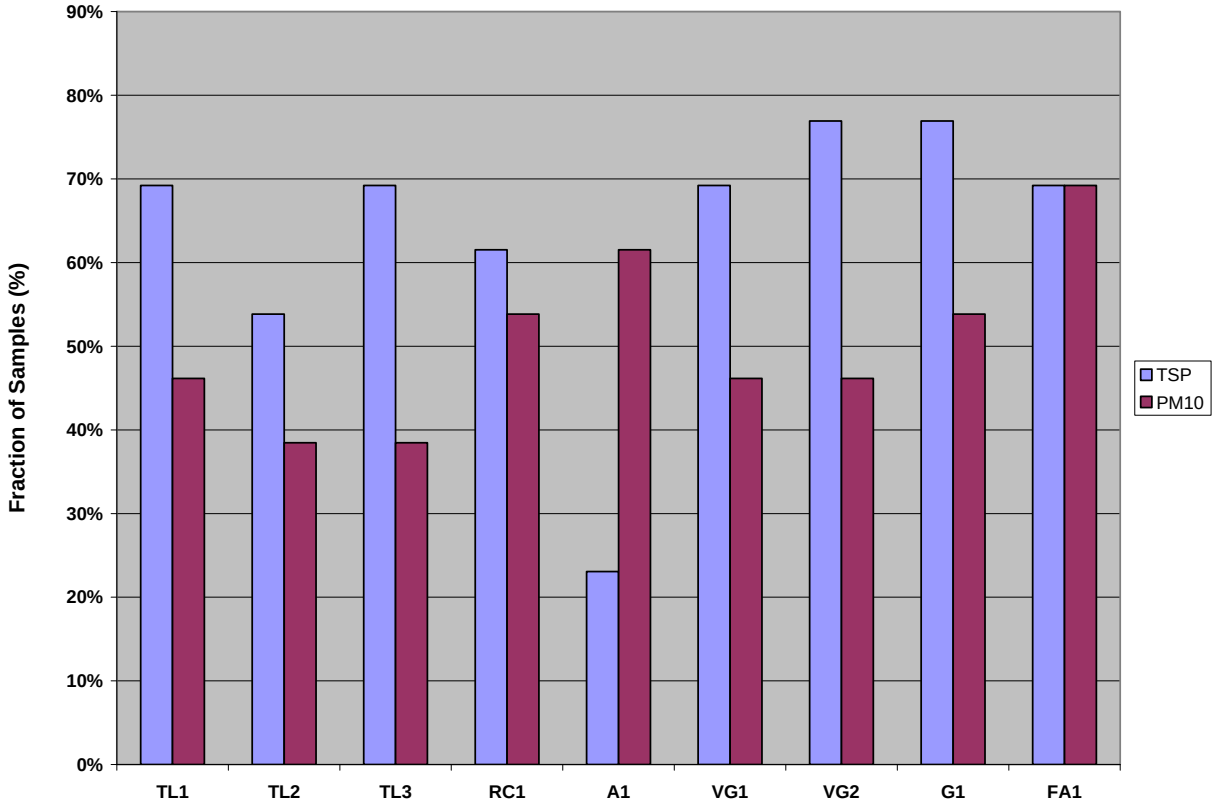

Table 3.1

Note:
ND = No Data
Concentrations in italics were calculated at the method detection limit

As indicated in Table 3.1, there were 21 samples in which measured PM_{10} levels were higher than TSP concentrations. However, only six of the 21 samples had PM_{10} levels greater than 5 $\mu g/m^3$, which is considered to be the 'noise' level for the MiniVol™ samplers. At very low concentrations, a difference of 5 $\mu g/m^3$ is not considered to be significant. For the remaining six samples, one sample at site FA1 was barely over the 5 $\mu g/m^3$ level, three samples at site TL2 were had PM_{10} concentrations that were from 5.6 to 8.5 $\mu g/m^3$ higher than TSP, and sites RC1 and VG1 each recorded one PM_{10} level that were 17 $\mu g/m^3$ higher than TSP. These differences may be due to operator error in mislabelling samples in the field or to mishandling of the sample filters prior to or after exposure.

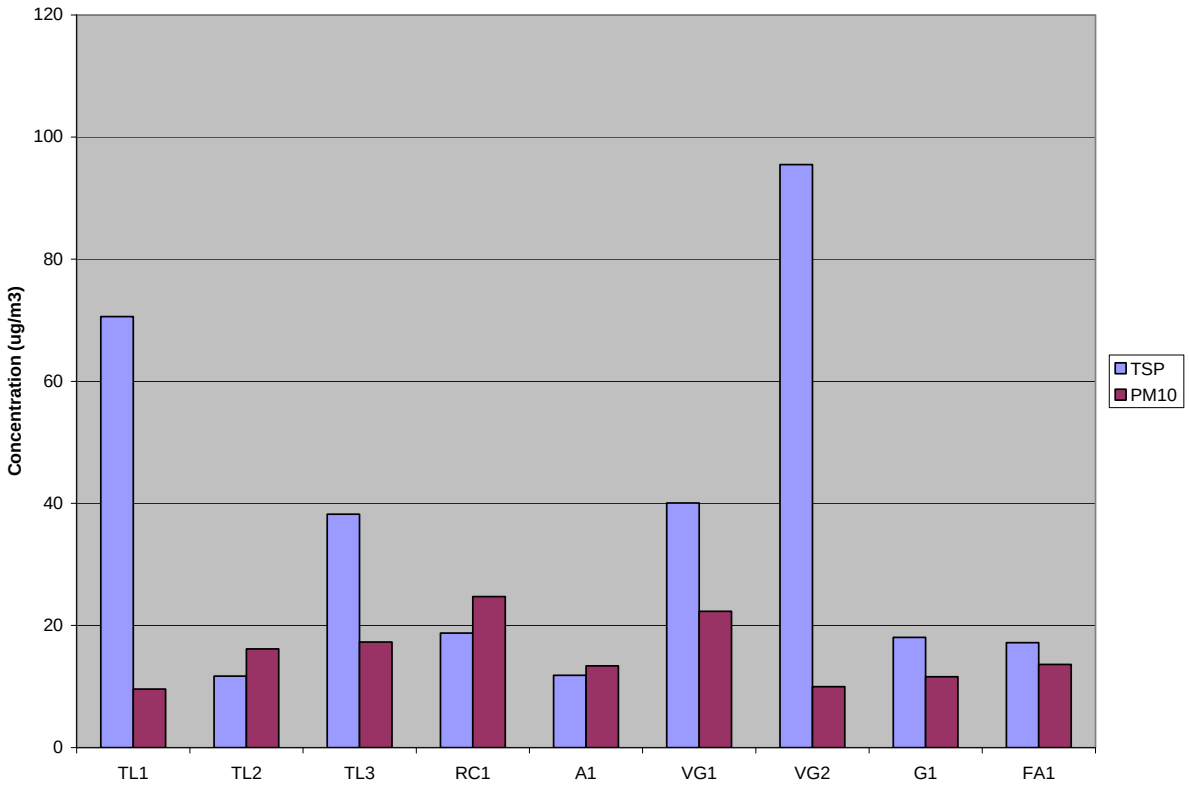
Figure 3.1
Fraction of Samples with Measurable TSP and PM_{10} Concentrations

3.1.2 TSP and PM_{10} Mass Concentrations

Figure 3.2 shows the maximum concentrations of TSP and PM_{10} at each of the sampling sites. All TSP samples were below the National Ambient Air Quality Objective (NAAQO) level of 120 µg/m^3. The highest TSP concentration was measured at site VG2 with 95.5 µg/m^3 on September 9th. The second highest concentration was measured at site TL1 with 70.6 µg/m^3 also on September 9th. All other sampling sites had low concentrations (<8 µg/m^3) on that date. The maximum recorded TSP levels at the other sites were at or below 40 µg/m^3. In fact, TSP levels at sites TL2, RC1, A1 and G1 were similar to, or lower than, the levels measured at site FA1 in the Town of Faro.

The highest PM_{10} concentration of 24.7 µg/m^3 recorded at site RC1 was half the objective level of 50 µg/m^3 that has been adopted by many provinces in Canada and recommended as a guideline value by the World Health Organization (WHO). Maximum PM_{10} concentrations at all other sampling sites were less than 20 µg/m^3, indicating that overall PM_{10} levels at the mine complex and in Faro are fairly low.

Figure 3.2
Maximum TSP and PM_{10} Concentrations in 2008



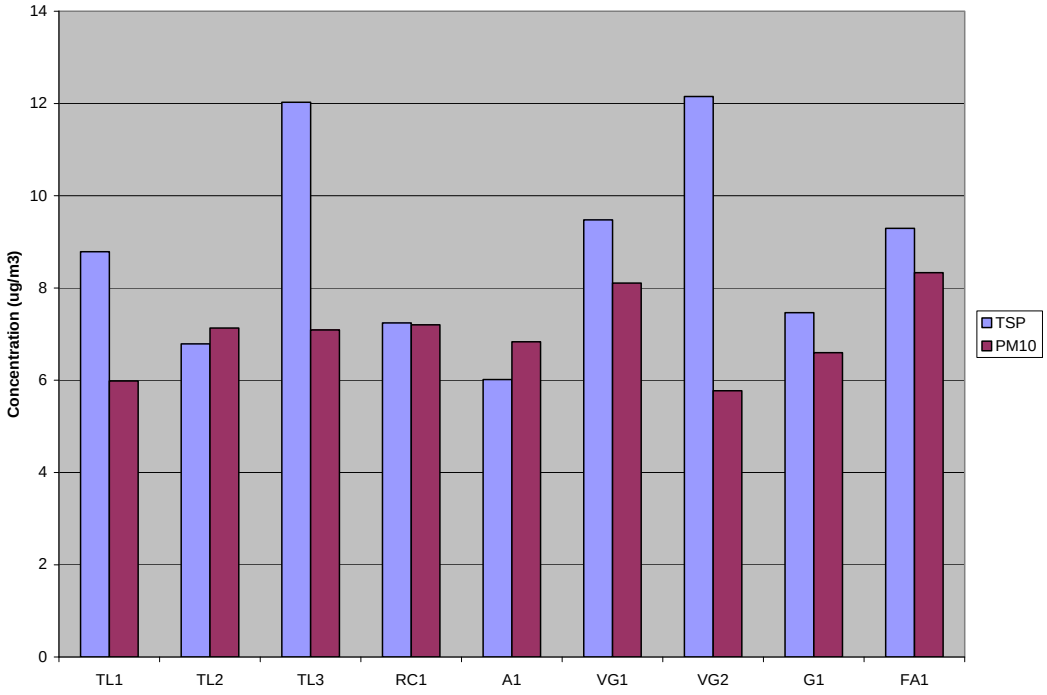


Figure 3.3 shows the geometric mean TSP and PM_{10} concentrations at the sampling sites. The geometric mean is the most appropriate measure of mean concentrations for log-normally

distributed data. Overall, the data show that mean TSP concentrations were very low at 12 μg/m^3 at sites TL3 and VG2, perhaps due to road dust emissions at these two sites. Mean PM_{10} levels were approximately 8 μg/m^3 or lower. In fact, given a MDL of <5 μg/m^3, the mean concentrations at several of the sites were <3 μg/m^3 above the MDL. Therefore, average TSP and PM_{10} concentrations at all sites were very low.

Figure 3.3
Geometric Mean TSP and PM_{10} Concentrations in 2008

3.1.3 Inorganic Trace Element Concentrations

Tables 3.2a, 3.2b and 3.2c summarize the maximum, minimum and geometric mean concentrations of trace inorganic species from the TSP and PM_{10} samples. The highest maximum and geometric mean values are indicated for each element. It should be noted that the highest concentrations are often indicated for site A1, and that these values are not truly representative of 24-hour average concentrations. The high values relate to one TSP sample collected at site A1 on August 4th for a sampling period lasting only 114 minutes (see Appendix A). Therefore, the highest values at site A1 should be regarded as outliers.

Table 3.2a
Summary of Trace Inorganic Element Concentrations

denotes highest concentration level for maximum and geometric means for each element

All of the values in Tables 3.2 a, 3.2b and 3.2c fall below the ambient air quality criteria listed in Table 3.3 that have been established for trace element concentrations in the Province of Ontario (N.B. Manitoba has adopted 24-hour average criteria for arsenic, cadmium, copper, lead nickel and zinc that are identical to those in Ontario, while the objective in British Columbia for lead is less stringent than the ones adopted by Ontario and Manitoba). All of the elemental concentrations listed in Tables 3.2a to 3.2c were below the AAQC levels in Table 3.3.

Table 3.3
Ambient Air Quality Criteria (AAQC) for Trace Inorganic Elements

Element	AAQC 24-h average ($\mu g/m^3$)	Rationale
Aluminium	n/a	
Antimony	25	health
Arsenic	0.3	health
Barium	10	health
Beryllium	0.01	health
Boron	120	particulate matter
Cadmium	2	health
Calcium	n/a	
Chromium	1.5	health
Cobalt	0.1	health
Copper	50	health
Iron	4	soiling
Lead	2	health
Magnesium	n/a	
Manganese	2.5	health
Molybdenum	120	particulate matter
Nickel	2	vegetation
Phosphorus	n/a	
Potassium	n/a	
Selenium	10	health
Silver	1	health
Sodium	n/a	
Strontium	120	particulate matter
Tellurium	10	health
Thallium	n/a	
Tin	10	health
Titanium	120	particulate matter
Vanadium	2	health
Zinc	120	particulate matter
Zirconium	n/a	

n/a – not applicable

Table 3.4 lists the highest concentration level measured for each element (excluding values for site A1), the sampling location and particulate matter fraction in which it was measured. Also listed are the AAQC for each element for comparison.

Table 3.4
Comparison of Maximum Observed Elemental Concentrations
And AAQC Values

Element	Maximum Observed Concentration ($\mu g/m^3$)	Sampling Location	PM Size Fraction	Ambient Air Quality Criteria	
				($\mu g/m^3$)	Rationale
Antimony	0.00185	TL1	PM_{10}	25	health

Table 3.4 shows that the highest concentrations of antimony, arsenic beryllium, boron, chromium, selenium tellurium and vanadium were recorded in the PM_{10} size fraction near the tailing areas at sites TL1 and TL2. The highest concentrations of barium, copper, lead, manganese, molybdenum, strontium, titanium and zinc were recorded in the TSP size fraction at site TL3. Only the highest concentration of cobalt was recorded at site TL3 in a PM_{10} sample. Site VG1 had the highest levels of nickel and tin in the TSP size fraction, while site VG2 had the highest iron concentration in the PM_{10} size fraction. The highest cadmium concentration was recorded in TSP at site RC1.

The concentrations of the following elements showed little variation between sites, and, excluding the anomalously high value at site A1, some were either frequently or almost always below the method detection limit:

- Antimony (Sb)
- Arsenic (As)
- Beryllium (Be)
- Boron (B)
- Cobalt (Co)
- Selenium (Se)
- Tellurium (Te)
- Tin (Sn)
- Vanadium (V)
- Zinc (Zn)
- Zirconium (Zr)

The trace elements that showed the largest degree of variation between sites were:

- Aluminium (Al)
- Barium (Ba)
- Cadmium (Cd)
- Calcium (Ca)
- Copper (Cu)
- Iron (Fe)
- Lead (Pb)
- Magnesium (Mg)
- Manganese (Mn)
- Sodium (Na)
- Thallium (Th)

The group of elements consisting of Al, Ca, Fe and Mg would all be consistent with surface soil-derived fugitive dust emissions, and are not necessarily associated with the Faro Mine Complex *per se*. There was some evidence of slightly elevated concentrations of the following elements in the vicinity of the mine complex compared with the Town of Faro:

- Chromium (Cr)
- Molybdenum (Mo)
- Nickel (Ni)
- Phosphorus (P)
- Potassium (K)
- Strontium (Sr)
- Titanium (Ti)
- Vanadium (V)

Figures 3.4 to 3.33 show the range of concentrations recorded at each of the sites using the values in Tables 3.2a to 3.2c. (Note that the anomalously high values at site A1 are included in Figures 3.4 to 3.33).

3.1.4 Samples with Elevated Particulate Matter Concentrations

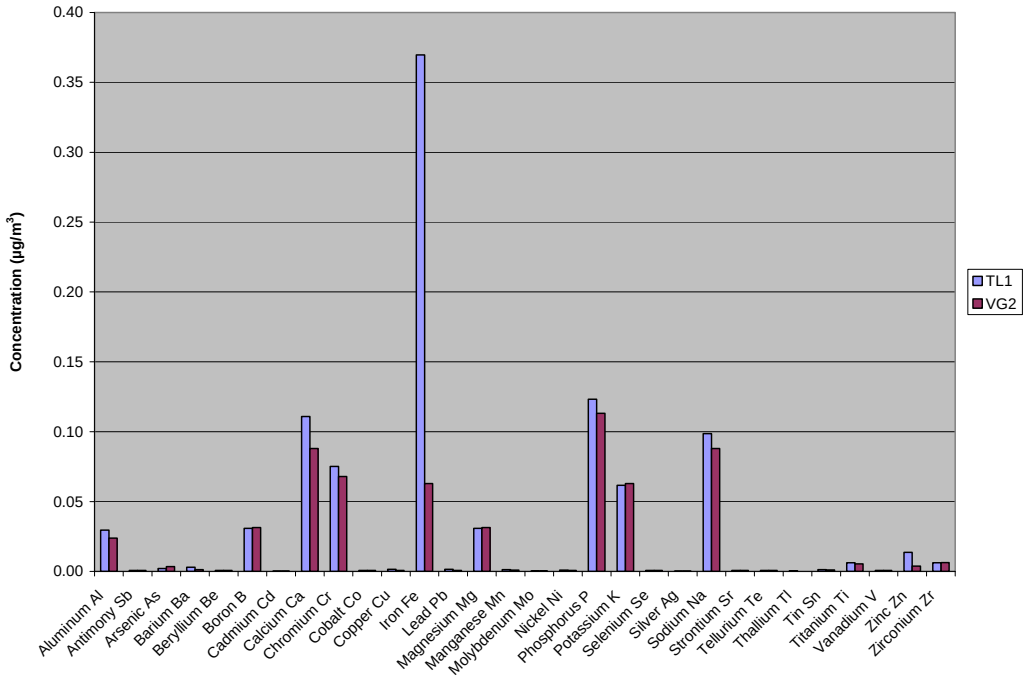
As noted in Section 3.1.2, the highest TSP concentrations were recorded on September 9th with concentrations of 95.5 μg/m^3 at site VG2 and 70.6 5 μg/m^3 at site TL1. The second highest sampling period for TSP concentrations occurred on August 4th with concentrations of 38.2 μg/m^3 at site TL3, 40.1 μg/m^3 at site VG1, and 36 μg/m^3 at site VG2. Figures 3.34 and 3.35 show that the levels of TSP at the other sampling sites were much lower on both days, as were the PM_{10} levels at all 9 sites. Therefore, the higher levels of TSP on August 4th and September 9th were limited to the TL1, TL3, VG1 and VG2 sites.

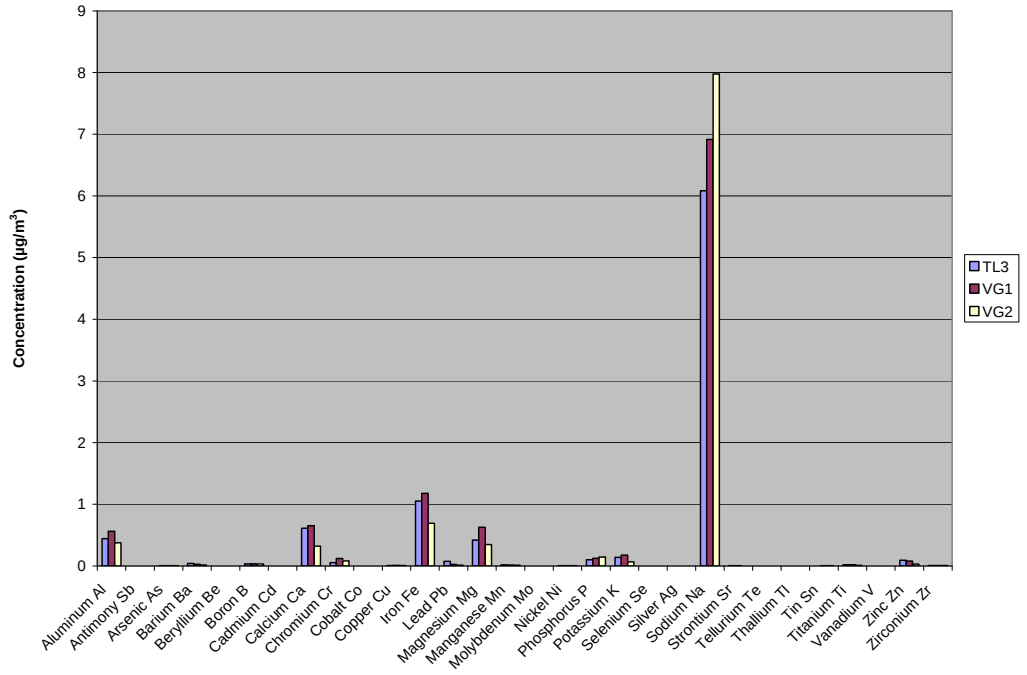
Figure 3.36 shows the elemental composition of the TSP samples at sites VG2 and TL1 on September 9th. They indicate that the major trace elemental constituents of the TSP consisted of aluminium, boron, calcium, chromium, iron, magnesium, phosphorus, potassium and sodium. Similarly, Figure 3.37 indicates that the elevated TSP samples on August 4th contained large amount of sodium, with smaller concentrations of aluminium, calcium, iron and magnesium.

There are no ambient air quality criteria for aluminium, calcium, magnesium, phosphorus, potassium or sodium as these are not of concern to human health (see Table 3.3, Section 3.1.3). Boron is only of concern with respect to exposure as particulate matter, while the AAQC for iron is based on soiling effects, not health concerns. Therefore, of the major constituents present on the TSP samples on August 4th and September 9th, only chromium is of concern to human health, and the maximum chromium concentration of 0.0752 μg/m^3 on September 9th was only 1/20th of the AAQC of 1.5 μg/m^3.

This level of chromium was comparable to the highest concentrations measured at any of the sites during the sampling program (see Figure 3.12), with the exception of the anomalous value recorded at site A1 on August 4th during an abbreviated sampling period lasting less than 2 hours. During that brief sampling period, the TSP level was 110.2 μg/m^3 (see Table A.1, Appendix A), with a chromium concentration of 1.16 μg/m^3. This suggests that both the TSP and chromium levels at A1 could have approached their criteria levels of 120 μg/m^3 and 1.5 μg/m^3, respectively, if the sampling period had been completed over the entire 24-hour period. Therefore, while the sampling program at site A1 was largely unsuccessful, with only 3 complete samples of the 13 sampling periods in 2008, the values on August 4th suggest that elevated concentrations at that location may be present and that sampling should be continued at this site in the future.

Figure 3.36: Elemental Composition of TSP Samples at Sites TL1 and VG2
September 9, 2008





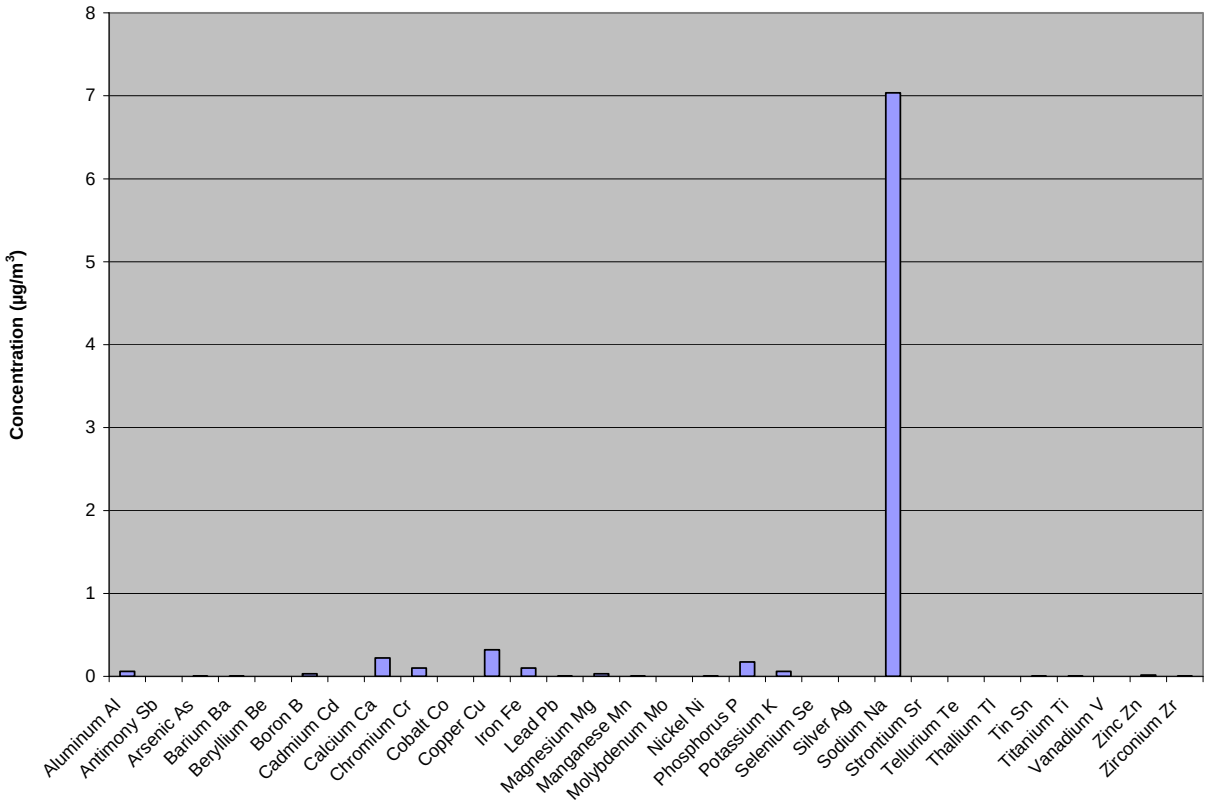


Figure 3.37: Elemental Composition of TSP Samples at Sites TL3, VG1 and VG2
August 4, 2008

The highest PM_{10} concentration during the sampling program was 24.7 µg/m^3 and was recorded at site RC1 on July 23rd. All other PM_{10} samples on that date were much lower at ≤12 µg/m^3. Figure 3.38 indicates that sodium was the major elemental constituent of the sample at RC1 on that date. Smaller quantities of aluminium, calcium, chromium, copper, iron, phosphorus and potassium were also present.

3.2 DUSTFALL SAMPLES

Table 3.5 lists the concentrations of total particulate matter and trace inorganic elements derived from the three sets of dustfall samples collected at site TL1 in 2008. The total dustfall was very low, with two of the samples (July and September) having dustfall levels at the method detection limit. The low value in July was not surprising because the sample represented only about half the month's potential dustfall deposition (i.e., from July 17th to 31st).

The maximum total dustfall deposition rate occurred in August with a rate of 0.12 mg/dm^2.day, although July's rate might have been higher if the sample had been collected over the entire month. This maximum deposition rate is an order of magnitude lower than the established dustfall criteria in British Columbia, Alberta and Ontario, as well as for new mines in Australia (see Table 3.6). It is also well below the most stringent dustfall depositions rates considered acceptable in residential areas of the United Kingdom and New York State.

The low dustfall levels are consistent with the generally low particulate matter concentrations observed in the TSP and PM_{10} samples.

With respect to elemental composition, most of the trace inorganic constituents were below the method detection limits for all three samples. The only contaminants that were observed to be higher than the detection limits included:

Arsenic (As)	Lead (Pb)
Barium (Ba)	Manganese (Mn)
Cadmium (Cd)	Molybdenum (Mo)
Calcium (Ca)	Silver (Ag)
Copper (Cu)	Strontium (Sr)
Iron (Fe)	Zinc (Zn)

With the exception of As and Zn, the remainder of the above elements were also noted to have somewhat elevated concentrations relative to the Town of Faro in the TSP and PM_{10} samples. This indicates a reasonable degree of consistency between the TSP/PM_{10} samples and the dustfall samples.

The highest concentrations of these 12 constituents in dustfall samples occurred either in July or August. All concentrations in the September sample were lower than in the previous two sampling periods.

Table 3.6
Dustfall Criteria from Various Jurisdictions

Jurisdiction	Application	Dustfall Criteria ($mg/dm^2.day$)	Comments
British Columbia	desirable	1.75	
Alberta	residential & recreational areas	1.75	averaged over 30 days
	commercial & recreational areas	5.3	averaged over 30 days
Ontario		2.3	averaged over 30 days
Australia	new mines	1.3	pro-rata compensation if level exceeded
		3.3	total compensation if level exceeded
United Kingdom	open country	1	95^{th} percentile - complaints likely if exceeded
	residential areas	1.5	95^{th} percentile - complaints likely if exceeded
	commercial areas	1.9	95^{th} percentile - complaints likely if exceeded
New York	Level I	1	
	Level II	1	
	Level III	1.3	
	Level IV	2	

The amount of dustfall in a month strongly depends on precipitation rates during that time. Since summer 2008 was noted to be a relatively wet summer, the dustfall amounts recorded and presented in this report may be lower than would be found in other years.

4.0 SUMMARY AND RECOMMENDATIONS

The TSP and PM_{10} sampling program was successfully completed at nine locations over the period July 17th to October 3rd, 2008. In addition, dustfall sampling was conducted at one of the TSP/PM_{10} sampling sites.

Data recovery of the TSP samples ranged between 54% and 77% for eight of the sampling sites, but only 24% at the key A1 site near the Faro mine pit. Data recovery was lower for PM_{10} samples than for TSP samples, ranging from 39% to 69%. Part of the reason for the low data recovery at some sites was due to operator error in the early part of the program due to unfamiliarity of the operator with the equipment. This was corrected after the initial period with help from an individual at the mine site who had previously operated similar samplers. It is hoped that the data recovery will be improved in 2009 if the same operator can be retained in order to minimize operational errors.

Many of the samples collected in 2008 had very low particulate matter loadings on the filters. This was also true of the dustfall samples collected at site TL1. Especially during sampling periods in September, many TSP/ PM_{10} samples were close to the 'noise' level of the MiniVol™ samplers of 5 $\mu g/m^3$, while two of the three dustfall samples were essentially below the method detection limit for dustfall sampling. These low particulate matter concentrations affected the degree to which trace elemental analysis could be used to determine concentrations of heavy metals in the samples. Although the standard TSP/PM_{10} sampling period for particulate matter is 24 hours, the program should consider increasing the sampling period to 48 hours in 2009 in order to provide higher filter loadings for laboratory analysis. The battery packs on the MiniVol™ samplers can be run for longer periods of up to 48 hours, so there is no operational limitation for increasing the sampling period.

There were some concerns related to a few samples where the measured PM_{10} concentrations were higher than the TSP levels at a given location. While operator error in mislabelling samples may be one cause for such discrepancies, it is also possible that some filters were damaged during handling. Furthermore, the space at the administration complex at the mine site that was made available for use in loading/unloading filters was not ideal with respect to minimizing dust levels during sample handling. It would benefit the monitoring program if a more suitable location could be identified for the 2009 sampling program.

Based on the results of the 2008 sampling program, all measured TSP, PM_{10} and trace inorganic elements were well within established ambient air quality criteria for all elements. Trace elemental concentrations were generally higher in July and August than in September, indicating that sampling in the early part of the summer season (June, July and early August) may be more important than sampling in late September or October.

The overall conclusion of the 2008 sampling program is that particulate matter and trace inorganic element concentrations at the Faro Mine Complex were very low, and were often similar to levels recorded in the Town of Faro. Even during the periods with the highest TSP loadings, the composition of the particulate matter is primarily made up of trace elements which either have no ambient air quality criteria or are not of concern for human health exposure. The exception may be chromium, although the concentrations of this trace metal remained well below any level of concern.

It is recommended that the particulate matter sampling program be continued in 2009 with the following changes:

1. The sampling program should be initiated as soon as possible after the loss of snow cover in late May or early June, depending on site conditions. The continuation of the sampling program to the end of September should be reconsidered, with a termination date in early September at the latest.
2. The same nine sampling sites should be retained for 2009, but the sampling periods should be extended to 48 hours in order to obtain higher particle loadings on the filters.
3. It would be preferable to add at least three additional dustfall sampling sites to the program. These should be established at sites RC1, A1 and VG2.
4. In order to minimize material loss or damage to the filters during handling, it is recommended that a 'clean' room be identified for this purpose. If this cannot be done at the mine administration building, consideration should be given to finding a location in the Town of Faro for that purpose.

Notes:

Cells highlighted in yellow indicate that MiniVols did not run for a 24 hr sampling period

Cells highlighted in green indicate that samples were not submitted for analysis.

Cells highlighted in blue indicate that hand writing on sampling log was not legible

Concentrations in italics were calculated at the method detection limit

SECTION 1

Introduction

This report provides detailed descriptions of the existing hydrological conditions at the Faro Mine Complex (FMC) and assesses the information and data used to characterize surface water flow regimes in natural channels and stream diversions. During mining and post-mining operations, considerable effort was exerted to monitor stream flow and meteorological conditions at the FMC. Data continue to be collected from existing monitoring locations, to maintain an active database of hydrological conditions. These monitoring locations are being maintained to monitor hydrological and meteorological variables that will support future remediation efforts at the FMC and will form a critical part of an active Adaptive Management Plan (AMP). The relevant baseline hydrology-related data consist primarily of stream flow data and meteorological data, collected over various intervals, as part of FMC monitoring programs or other regional or federal data collection programs.

This document also summarizes additional supporting data sets that were collected as part of the FMC site characterization efforts, consisting of physical data related to watershed and subwatershed catchments at the FMC; it also incorporates available information from ongoing hydrological studies. Many of the historical data included in this baseline report were collected and reviewed as part of previous studies at the FMC, to determine the requirements for managing surface water and directing other site activities. This report also describes surface water management activities at the FMC. These are a significant component of the overall site hydrology; they include diverting surface water and managing potentially contaminated surface water, via containment and pumping for treatment.

Lastly, this report discusses the analysis methods used to characterize hydrology at the FMC and describes the hydrological and meteorological conditions at the FMC, based on available data and the results of previous and ongoing studies.

SECTION 2

Methods

Various forms of relevant climate- and hydrology-related site information and monitoring data were collected from a variety of sources to assess baseline hydrological site conditions, including:

- Historical data collection reports
- Design study reports for various site activities
- Site characterization reports and assessments

Raw data sets, as well as data that had already been compiled and assessed for quality assurance/quality control (QA/QC) purposes, were reviewed to identify gaps and errors. Most of these data sets comprised FMC related data collected through post-mining monitoring programs. Additional data were collected from long term monitoring sites established as part of Environment Canada's climate monitoring network. Supportive site characterization data (i.e, those developed through Light Detection and Radar [LiDAR]) surveys were also used to develop watershed and subwatershed topographical characteristics and boundaries.

Section 2 describes the sources of hydrologically relevant information, including hydrological and meteorological data sets and information from previous studies and reports, and summarizes the sources of information. It also defines the study area that is relevant to baseline hydrology for the Faro Mine Interim Works (IW).

2.1 Study Area

The FMC is located within the regional Vangorda Creek and Rose/Anvil Creek watersheds. The watercourses within these basins are tributaries of the Pelly River. Figure 6F-1 illustrates the hydrology study area for the IW, which includes the Vangorda Creek Watershed and the Rose Creek Watershed to a location downstream of the FMC. This report defines the baseline hydrology conditions within the study area by evaluating conditions in subwatersheds within the FMC that are interconnected with the larger regional watersheds. Baseline conditions within the FMC study area subwatersheds are examined in the context of these broader watershed areas.

2.1.1 Faro Mine Complex Major Hydrological Features

A number of hydrological features within the FMC are important from a surface water hydrological perspective, and are monitored as part of ongoing remediation efforts. These include pre-mining sections of local watercourses, stream diversions, and surface water impoundments that were developed to facilitate mining operations. Table 6F-1 lists these features, which are also illustrated in Figures 6F-2 and 6F-3.

TABLE 6F-1
FMC Hydrology-related Features
Faro Mine Interim Works

FMC Feature	Description	Hydrological Relevance
Faro Pit	Main excavated pit in Faro Mine Area	Receives local surface water and pumped water from the ETA, Intermediate Dam Pond and groundwater from the Zone 2 wells and S-wells
		No direct contribution to surface water hydrology
Various WRDs	Waste rock from pit excavation	Potential surface water runoff during extreme rainfall events; contributes to surface flow quantity
Intermediate Dam Pond	Containment of contaminated surface water behind intermediate dam	Water pumped to the Faro Pit. Spillway from dam is being upgraded as part of IW
Various seepage collection systems	Collect potentially contaminated seepage	Contained and pumped for treatment

TABLE 6F-1
FMC Hydrology-related Features
Faro Mine Interim Works

FMC Feature	Description	Hydrological Relevance
Cross Valley Pond and CVD	Surface water containment area behind CVD	Pond acts as a water treatment polishing pond
RCD	Diversion of Rose Creek uncontaminated water around tailings area	Requires minor upgrades to convey 1:500 year design rainfall event
NFRC	Undisturbed section of Rose Creek conveying uncontaminated surface water and seepage from WRDs	Conveyance of regional flows
North Wall Interceptor Ditch	Collects uncontaminated surface water from north side of Rose Valley	Conveyance of local runoff
NFRD	Haul road crossing of Rose Creek	Creates a surface water retention area upstream of drain and limits flow
Upper Guardhouse Creek	Collects local uncontaminated surface water and directs to North Wall Interceptor Ditch	Conveyance of local runoff
Lower Guardhouse Creek	Collects potentially contaminated mill area surface water	Collected in the Intermediate Pond and pumped for treatment
Faro Zone II Pit	Collects potentially contaminated groundwater	Collected and pumped to Faro Pit
Faro Creek	Undisturbed section of Faro Creek collecting uncontaminated surface water	Conveyance of regional flows
Faro Creek Diversion	Diversion of Faro Creek around Faro Pit	Conveys uncontaminated surface water around Faro Pit
Pumphouse Pond and Dam	Collects uncontaminated surface water	Discharges into Rose Creek
Vangorda Pit	Excavated mine pit in Vangorda/Grum Area	Receives local surface water and seepage No direct contribution to surface water hydrology under operations of Vangorda Diversion within design parameters. Also receives pumped water from Little Creek Pond, Grum Pit, Grum V15, and Grum Sulphide Cell Surface Water Collection Ponds.
Grum Pit	Excavated mine pit in Vangorda/Grum Area	Collects local surface water
Vangorda Creek	Undisturbed section of Vangorda Creek collecting uncontaminated surface water	Conveyance of regional flows
VCD	Diversion of Vangorda Creek around Vangorda Pit	Conveys uncontaminated surface water around Vangorda Pit
Moose Pond	Small pond collecting local surface water	Connected to Vangorda Creek system
Sheep Pad Ponds	Collect Grum Northeast Interceptor Ditch (Grum Interceptor Ditch) water for solids settling	Connected to Vangorda Creek system
Grum Northeast Interceptor Ditch (Grum Interceptor Ditch)	Collects uncontaminated surface water and discharges to Vangorda Creek	Collects local surface water and receives discharge from Vangorda water treatment plant

TABLE 6F-1
FMC Hydrology-related Features
Faro Mine Interim Works

FMC Feature	Description	Hydrological Relevance
Little Creek Pond and Dam	Collects water from Vangorda Waste Dump	Pond water is pumped to Vangorda Pit
Dixon Creek	Conveys local uncontaminated surface water	Connected to Vangorda Creek system

Notes:
CVD = Cross Valley Dam
ETA = Emergency Tailings Area
NFRC = North Fork Rose Creek
NFRD = North Fork Rock Drain
RCD = Rose Creek Diversion
VCD = Vangorda Creek Diversion
WRD = waste rock dump

2.1.2 Climatic Conditions

The FMC is located in the Anvil Range Mountains, within the Macmillan Highlands of the Yukon Plateau-North ecoregion that is within the Boreal Cordillera Ecozone (AECOM, 2009). Climate in this ecozone is represented by long, cold winters and short, warm summers, with ranges in humidity from sub-humid to semi-arid. The climate is classified as sub-Arctic continental and characterized by a large annual range in temperature and relatively moderate amounts of annual precipitation. The strong seasonal variation in temperature is further accentuated by elevation difference. Winter temperatures can be 10 degrees Celsius (°C) lower in valley bottoms than in uplands, because of temperature inversions. During the summer months, temperatures adhere more closely to the environmental lapse rate, with valley bottom temperatures higher than upland areas (Janowicz et al., 2006).

2.2 Sources of Data and Information

The majority of site-specific data was collected during the post-mining maintenance period. These data are available through a variety of compiled sources, including annual reports generated through care and maintenance activities.

Meteorological and flow data for the regional area relevant to but outside of the FMC are available from government agency monitoring locations. Climate data are available through the Environment Canada Climate Archive (http://climate.weather.gc.ca/). Flow monitoring data are available through the Environment Canada water survey database (http://www.ec.gc.ca/eau-water).

2.2.1 Flow Data

2.2.1.1 FMC Continuous Flow Monitoring

Flow-monitoring stations have been established at a number of locations within the FMC, to monitor flows in various stream systems and creek diversions. Data from the stations were historically used to develop water balances for the FMC, support water quality studies, and track seasonal variability in flow. The information collected at these stations provides sufficient data to form an understanding of the baseline FMC hydrology. The available data identified in Table 6F-2 was reviewed; the findings of this review can be found in Section 2.3.

Figure 6F-4 presents the locations of the continuous flow monitoring stations, and Figure 6F-5 illustrates the available flow data and gaps, compared with the available meteorological data. Table 6F-2 summarizes the availability of continuous flow monitoring data from surface water monitoring stations.

TABLE 6F-2
Summary of Continuous Flow Monitoring Locations and Available Data
Faro Mine Interim Works

Station ID	Available Range	% Complete Data Set [a]	% Complete Years [b]	Data Interval
Faro Mine Area				
R7	2001-2007 2009-2011	42%	9%	Daily; every 15 or 30 minutes during select years
X2	2011	45%	0%	Every 15 minutes
X14	2001-2002 2004-2011	58%	0%	Every 30 minutes from 2004 to 2007; every 15 minutes for 2009 to 2011
X23/FCS-1	2005-2008	33%	20%	Daily; every 10 minutes for 2005 to 2008
Vangorda/Grum Area				
V1	2008-2011	43%	0%	Daily for 2010; every 15 minutes for 2008, 2009, and 2011
V8	2008-2011	45%	0%	Daily for 2008 – 2009; every 15 minutes for 2010-2011
29BC003	1977-1985, 1989 - present	33%	0%	Daily, Monthly

[a] Represents a comparison of the number of actual data points to the number of expected data points based on 365 days a year and the measurement frequency.

[b] Represents how many years within the data set are complete based on 365 days a year and measurement frequency.

Notes:

% = Percent
ID = identifier

2.2.2 Meteorological and Climate Data

Meteorological and climate data relevant to this baseline hydrology assessment are available from five sources: three Environment Canada stations (the Faro A Station and the Faro AUT Station at the Faro Airport and the Faro Station in the Faro town site) and two FMC stations (the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations, which are currently maintained by the site care and maintenance contractor) (Figure 6F-6). Environment Canada publishes data from their three Faro stations through the Environment Canada Climate Achieve. The Environment Canada Faro Station includes recorded data from 1972 to 1977, but the station is no longer in operation. The Faro A and the Faro AUT stations include recorded data from 1978 to present and 1994 to present, respectively. The Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations were established in December 2003 and include recorded data to present day.

The station at the Grum Overburden Dump is representational of the Vangorda/Grum Area (Janowicz et al., 2006). The Faro Valley Waste Dump meteorological station is representative of the Faro Mine Area. The elevation of the Grum Overburden Dump station is 1,250 metres above sea level (masl), and the elevation of the Faro Valley Waste Dump station is 1,200 masl (Janowicz et al., 2006); these are approximately 500 metres (m) higher than the

Faro A Station and the Faro AUT Station at 716 masl (AECOM, 2009). These stations measure the following conditions:

- Air temperature
- Relative humidity
- Incoming, outgoing, and net radiation
- Wind speed and direction
- Rainfall
- Snowfall
- Snow depth
- Soil moisture
- Temperature and soil heat flux

Attachment 6F-1 summarizes the relevant available climate data, tabulated by parameter and source.

2.2.2.1 Snow Data Collection Programs

The first snow data collection conducted near the FMC was carried out as a snow pack survey at a regional snow course, located near Rose Creek, and measured snowpack and snow density in recorded intervals from 1975 through to 1985 and again from 2005 to 2007 (AECOM, 2009). The FMC Meteorological Stations (located at the Faro Valley Waste Dump and Grum Overburden Dump) have measured snow depth on a continuous basis since 2003 (AECOM, 2009). Detailed snow pack monitoring, as part of the care and maintenance contract at the FMC, began in February 2010. As part of the snow pack monitoring efforts, snow course surveys have been carried out twice a year during 2010, 2011, and 2012 to determine snow core weights and snow water equivalents (Denison Environmental Services [DES], 2011, 2012). Also as a component of the snow pack monitoring, data are collected from the snow depth gauges that were installed on the north, south, east, and west portions of the Faro Valley Waste Dump and on the south and west portions of the Vangorda WRD as part of an earlier revegetation cover trial study (DES, 2011, 2012).

2.2.2.2 Icing Conditions

Icing, or Aufeis, develops in valley systems or stream channels in arctic or sub-arctic regions, when groundwater or surface water that overflows ice dams freezes. This type of icing can build up in streams and diversions during the winter months at the FMC and cause flooding and slope erosion or failure. As part of the RCD upgrade study completed by CH2M HILL (2012a), Matrix Solutions Inc. completed an Icings White Paper that describes the potential for, and causes of, icing at the FMC in relation to the RCD. This White Paper is considered a basis for potential icing conditions to develop on the RCD. It also describes the potential for icing to occur at other onsite stream and diversion locations.

2.2.2.3 Evaporation and Evapotranspiration Estimates

Evaporation is measured as the loss of water from free water surfaces, and is usually represented as a rate of water loss in monthly or annual millimetres (mm) of depth. Evapotranspiration is the loss of water from land surfaces. It is also normally expressed in terms of monthly or annual mm, and represents a combination of evaporation from the ground surface and transpiration by vegetation. Estimates of evaporation and evapotranspiration rates for the FMC have been calculated from meteorological data collected at onsite climate stations, and from regional climate stations, using the Environment Canada National Hydrology Research Institute (NHRI) WREVAP Model (NHRI, 1985). Relevant monthly and annual evaporation and evapotranspiration rates for the climate stations were compiled in the *Faro Mine Complex Closure and Reclamation – Project Proposal* (AECOM, 2009) and are attached in Attachment 6F-2.

2.2.2.4 Faro Mine Complex Field Data Collection Programs

In addition to data from continuous monitoring stations, spot measurement records for flow velocity and weather conditions are collected as part of the care and maintenance activities, and are maintained as part of the overall FMC database. Field measurements are typically collected on a monthly basis during the ice-free period.

2.3 Data Analysis Methods

A number of studies used the available FMC hydrological, meteorological, and physical site data to determine baseline hydrological conditions. The available data were reviewed and integrated into the baseline analysis through a quality assurance/quality control (QA/QC) process that determined the most suitable data for inclusion in the analysis. The data analysis carried out to develop baseline hydrological data and the steps applied during the review and QA/QC process for each relevant data set are discussed in this section.

2.3.1 Flow Data

2.3.1.1 Faro Mine Complex Continuous Flow Monitoring

CH2M HILL compiled historical flow data from archived FMC data records, from records maintained as part of previous FMC studies, and from regional flow monitoring stations maintained by Environment Canada. For historical data and data collected at the regional flow monitoring stations, CH2M HILL conducted a QA/QC review to ensure they were representative of site or regional conditions. In addition, a number of past stream gauging efforts carried out as part of the site care and maintenance contract included QA/QC inspections at flow monitoring installations. These inspections were conducted when required during data collection field seasons. These efforts included regular equipment maintenance and spot flow measurements to update rating curves for the continuous flow monitoring locations. The hydrological analyses provide the necessary characterizations to support the IW.

2.3.2 Down Valley Interim Hydraulic Upgrades

Hydrological and hydraulic analyses took place during the Down Valley Interim Hydraulic Upgrades Study and were reported in *Down Valley Interim Hydraulic Upgrades Phase 2 – Basis of Design Report* (CH2M HILL, 2014). The report presents a summary of previous work and describes current efforts to verify the flows (discharge) for various flood events, including the 1-in-500-year design flood event. These flows were determined separately for the South Fork Rose Creek (SFRC) and the NFRC. The task included the following hydraulic/hydrological modelling components:

- Estimate the attenuation of flood flows in the NFRC at the NFRD and incorporate them into the estimate of flood flows entering the RCD.
- Evaluate the probable maximum flood (PMF) flood retardation in the NFRD.
- Determine the 1-in-50-, -100-, and -500-year flood flows into the RCD.

Previous Hydrologic Studies

Previous hydrological studies for the FMC reported in CH2M HILL (2014) generally focused on determining instantaneous peak flows for a range of recurrence interval events. The studies have relied on regional analyses to determine discharge yield based on catchment area for a range of flood events. Northwest Hydraulic consultants. (NHC) and BGC Engineering, Inc. (BGC) (2004) conducted a regional analysis based on data obtained from seven regional gauges. During the study, the period of record represented by the gauges ranged from 14 years to 40 years. The catchment areas for the gauges ranged from 91 square kilometres (km^2) to 7,250 km^2. Instantaneous peak discharges were estimated for the mean annual event and for the 1-in-50-, 1-in-100-, 1-in-200-, 1-in-500-, and 1-in-1,000-year return period. The 2003 Alternative Assessment for the Vangorda Creek Diversion by SRK Consulting Engineers and Scientists (SRK) also referenced regional analysis as the source for the peak instantaneous flow identified for the diversion design (SRK, 2003). This design report (SRK, 2003) identifies the 1-in-500 year, PMF, and ½ PMF as the potential alternatives for design flows. The results of the historical SRK regional flow analysis from 2003 as well as the SRK Getechnical/Hydraulic design flow analysis of the VCD (SRK, 1990) and the flow analysis from the VCD design report (SRK, 2010) are included in Section 3.2 of this report.

2.3.3 HEC-HMS Hydrologic Modelling

The Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS) (U.S. Army Corps of Engineers, 2000) was used to characterize the hydrological conditions at the FMC (CH2M HILL, 2012b) and enhance the

understanding of FMC hydrology baseline conditions. Using the continuous monitoring records, monthly base flow estimates were developed to create the site-wide HEC-HMS hydrological model. This method of accounting for base flow in the model was selected based on the availability of continuous flow records. The continuous flow data sets for monitoring locations R7 and V1 were examined, and representative base flow values were then applied to the respective tributary catchments (RC1 and VC1, respectively). These patterns were factored to the other catchments according to where they were located, relative to RC1 and VC1. The base flow rates and monthly distributions were selected for model input based on the analysis of many years of low-flow data at various flow monitoring stations. The HEC-HMS model development and results are part of the CH2M HILL Fiscal Year 2012 Water Modelling Analysis Report (CH2M HILL, 2012b). Section 2, the Hydrology Modelling section of that report, is provided in Attachment 6F-3.

2.3.4 HEC-HMS Model Calibration

Attachment 6F-3 discusses the hydrological model development and calibration in detail. This attachment also compares the observed versus modelled hydrographs at flow monitoring stations R7, X2, and X14 (for the Rose Creek Model) and V1 and V8 (for the Vangorda Creek model). Attachment 6F-3 also includes separate figures for each flow monitoring station.

2.3.5 Regional Analysis

Previous FMC study efforts have applied regional analysis to support FMC hydrology characterization. AECOM (2009) documents the most recent efforts, and refines the regional analysis developed for the 1996 Integrated and Comprehensive Abandonment Plan (ICAP) report (Robertson GeoConsultants Inc. [RGC], 1996). Regional analysis examines available data to develop empirical relationships that can be used to estimate flow at ungauged locations. These empirical relationships relate a flow statistic (e.g., Mean Annual Runoff [MAR]) to a catchment characteristic (e.g., drainage area).

In AECOM (2009), the regional analysis methodology was applied to develop a site-wide water balance and relationships for mean annual runoff and low flows. A brief review of the data used in the regional analysis indicated there are more recent data available which could further refine this analysis.

A four-step algorithm was used by AECOM to estimate long-term average flows for the FMC. AECOM (2009) summarizes the algorithm as follows:

1. Identify a point of interest on a topographical map and determine the catchment area tributary to that point.
2. Determine the drainage area and median catchment elevation.
3. Determine the corresponding MAR value from the median elevation from Figure 6F-7 (excerpted from AECOM [2009, with Government of Yukon's permission]).
4. Multiply the MAR by the drainage area to estimate the long-term average annual flow for the point of interest.

The following equations from AECOM (2009) can be applied to predict absolute flow values, to better understand low-flow FMC hydrology:

2-year annual minimum 7-day flow	$7Q2 = 0.034\ A \cdot MAR^{0.605}$
10-year annual minimum 7-day flow	$7Q10 = 0.030\ A \cdot MAR^{0.553}$
50-year annual minimum 7-day flow	$7Q50 = 0.032\ A \cdot MAR^{0.481}$
2-year low annual flow	$365Q2 = 0.026\ A \cdot MAR^{1.034}$
10-year low annual flow	$365Q10 = 0.0081\ A \cdot MAR^{1.188}$
50-year low annual flow	$365Q50 = 0.0040\ A \cdot MAR^{1.277}$

Where catchment area is A (in km^2), the MAR is in mm, and the resulting low flow is in litres per second (AECOM, 2009).

SRK (2006) performed an independent regional analysis in 2006, building on previous work performed by NHC (2001). The purpose of this regional analysis was to develop the design hydrograph for the ETA and examine 1-in-100-year flood events. In this case, the regional analysis developed empirical relationships that can transpose flood event data to the ETA. SRK (2003) also applied regional analysis to determine the appropriate peak instantaneous design flow (1-in-500-year return period event) for the Vangorda Creek Diversion Design (SRK, 2003). These analyses and study also reference the relationship between MAR and elevation developed for RGC (1996), and indicates these relationships can also be used to estimate peak instantaneous flow volumes at ungauged locations within the FMC.

2.3.6 Probable Maximum Flood

The probable maximum precipitation (PMP) and PMF are events that occur with less frequency than once in every 1,000 years. The PMF is a key design event for the components of the Rose Creek system at the FMC. A study performed by Water Management Consultants and a committee of the Faro Mine Closure Planning Office (2006a) examined the FMC PMF event in detail. This study was conducted in two steps: the first developed the PMP event and the second used the PMP to develop the PMF event. The PMP development process was also peer-reviewed to ensure valid assumptions were used and the outcomes were realistic. The PMP report (Taylor and Hale, 2006) and PMF reports (Water Management Consultants, 2006a and 2006b) are attached to the *Down Valley Interim Hydraulic Upgrades Phase 2 – Basis of Design Report t* (CH2M HILL, 2014).

CH2M HILL has reviewed the reports and has found the assumptions and peer-reviewed work to be appropriately conservative.

2.3.7 Faro Mine Complex Surface Water Catchment Delineation

The existing surface water catchment delineations (AECOM, 2009) were reviewed to determine their suitability for the development of current baseline hydrology. This review determined the original FMC catchments needed to be re-delineated as previous efforts emphasized catchment boundaries by significant site features rather than site topography.

To support the revision of catchment delineations, CH2M HILL reviewed recent LiDAR data. LiDAR data were collected for the FMC on two separate occasions in 2012. These data provide a high-resolution data set for the FMC (1 square metre [m^2] per pixel). Only standard topographic information was available for the surrounding regional area. The preliminary catchments developed through the review of the LiDAR and topographic information were compared with available data, including aerial photographs, culvert survey data, previous catchment delineations, and accumulated site observation knowledge. Figure 6F-1 shows the combined local and regional catchments that were developed through this analysis, including the tributary areas for Rose Creek and Vangorda Creek. The Rose Creek catchment has an area of 26,129 hectares and consists of eight subcatchments. The Vangorda Creek catchment has an area of 8,815 hectares and consists of five subcatchments. Figure 6F-8 shows the subcatchments within the watersheds. Table 6F-3 summarizes the catchments delineated for the FMC.

TABLE 6F-3
Surface Water Catchments
Faro Mine Interim Works

Catchment ID	Description	Area (hectares)	Mean Elevation (masl)
Rose Creek Regional Catchment (Tributary to X14 monitoring location)			
RC1	NFRC (Upper) – includes the extent of the NFRC to the confluence with the FCD. The flow contributed to the FMC hydrology is monitored by the R7 station.	9,874	1,480
RC2	Faro Creek and FCD –includes both the Faro Creek and FCD to its confluence with the NFRC.	1,589	1,540
RC3	NFRC (Lower) – includes the area tributary to the NFRD at the Haul Road.	992	1,110

TABLE 6F-3
Surface Water Catchments
Faro Mine Interim Works

Catchment ID	Description	Area (hectares)	Mean Elevation (masl)
RC4	SFRC – includes the extent of the area tributary to the SFRC to the confluence with the NFRC (just south of the NFRD) and is bound by the Vangorda Creek catchment to the east.	7,253	1,450
RC5	RCD – RC5 is tributary to RC6 and represents the NFRC between the NFRD and confluence with the SFRC. RC6 represents the RCD around the tailings area.	124	1,220
RC6		1,842	1,310
RC7	Upper Guardhouse Creek and North Wall Interceptor Ditch – includes the extent of the area tributary to the Upper Guardhouse Creek and North Water Interceptor Ditch before the confluence with Rose Creek.	637	1,290
RC8a	Faro Pit –includes the area tributary to the Faro Pit. The pit is considered a water storage location in the context of surface water hydrology.	305	1,140
RC8b	Tailings Area – includes the tailings area and the area between the Faro Pit and tailings area; the flow within this area is monitored by the X23 station. This catchment outlets to the Rose Creek Catchment by the Siphon at the CVD.	539	1,130
RC9	Rose Creek west of the FMC – includes the remaining area tributary to the Rose Creek, upstream of the X14 monitoring location. Water exiting this catchment flows to Anvil Creek and, eventually, the Pelly River.	2,974	1,380
Vangorda Creek Regional Catchment			
VC1	Vangorda Creek and VCD – includes the extent of the area tributary to Vangorda Creek and VCD; flow through this catchment is represented by the V1 monitoring location.	2,007	1,460
VC2	Vangorda Creek and Shrimp Creek – includes the area tributary to the Vangorda Creek between the VCD and downstream of the confluence with Shrimp/Dixon Creek.	842	1,180
VC3	Grum Pit – represents the area tributary to the Grum Pit.	176	1,310
VC4	Shrimp Creek/Dixon Creek – includes the extent of the area tributary to Shrimp/Dixon Creek upstream of the confluence with Vangorda Creek and the V27 monitoring location.	1,360	1,210
VC5	Vangorda Creek – includes the remaining areas tributary to Vangorda Creek upstream of the V8 monitoring location.	4,430	1,240

Notes:
FCD = Faro Creek Diversion
ha = hectares

Figure 6F-9 illustrates the general surface water flow regime through the FMC, based on the delineation of subcatchment areas.

2.3.8 Meteorological and Climate Data

2.3.8.1 Environment Canada

Environment Canada performs preliminary QA/QC on the meteorological and climate data collected at their network of stations before it is available on the online climate archive. Data from the archive indicates the level of quality review performed by Environment Canada, as well as flags for each parameter, indicating where there may be questionable measurements.

CH2M HILL reviewed the Environment Canada data as well as the rainfall analysis provided in AECOM (2009) to determine whether the analysis approach used by AECOM was suitable to fill data gaps in the climate readings at

the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations. This review found that the analysis provided a suitable methodology to augment data from at the FMC meteorological stations.

2.3.8.2 Faro Mine Complex Meteorological Stations

AECOM originally reviewed and processed the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Station records for 2003 to 2008 (AECOM, 2009). This review was limited to the rainfall and temperature records, as the purpose of this effort was to support the development of the site-wide water balance. The data recorded at the FMC stations do not include flags to indicate potential data quality issues. The level of QA/QC performed on these data by the care and maintenance staff is unknown; therefore CH2M HILL reviewed them for quality before surface water modelling took place in 2012 and 2013 (CH2M HILL, 2013a).

Data recorded after 2008 are available through annual reports produced by the FMC care and maintenance contractors. The purpose of this review was to develop the meteorological database required for the CH2M HILL site-wide HEC-HMS hydrologic model and to identify data gaps and potential data errors.

2.3.9 Precipitation Record

CH2M HILL developed estimated precipitation data sets for the Faro Valley Waste Dump and Grum Overburden Dump to complete the site-wide HEC-HMS hydrological model. The *Fiscal Year 2012 Water Modelling Analysis Report* (CH2M HILL, 2013a) describes the development of these data sets in detail. Section 2 of that report is presented in Attachment 6F-3.

The precipitation data sets were developed using the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Station rainfall measurements and precipitation measurements collected at the Environment Canada Faro A and Faro AUT climate stations. Linear regressions, developed in 2009 by AECOM, were applied to the rainfall records to form a complete data set. The resulting data set is a total daily precipitation record for 2000 to 2011, except for 2002 and 2003, where there was not enough data to develop estimates.

2.3.10 Air Temperature

To develop a temperature data set for the HEC-HMS hydrological model, CH2M HILL developed a patched or augmented temperature record for the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations using several data sources to fill in data gaps and form a contiguous daily temperature data set. The Fiscal Year 2012 Water Modelling Analysis Report (CH2M HILL, 2013a) and Attachment 6F-3 describe the development of these data sets in detail.

The air temperature record utilizes the Faro Valley Waste Dump and Grum Overburden Dump meteorological data as well as data collected at the Environment Canada Faro A and Faro AUT climate stations. Faro A and Faro AUT are located at the Faro Airport, approximately 145 m apart. The record includes an average daily temperature record for all years from 2000 to 2011, except for 2002 and 2003, where there was not enough data to develop a patched record.

The temperature record for input to the hydrological model must represent a continuous daily record for an entire calendar year. Data gaps identified during the review process were patched using several methods and a number of steps, depending on the type of data gap.

The first step involved filling gaps in the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations' air temperature records using air temperature data recorded at the Faro Airport Stations. Where there were gaps in the FMC meteorological station records, and there was no coincident data recorded at the Faro Airport Stations, data gaps were filled as follows:

1. Data gaps with between 1 week and 1 month of consecutive missing data were patched using average daily air temperature over the available period of record. Review of the patched data sets was carried out to verify that this approach preserved existing trends and matched climate normals for the region.
2. Data gaps with no more than 6 consecutive days of missing data were patched using the air temperature from adjacent days, keeping the trend before and after the missing data point(s). For example, if one data point is missing and the air temperature trend was increasing before and after the missing data point, the higher of

the two adjacent data points was used to fill the data gap. For consecutive data gaps, between 2 and 6 days, the observed trend is maintained by filling the gap evenly with the adjacent temperature readings.

2.3.10.1 Snow Records

Total snow depth data from the FMC snow monitoring program at the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations were processed through a QA/QC procedure in an effort to eliminate gaps and errors in the record. It was determined that the historical data were not sufficiently reliable for use in the CH2M HILL HEC-HMS hydrological modelling efforts. AECOM (2009) compared snow pack water content at the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations to snowfall records at the Faro Airport Stations and determined that the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations received approximately 25 percent more snowfall (as a water equivalent) than the Faro Airport Stations. This is consistent with the altitude differences between the two locations. Therefore, to construct a snow record for the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations, snow depth at the Faro Airport Stations was increased by 25 percent and applied to the two FMC Stations. Due to the lack of recorded snowfall data at the FMC stations, it was not possible to account for days when snow occurred at the Faro Airport and not at the FMC.

2.3.10.2 Evaporation and Evapotranspiration Analysis

Evaporation and evapotranspiration rates were calculated for the FMC using the Environment Canada NHRI Model WREVAP (NHRI, 1985) and presented in AECOM (2009). The evaporation and evapotranspiration rates defined in AECOM (2009) were used by CH2M HILL to complete the recent site-wide HEC-HMS hydrological modelling (CH2M HILL, 2013a). AECOM (2009) (Attachment 6F-2) describes the WREVAP model and the calculations of evaporation and evapotranspiration carried out by AECOM.

2.3.10.3 Climate Change

It is difficult to differentiate between natural variability and longer term trends related to climate change in meteorological and flow conditions over the 10-year period for which the baseline analysis has been prepared. The 10-year period associated with the IWPP is not significant in the context of the rate of change anticipated for climate change impacts. This baseline analysis has, therefore, not considered the effects of climate change.

2.3.11 Surface Water Management

Surface water management at the FMC affects the site's baseline hydrological characteristics, and takes place to meet a number of objectives:

- Separate uncontaminated surface water from potential contaminant sources.
- Contain contaminated surface water and direct it to treatment facilities.
- Manage the quantities of available surface water during a range of hydrological conditions to prevent damage from erosion or dam/dike failures.

To meet these objectives, surface water is managed to maintain water levels within various hydrological features at or below defined threshold levels. The threshold levels were selected to protect surface water features from excessive quantities of flow that may cause containment failures and from potential overflows of contaminated water that may cause impacts to surface water quality. Attachment 6F-4 includes two technical memoranda (CH2M HILL, 2013b) that summarize the analysis of these water management strategies.

SECTION 3

Results

The FMC hydrological data analysis provides a characterization of existing hydrological conditions at the FMC to support the effects assessment for the IW. The hydrological characterization has also supported planning and design for interim activities like the Down Valley Interim Hydraulic Upgrades and will support planning and design for remediation activities that will be part of the Faro Mine Remediation Project. This section assesses the results of the various analyses and databases that support the characterization.

3.1 Down Valley Interim Hydraulic Upgrades

Characterization of hydrological conditions in Rose Creek and the risks associated with conveyance of flows through the Rose Creek Tailings Area have been addressed in planning for the Down Valley Interim Hydraulic Upgrades that are part of the IW. The *Down Valley Interim Hydraulic Upgrades Phase 2 – Basis of Design Report* (CH2M HILL, 2014) describes the hydraulic analysis carried out to assess the Down Valley Dam interim hydraulic upgrade requirements. The report provides the detailed hydraulic results of the analysis and also describes additional analysis results from previous hydrological studies, including the following:

- FMC Flood Hydrograph Development
- FMC Design Flood Hydrographs
- NFRD Flow Attenuation Characteristics

3.2 Previous Hydrological Studies

Previous hydrological studies for the FMC reported in CH2M HILL (2014) have generally focused on determining instantaneous peak flows for a range of recurrence interval events. The studies have relied on regional analyses to determine discharge yield, based on catchment area for a range of flood events. NHC and BGC (2004) conducted a regional analysis based on data obtained from seven regional gauges. During the study, the period of record represented by the gauges ranged from 14 years to 40 years. The catchment areas for the gauges ranged from 91 km^2 to 7,250 km^2. Instantaneous peak discharges were estimated for the mean annual event and for the 1-in-50-, 1-in-100-, 1-in-200-, 1-in-500-, and 1-in-1,000-year return period floods. Table 6F-4 summarizes the peak discharge estimates at the R7 gauge (NFRC, upstream of the FMC), NFRD, SFRC, and X14 gauge (Rose Creek downstream of FMC) locations and indicates recurrence interval peak discharge values that were selected for this study.

CH2M HILL (2013a and 2014) describe the hydrology analysis of previous studies in detail.

TABLE 6F-4
Summary of Peak Discharge Hydrology (Previous Studies)

N/A = not applicable
WMC = Water Management Consultants Inc.

Another regional study took place to determine average daily flows for the 1-in-2-, 1-in-100-, 1-in-200-, 1-in-500-, and 1-in-1,000-year floods, as detailed in *Anvil Range Mining Complex 2005 Seepage Investigation at the Emergency Tailings Area* (SRK, 2006). The recurrence interval floods were determined for flow durations ranging from 1 to 365 days. Using plots of peak discharge vs. catchment area, a relatively constant discharge per square kilometre was observed for flow records that represented catchment areas ranging from 13.7 km^2 to 7,250 km^2. This observation led to the conclusion that catchment response to floods could be estimated by using recurrence interval estimates from a single gauge with the most extensive period of record. This conclusion was reached because catchment unit discharge during recurrence interval events appeared to be independent of total catchment area. Table 6F-4 summarizes the daily average peak discharge estimates calculated using the unit discharge estimates for a 1-day-duration flood at the R7 gauge, SFRC sub-basin outlet, NFRD, and X14 gauge locations.

As part of a draft design report for the Vangorda Creek Diversion (SRK, 2010) SRK performed a regional analysis to estimate instantaneous peak discharge for 1-in-2-, 1-in-100-, 1-in-500-, and 1-in-1,000-year floods on Vangorda Creek. The relationships developed between peak instantaneous discharge and catchment area were used to estimate recurrence interval peak discharges at the R7 gauge, SFRC sub-basin outlet, NFRD, and X14 gauge locations. Table 6F-4 summarizes the results of applying the regional analysis curves to the locations on Rose Creek and Vangorda Creek.

Water Management Consultants (2006) conducted a PMF analysis for the Rose Creek watershed. The PMF study applied the 24-hour PMP (Taylor and Hale, 2006) to the Rose Creek catchment. The antecedent conditions assumed saturated soil conditions and a shallow snowpack across the entire Rose Creek catchment. Water Management Consultants used the HEC-HMS software to simulate the rainfall-runoff processes occurring during the PMP event. Outflow hydrographs at the NFRD, SFRC outlet, and lower end of the RCD (assumed to be near gauge X14) indicate the PMF responds to the PMP over approximately 2 to 3 days. For all catchments, peak flows occur between 16 and 17 hours after the PMP event is initiated. The analysis assumed the NFRD would not be in place during the PMF; therefore, no attenuation was modelled through the rock drain. Peak flood discharges in the NFRC and SFRC were estimated to be approximately 384 and 300 m^3/sec, respectively. Peak flood discharge at the lower end of the diversion channel was estimated to be approximately 692 m^3/sec. Table 6F-4 summarizes the PMF peak discharges.

3.3 HEC-HMS Hydrological Modelling

The objective of the CH2M HILL HEC-HMS hydrological modelling was to develop a dynamic hydrological model of the FMC, to provide a better understanding of its hydrological characteristics and support future design and supporting activities.

CH2M HILL (2013a) and Attachment 6F-3 discuss the model calibration methodology and results in more detail.

3.3.1 HEC-HMS Model Application

The surface water model described in CH2M HILL (2013a) and Attachment 6F-3 was used to simulate rainfall-runoff processes at the FMC on a continuous, multiyear simulation basis. It simulated the timing and magnitude of runoff events throughout the year, ranging from low-flow (i.e., base flow) conditions to the peak flows during the spring freshet. The design and investigative studies will use a regional analysis process to establish diversion design flow rates that exceed those produced by the freshet. This will involve transposing flood data from the regional flow gauging stations to the outlets of the respective diversions.

The surface water flow models will need to be refined to support the design of particular surface water diversion structures planned for the FMC, and to support various other design activities. This process will include refining the existing model so it is easier to evaluate potential future hydrological and hydraulic stream diversion behaviour under a variety of flow conditions, up to and including the PMF event. The surface water flow model will be used primarily to develop stream diversion designs, but will also be further integrated with other modelling efforts to support the Faro Mine Remediation Project.

3.3.2 HEC-HMS Model Use and Limitations

The hydrological model detailed in Attachment 6F-3 was developed and calibrated based on available meteorological and flow data collected at the FMC over a number of years, as well as data collected at offsite stations such as the Faro Airport Stations. Modelled hydrographs compare well with those observed at the continuous flow monitoring stations during the analysis. However, continuous flow data were available at a relatively small number of stations, which resulted in the need to lump large catchment areas. The current model catchments are sufficient to define the baseline FMC hydrology for the IW. Refining the model will support diversion and channel design for the Faro Mine Remediation Project.

3.3.3 HEC-HMS Base Flow Modelling

Hydrological modelling enhances the understanding of the FMC hydrology baseline conditions. The following sections summarize the base flow assessment results and compare modelled and monitored flows. Tables 6F-5 and 6F-6 summarize the monitored base flow values for each of the catchments of Rose Creek and the Vangorda Creek watershed.

The continuous flow data sets for R7 and V1 were examined and representative base flow values were then selected from these records to represent average base flow conditions. This is the most appropriate use of this data since the intent of the model was to simulate average conditions.

3.3.4 HEC-HMS Model Calibration Flows

The detailed hydrological model development and calibration discussion provided in Attachment 6F-3 compares the observed and modelled hydrographs at flow monitoring stations R7, X2, and X14 (for the Rose Creek Model) and V1 and V8 (for the Vangorda Creek model). The comparison of the observed and modelled hydrographs spans the years of continuous flow data available for each station

The spot-flow measurements in the *2010 Annual Environmental Monitoring and Activities Report* (DES, 2011) typically did not coincide with significant hydrological events such as a spring freshet or a peak summer storm. Therefore, the general comparison of these data sets to the model results was not always definitive. Results from the *2005 Preliminary Observations Continuous Recording Sites* (Laberge, 2005a) provide data for a more definitive comparison because the spot-flow measurements were taken on May 11 and 12, 2005, which coincides approximately with the peak of the spring freshet (May 17, 2005). Measurements were collected at various locations along the NFRC and the RCD (at R7, X2, X14), and were compared to both the model results and the observed continuous data (Tables 6F-7 and 6F-8, respectively). Note, X14 is the nearest continuous flow monitoring station to Station RCDC4 that includes runoff from both NFRC and SFRC. Although the catchment area tributary to Station X14 is larger than the tributary to Station RCDC4, it is the most representative station for comparison to reported peak flows. Spot flow measurements taken in 2007 (Laberge, 2007) illustrate the potential variability between spot flow measurements and the continuous flow data records that represent the daily average. The HEC-HMS model utilized a daily time step and was calibrated to the continuous flow data.

3.3.5 Precipitation

To complete the site-wide HEC-HMS hydrological model, CH2M HILL developed estimated precipitation data sets for the Faro Valley Waste Dump and Grum Overburden Dump. CH2M HILL (2013a) and Attachment 6F-3 describe the development of these data sets in detail. CH2M HILL used the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Station rainfall measurements, precipitation measurements collected by the Environment Canada Faro A and Faro AUT climate stations, and linear regressions developed in 2009 by AECOM to form a complete data set with total daily precipitation record for 2000 to 2011 (except for 2002 and 2003, when there was not enough data to develop an estimate).

3.3.5.1 Rainfall Record

The preferred data source is data collected at the FMC meteorological stations. The data collected at the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations were converted to daily rainfall totals and reviewed for data gaps. The daily rainfall recorded at the Faro Airport Stations was used to augment the rainfall data collected at the FMC by filling identified data gaps with the information collected at the airport. AECOM (2009) developed relationships between the Faro Airport Stations and the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations. These correlations indicate the Faro Valley Waste Dump and Grum Overburden Dump Meteorological Stations receive 6.79 percent and 10.01 percent more rainfall, respectively, than the Faro Airport Stations. These correlations were developed only for the rainfall period between May and September; as such, they were only applied to fill gaps in the FMC rainfall records for that timeframe. If rain fell at the Faro Airport between October and April, the winter correlation was applied. The winter correlation indicated that the FMC stations received approximately 25% (as a water equivalent) more snowfall than the Faro Airport Stations. This was compared with the air temperature record to confirm rainfall was plausible during this period. Figures 6F-10 and 6F-11 show the rainfall records developed for the Faro Valley Waste Dump and Grum Overburden Stations, respectively.

3.3.5.2 Total Precipitation Estimate

The rainfall and snowfall data sets were developed using the described methodology, and were used to compile complete precipitation data sets for each of the two FMC meteorological stations. The precipitation data for the Faro Valley Waste Dump and Grum Overburden Dump Stations are shown on Figures 6F-12 and 6F-13, respectively. When these data sets were reviewed, several outliers were identified, which are shown on these figures.

Outliers were identified by comparing the data with the climate normal reported by Environment Canada for the Faro Airport Station. If an extreme event occurred that was not documented in the available site records, it was determined to be a likely outlier. Where possible, these events were compared with the available continuous flow monitoring data collected at the FMC. If the continuous monitoring data did not reflect a similar increase in surface water flow, the event was corrected using rainfall and snowfall data from one of the nearby stations.

Table 6F-9 compares modelled precipitation estimates, developed as described, for the Faro and Vangorda/Grum Areas of the FMC, with the climate normal for the region, as reported by Environment Canada. This table also presents the percent difference from the Faro Airport Station for each area of the FMC.

TABLE 6F-9
Comparison to Climate Normals
Faro Mine Interim Works

Description	Faro Airport	FMC – Faro Area		FMC – Vangorda/Grum Area	
		Estimate	% Difference	Estimate	% Difference
Average Yearly Rainfall (mm)	214 mm	215 mm	0%	225 mm	5%
Average Yearly Snowfall (cm)	112 cm	162 cm	37%	162 cm	37%
Average Total Precipitation (mm)	316 mm	377 mm	17%	387 mm	20%
Extreme Daily Rainfall (mm)	24.8 mm	28 mm	11%	29 mm	14%
Extreme Daily Snowfall (cm)	12.8 cm	17 cm	27%	17 cm	27%

Notes:

Faro Airport Climate normals are for 1971 to 2000.

Extremes are for period of record.

FMC Area comparison values are for the data available between January 2000 and December 2011 (excluding 2001 and 2002).

cm = centimetre

3.3.6 Air Temperature

CH2M HILL developed a patched temperature record for the Faro Valley Waste Dump and Grum Overburden Dump to complete the surface water modelling task. CH2M HILL (2013a) describes the development of these data sets in detail. Section 2, the Hydrology Modelling section, is provided in Attachment 6F-3. A review of the air temperature records for the Faro Valley Waste Dump and Grum Overburden Dump determined the data to be stable and within climate normals for the region.

Figures 6F-14 and 6F-15 show the complete air temperature records developed by CH2M HILL, indicating the data points from each source respectively.

3.3.6.1 Snowfall Record

As previously discussed, the Faro Valley Waste Dump and Grum Overburden Dump Stations do not record snowfall in water equivalents. AECOM (2009) compared snowpack water content at the Faro Valley Waste Dump and Grum Overburden Dump Stations with accumulated snowfall at the Faro Airport Stations. This analysis indicated the FMC Stations receive about 25 percent more snowfall (as water equivalent) than the Faro Airport. Orographic effects and impacts of blowing snow do influence snow accumulation at the FMC. Therefore, to construct a snow record at the Faro Valley Waste Dump and Grum Overburden Dump Stations, snow depth recorded at the Faro Airport was increased by 25 percent and applied to both stations.

The following assumptions were made while developing the snowfall (as water equivalent) record:

1. To convert the snowfall (reported in cm) recorded at the Faro Airport Station to water equivalents, it is reasonable to assume a snow density of 1 cm equals 1 mm of water equivalent.
2. Where snowfall data are missing for winter months, it is reasonable to patch the data with average-day snowfall from the period of record for the missing dates.
3. It is reasonable to assume that, when snowfall data are missing during summer months (i.e., June to September), no snow fell.

Where gaps exist in the Faro Airport Station records, the average day snowfall was used to patch data gaps. Figure 6F-16 illustrates the snowfall record developed for the FMC for the hydrological modelling.

3.3.6.2 Probable Maximum Flood

Water Management Consultants (2006a) examined the FMC PMF event in 2006. The PMP for this analysis was determined by Taylor and Cadee, also in 2006. The PMP was determined to be a 175-mm-in-24-hours, rain-on-snow event, which is most likely to occur in June. Table 6F-10 summarizes the PMF findings for Rose Creek. CH2M HILL has reviewed Water Management Consultants (2006a) and has found the assumptions and peer-reviewed work to be appropriately conservative.

TABLE 6F-10
Summary of PMF for Rose Creek
Faro Mine Interim Works

Area [a]	PMF (m^3/s) [a]
NFRC	384
Upper end of Rose Creek Diversion	674
Lower end of Rose Creek Diversion	692

[a] Water Management Consultants (2006a)

3.3.6.3 Evaporation and Evapotranspiration Data

The monthly evapotranspiration values for the FMC are shown in Table 6F-11, these are summarized from AECOM (2009). Attachment 6F-2 provides additional evaporation and evapotranspiration data that was used to develop baseline conditions for the FMC.

TABLE 6F-11
Monthly Evapotranspiration Data

Attachment 6F-2
Faro Mine Complex Closure and Reclamation – Project Proposal. Current Environmental Conditions Supporting Document (Hydrology)

3. Water Resources

3.1 Hydrology

3.1.1 Introduction

The Faro Mining Complex is located within the catchments of two right-bank tributaries of the Pelly River: Vangorda Creek and Anvil Creek. The drainage areas of these two tributaries are 91 km^2 and 980 km^2, respectively. The Pelly River controls an area of 22,100 km^2 at a point just downstream of Vangorda Creek. The catchment of this river increases to 23,500 km^2 below the confluence of Anvil Creek and Pelly River. The Vangorda Plateau development is wholly contained within the catchment of Vangorda Creek. The Faro development is located near the geographic centre of the largest tributary of Anvil Creek, namely Rose Creek. A haul road and a mine access road connect the two mine developments, both crossing the drainage divide shared by Vangorda Creek and Rose Creek. Figure 3.1-1 is a small scale map showing the locations of the two mine developments within the catchments of Anvil Creek and Vangorda Creek. Figures 3.1-2 and 3.1-3 are larger scale maps that display the stream network in the immediate vicinity of, respectively, the Faro development and the Vangorda Plateau development.

The objective of this section of the report is to characterize present-day hydrological conditions within the Anvil Creek and Vangorda Creek catchments. As Faro and Vangorda Plateau are existing mines, this characterization must take into account the impact that these two developments have had on surface hydrology. For the most part, this impact is very localized when looked at from a quantity perspective (i.e., in terms of flow rates and volumes). At the mouths of Anvil Creek and Vangorda Creek, the difference in present-day and pre-mining hydrological conditions is practically imperceptible. However, the influence of the mine is significant in the immediate vicinity of the two developments. The mines have impacted the hydrology in a number of different ways. One of these ways is related to the construction of diversion and collection ditches to facilitate the mining of ore and the placement of waste rock and tailings. These ditches had the effect of altering drainage patterns. For example, the development of the Main Pit at Faro required the diversion of the headwaters of Faro Creek. This diversion increased the drainage area of the main tributary of Rose Creek (the North Fork) by some 16 km^2.

The excavation of four open pits at the Faro Mining Complex has also impacted the local hydrology. The pits act as sinks for the groundwater system, locally drawing down water tables and shifting the locations of groundwater divides. Three of the pits contain lakes while the fourth (Zone II Pit) is buried in waste rock. The lakes have locally enhanced evaporation losses.

The tailings deposits and waste dumps have had an important influence on the local hydrology. They contain immense void space that tends to regulate the runoff response from these deposits. In other words, some portion of the runoff that infiltrates into these deposits is temporarily stored within the voids for subsequent release to the receiving streams at a slow rate throughout the year. This is potentially problematic from a water quality perspective because the pattern of releases from the waste rock and tailings is subdued relative to the flow pattern in the receiving streams. This means releases from waste dumps and tailings can be relatively high during periods when the flows in the receiving streams are low, such as winter.

Another influence of the mine developments on surface hydrology is the water management strategy that has been adopted to deal with contaminated drainage at the two mines. This strategy causes an artificial control on the movement and storage of water within the mine developments. For example, contaminated drainage from one of the waste dumps at the Vangorda Plateau development is collected in a small reservoir. This reservoir is normally drawn down once a year, typically during the summer. The collected water is pumped to an open pit, and from there it is delivered to a water treatment plant. Releases from the water treatment plant supplement the flows in Vangorda Creek.

The hydrology of the two mine developments is complex, being influenced by numerous mine elements (e.g., diversion channels, collector ditches, open pits, tailings facilities, and waste dumps) and many individual water management activities (e.g., pumping water to a storage facility, dewatering groundwater systems and operating water treatment plants). To help explain this complexity, flowsheets were prepared to illustrate the generation, movement and storage of water within the mine developments and the associated receiving streams. The flowsheets were made to represent the average conditions in the Vangorda Creek and Anvil Creek catchments during the three-year period from January 2005 to December 2007. Much of the discussion on baseline hydrology is devoted to the development of these flowsheets (see Section 3.1.4). Before these flowsheets could be prepared, it was necessary to characterize key climatic and hydrologic elements, such as evaporation, precipitation and runoff. Section 3.1.3 describes the steps undertaken to characterize these elements. The subsection that follows immediately below lists the data that were available to conduct both the characterization analyses and the reconstruction of the site-wide water balance flowsheets.

3.1.2 Available Data

The hydrology of the Faro Mining Complex was characterized using a mix of regional and site-specific data. Government agencies operate reasonably dense networks of streamflow gauging stations, climate stations and snow courses in the region. The interim receiver and former operators of the Faro Mining Complex have established a network of flow gauging stations within the catchments of Anvil Creek and Vangorda Creek. These stations monitor runoff from catchments ranging in size from 1.8 km^2 to 232 km^2. Most of the stations have been equipped with pressure transducers to provide near-continuous records of water level.

3.1.2.1 Flow Data from Government Agencies

The hydrology of the two mine developments, and their associated receiving streams, was partially characterized using a technique known as Regional Analysis, which entailed developing a set of empirical relationships that could provide flow estimates at ungauged locations. Each empirical relationship relates a flow statistic, such as mean annual runoff, to a catchment physiographic characteristic such as drainage area or catchment elevation. The key input for deriving these relationships was a database of streamflow records representing catchments with a wide range of physiographic characteristics. To locate such data for the analysis, the streamflow monitoring networks of the Water Survey of Canada (WSC) and the Water Resources Branch of Environment Yukon (EY) were searched. This search identified a total of 21 streamflow gauging stations that could provide useful data for the hydrological assessment (18 of which were operated

by the WSC and 3 by EY). Table 3.1-1 provides details of these stations, including their period of record and catchment area. Other information in this table will be discussed below in Section 3.1.3.

The selected WSC and EY stations monitor the runoff from a wide range of drainage areas from 91 km^2 to 49,000 km^2. The periods of record of the stations range from four to 56 years. Over half of the government stations are no longer monitored, most having been closed in the mid-1990's. Their historical streamflow records were, nonetheless, of importance in estimating the site hydrology. Most of the selected stations measure unregulated flows, or flows that have been minimally influenced by human activities.

Two of the government stations listed in Table 3.1-1 were operated on minesite streams. The WSC operated a station on Rose Creek below Faro Creek (Station No. 09BC003) for the period August 1966 to December 1969. This record contained some data gaps. The flows measured at this station were natural up to September 1968 and afterwards were affected by operation of the mine's water supply dam on the South Fork of Rose Creek. EY presently operate a hydrometric station on Vangorda Creek upstream of the Faro Townsite road crossing (Station No. 29BC003). Initially, this station was operated in 1975 and 1976 by a consultant as part of a baseline study for the Vangorda Plateau development. The government then assumed responsibility for this station and operated it from 1977 to present with a three-year break from 1986 to 1988 and a single-year break in 2001. The Vangorda Creek station has only operated during ice-free periods. The locations of Stations 09BC003 and 29BC003 are presented in Figures 3.1-1 and 3.1-2.

3.1.2.2 Flow Data Collected by Site Personnel and Consultants

Over the years since the Faro mine first began operations in the late 1960's, flow data have been collected at over 50 locations within the Anvil Creek and Vangorda Creek catchments. The monitoring effort at these various locations has varied from a few spot measurements to nearly two decades of near-continuous stage measurement. Of all the data collected by site personnel and consultants, the data from a total of 12 stations were of particular importance in characterizing the present-day water balance of the Faro Mining Complex. Table 3.1-2 provides details of these monitoring stations, including period of stage monitoring, drainage area, and number of direct flow measurements made at the site (by bucket and stopwatch, current metering or salt dilution). The first eight stations are located within the Anvil Creek catchment, while the remainder are located within the Vangorda Creek catchment. The locations of the 12 selected monitoring stations are shown on Figures 3.1-1 to 3.1-3. Figures and tables within Sections 3.1.3 and 3.1.4 present the data collected at the 12 stations. In cases where the construction of the present-day water balance only required a subset of the full available record at a station, only the relevant portion of the station's record may be presented in this report.

Data from many of the other locations monitored at the mining complex, and not listed in Table 3.1-2, have played an indirect role in the reconstruction of the Faro Mining Complex historical water balance. For example, many groundwater investigations have been performed over the years and these have provided valuable input to the development of the minesite water balance. Many of these investigations relied on spot flow measurements in local streams, particularly during baseflow conditions, to help characterize groundwater flow rates. Thus, flows collected at sites other than listed in Table 3.1-2 have influenced the understanding that has been developed of the Faro Mining Complex hydrology.

In addition to the flow measurements, the reconstruction of the Faro Mining Complex water balance required information on changes in storage within the various reservoirs at the mine (i.e., the four open pits, Little Creek Dam, and the ponds formed behind the Intermediate Dam and the Cross Valley Dam). At all these reservoirs, site personnel maintain detailed records of water level, often measuring water level at weekly intervals but sometimes as frequently as daily during periods of large water level fluctuation. Since the elevation-capacity relationships for these reservoirs are known to high accuracy, the water level records could be converted into equivalent storage volumes at the end of each calendar month. By taking the difference in storage between successive months, it was possible to estimate net monthly inflows to the reservoirs. This is discussed further in Section 3.1.4.

3.1.2.3 Climate Data

In addition to streamflow data, reliance was also placed on climate data collected by government agencies to help characterize the minesite hydrology. The records from a total of nine climate stations and one snow course were utilized in this hydrology study. These stations are operated by either the Meteorological Service of Canada (MSC) or the Water Resources Branch of Environment Yukon. Table 3.1-3 provides details of all the selected stations, including a listing of the climatic elements that each station provided for the study. Five of the stations are located within or just outside the Anvil Creek and Vangorda Creek catchments (Anvil, Faro Airport, Faro Dump, Grum Dump and Rose Creek). The locations of these five stations are shown on Figures 3.1-1 to 3.1-3.

The Faro Dump and Grum Dump stations provided the most valuable climatic information for the hydrological assessment. The former station is located on the top of the Faro Main Dump at an elevation of approximately 1,225 m. The latter station is located near the eastern edge of the Vangorda Plateau's Grum Dump at an elevation of approximately 1,220 m. The two stations, established in December 2003, are identical in terms of instrumentation and include the following sensors: air temperature, relative humidity, wind speed, wind direction, net radiation, solar radiation, soil temperature (3 levels), soil moisture, rainfall, and snow depth. In February 2008, a weighing precipitation gauge was added to each station, so that precipitation during the winter could be directly measured.

3.1.3 Methods for Estimating Flows at Ungauged Locations

The reconstruction of a minesite water balance requires the evaluation of flow rate at numerous locations. Although the flow monitoring network at the Faro Mining Complex is extensive, it was not practical to measure flow at all the points of interest. Accordingly, techniques had to be developed to estimate flows at the ungauged locations. The two methods adopted for this study, namely climatic water balance and Regional Analysis, are presented below under separate headings. Before the Regional Analysis could be completed, it was necessary to "patch" gaps of missing data in some of the local streamflow records. The methods of making estimates for these missing data are also presented below.

3.1.3.1 Climatic Water Balance

A climatic water balance can provide an indirect estimate of mean annual runoff, as follows:
MAR = MAP – MAET

where: MAR = mean annual runoff;
MAP = mean annual precipitation; and,
MAET = mean annual evapotranspiration (actual, not potential).

All three variables are expressed as depths, usually in units of millimetres. The above equation applies to conditions on a land surface. For a lake, MAET is replaced by the variable MAE, or mean annual lake evaporation.

The methods used to estimate MAP, MAET and MAE are presented below. The application of the climatic water balance to specific points within the Faro Mining Complex is presented in Section 3.1.4.

Precipitation

The distribution of precipitation within a mountainous region tends to vary according to elevation. This observation was exploited to provide a basis for estimating MAP at key locations within the Faro and Vangorda Plateau developments. Figure 3.1-4 presents the analysis undertaken to explore the dependence of MAP on elevation. The data from five local stations, including the two weather stations located on the Faro and Grum waste dumps, were used to develop the relationship.

For the three climate stations not located on waste dumps, the MAP values were simply read from the climate normals published by the MSC (Environment Canada, 2008a). For the two stations on the waste dumps, the data collected at these stations had to undergo initial processing before estimates of MAP could be made. Until recently, the weather stations were not equipped with an instrument that could measure precipitation on a year-round basis. Instead, reliance was placed on two instruments. A tipping bucket rain gauge (equipped with a windshield) was used to measure precipitation during summer, while an acoustic distance sensor was used to measure snow depth. In February 2008, the stations were equipped with a weighing precipitation gauge that should provide reasonably accurate precipitation measurements throughout the year. The records collected at these new instruments were not of sufficient length to be useful at the time this hydrological assessment was prepared.

The tipping bucket rain gauges provided direct measurements of monthly precipitation for the period May to August. For the rest of the year, correlations between the weather station data at the waste dumps and the precipitation record at the Faro Airport were required to estimate monthly precipitation amounts. The analyses essentially involved determining the effects of topography on precipitation during periods of rainfall and snowfall. Figure 3.1-5 examines the orographic effects on rainfall. The top plot on this figure shows the correlation between summer precipitation (mostly rainfall) at the Grum Dump and the coincidental precipitation at the Faro Airport. The middle plot on Figure 3.1-5 shows the same analysis for the Grum Dump weather station. These correlations indicate that the waste dumps tend to receive 7% to 10% more rainfall than does the Faro Airport in the valley bottom.

The top plots on Figures 3.1-6 and 3.1-7 show the observed snow depths at the Faro Dump and Grum Dump weather stations, respectively, for the period December 2003 to July 2008. The water content of the snowpack at the dumps was inferred using data from the closest regional snow course (Rose Creek) and from periodic snow surveys conducted on the mine dumps (see bottom plots of Figures 3.1-6 and 3.1-7). The water contents at late winter were used to estimate orographic effects during snowfall. Table 3.1-4 shows the mechanics of comparing the snowpack contents at the waste dumps with the accumulative winter precipitation at the Faro Airport. The analysis indicates that the dumps receive about 25% more snowfall (as a water equivalent) than does the Faro Airport. This suggests that orographic effects tend to be greater during periods of colder weather.

Table 3.1-5 illustrates how the orographic factors estimated above were used to patch the winter precipitation records (October to April) for the two waste dump stations. When rainfall occurred at the Faro Airport, the Faro Dump was estimated to receive 7% more precipitation than measured at the Faro Airport. The Grum Dump, on the hand, was estimated to receive 10% more rainfall. During periods of snowfall at the Faro Airport, both waste dumps were assumed to receive 25% more snowfall than measured at the airport. The patched winter precipitation values were added to the measured summer precipitation values to arrive at estimates of MAP at the two dump weather stations.

Once the MAP values for all stations were assessed, the next step in the analysis was to develop an empirical relationship between MAP and elevation. The data provided by the five local climate stations were plotted on a graph of MAP versus elevation (see Figure 3.1-4). The data exhibited the expected trend of increasing MAP with elevation but also exhibited significant scatter at the low end of the relationship. A linear regression was fitted to all the data points to provide a means of generating estimates of MAP at ungauged locations. The slope of the regression suggests that MAP increases by an average of 15 mm per 100 m of ascent, at least in the elevational range of 700 m to 1,300 m.

Evaporation

Two rates of evaporation were of interest, namely lake evaporation and actual evapotranspiration. The former refers to evaporation from a free-water surface, while the latter refers to evaporation from a land surface, including transpiration from vegetation. Both rates were estimated using the computer model WREVAP, which was developed by Environment Canada's National Hydrology Research Institute (NHRI, 1985). WREVAP is a semi-empirical, semi-physical model that estimates evaporation from meteorological data (humidity, air temperature and sunshine duration or solar radiation). The model uses different routines to estimate lake evaporation and land evapotranspiration. The lake evaporation routine has been tested against the results of detailed water-budget estimates of 11 lakes in North America and Africa. The evapotranspiration routine has been tested against the long-term water-budget estimates of 143 experimental river watersheds in North America, Ireland, Australia and New Zealand (Morton, 1983).

As indicated in Section 3.2.3, the two dump weather stations monitor the necessary input data for the evaporation model. Accordingly, the WREVAP model was applied to the data sets provided by these two stations. To help detect potential spatial and elevational changes in evaporation rates, the model was also applied to three other climate stations in the Yukon. The results of applying the model to the five stations are presented on Figure 3.1-8. The top plot shows the estimates of average monthly evapotranspiration while the

bottom plot presents estimates of average monthly lake evaporation. The computed mean annual evapotranspiration (MAET) rates for the Faro Dump and Grum Dump weather stations are 229 mm and 246 mm, respectively. These rates are somewhat higher than estimated for the three regional stations, which are all located at lower elevations than the waste dump stations. Three potential reasons are hypothesized for this difference. Firstly, the evapotranspiration rates at the lower stations may be partially limited by availability of moisture, as these stations have lower MAP values than do the dump weather stations. Secondly, the waste dumps may serve to enhance evaporation losses because of the heat generated by the oxidation processes going on within the dumps. Thirdly, the humidity data collected at the waste dump stations may be influenced by evaporation from the nearby pit lakes and, accordingly, the model results may be providing a biased (high) estimate of evaporation from the dump surface.

The computed mean annual lake evaporation (MAE) rates for the Faro Dump and Grum Dump are 472 mm and 484 mm, respectively, or roughly double the corresponding MAET rates. The computed MAE values for the two dump weather stations are similar to the value computed for Mayo Airport and slightly less than the values computed for the two other regional stations.

As partial validation of the lake evaporation values, the bottom plot also shows estimates of lake evaporation for the two closest MSC stations that monitor Class A pan evaporation, namely Whitehorse Airport and Pelly Ranch. The adjusted pan data for these two stations correspond reasonably well with the estimates of lake evaporation provided by the WREVAP model.

3.1.3.2 Patch Missing Streamflow Data

As mentioned in Section 3.1.1, the main method selected for documenting the hydrology of the Faro Mining Complex, and its associated receiving streams, was the development of a historical water balance representing conditions over the recent past (January 2005 to December 2007). To characterize seasonal variations in flow, the historical water balance was constructed on a monthly time step. This necessitated that the flow record for each component of the historical water balance be continuous over the period January 2005 to December 2007. In other words, the average flow for each month in the 36-month study period had to be quantified. Each component of the water balance could be represented solely by measured data, solely by estimated data, or a combination of measured and estimated data. An effort was made to use measured data as much as possible in characterizing the various water balance components. However, few of the records were complete over the 36-month study period and methods were required to patch the gaps of missing data. This section describes how estimates were made for the gaps in the site-specific streamflow records. Development of the Regional Analysis also required the use of patched streamflow records.

The reconstruction of the Faro Mining Complex historical water balance relied heavily on the flow data collected at the following three streamflow gauging stations:

1. R7 – North Fork of Rose Creek above Outlet of Faro Creek Diversion;
2. X14 – Rose Creek below Cross Valley Dam and Rose Creek Diversion Channel; and
3. 29BC003 – Vangorda Creek at Faro Townsite Road.

Stations X14 and 29BC003 were only operated during the open water season over the period January 2005 to December 2007. Although Station R7 was operated year round during this same three-year period, some of the water level data for this station had to be rejected because of backwater effects caused by ice conditions at the gauging site. To provide continuous records of flow over the full three-year study period, the missing data in the records were patched using correlations with a neighbouring WSC station. The independent data used in the correlations for all three minesite stations was provided by the WSC station located on Ross River (09BA001).

Figures 3.1-9, 3.1-11 and 3.1-13 show the correlations used to patch the streamflow records of, respectively, R7, X14 and 29BC003. Figures 3.1-10, 3.1-12 and 3.1-14 present the complete daily flow records for these three stations. Measured data are denoted by blue lines, while patched data are represented by green lines. Tables 3.1-6 and 3.1-7 provide the monthly average flows at R7 and X14, respectively. These tables only present monthly averages for those months with no or very few missing days of measured data.

The streamflow records of Stations X14 and 29BC003 were each patched with a single correlation. These correlations were based only on data collected during the open water season. The tacit assumption was made that these summer correlations were also representative of conditions during the winter. The estimated winter flows for 29BC003 were checked against some direct measurements of flow at Station V8 during winter baseflow conditions in 1992 (see Table 3.1-8). The difference in drainage areas controlled by Stations V8 and 29BC003 is small and, accordingly, the flows at the two stations should be comparable. Examination of the data in Table 3.1-8 suggests that the correlation shown in Figure 3.1-13 may underestimate the true winter baseflows in lower Vangorda Creek. Despite this observation, no adjustment was made to the estimated winter flows at 29BC003 because the accuracy and methodology of the early direct flow measurements at V8 are unknown. Furthermore, two recent spot measurements of flow at V8 in January and February of 2009 suggest that some of the earlier flow measurements at V8 may be overestimating the true baseflow condition (particularly considering that baseflows in 2009 were likely higher than average, given the wet conditions that preceded the 2008/2009 winter).

Numerous direct flow measurements have been made during the winter at Station X14, however most of these were made during periods when the mine was operating and are, therefore, not representative of present-day conditions. The patched winter flows for X14 can be partially validated using the direct flow measurements that were made at X14 just prior to the start of spring freshet in each of the Years 2005, 2006 and 2007 (see bottom plot of Figure 3.1-12). These direct measurements suggest that the patched winter flows for X14 are reasonably accurate. The streamflow record for X14 is not representative of a stationary series because mine operations have had varying degrees of influence on the Rose Creek hydrology over the years. For example, for the period prior to 1993, discharge from the mine's milling facilities represented a large component of the winter baseflows at X14. Up to 2004, the flows at X14 were influenced by the operation of the old water supply reservoir that was located upstream on the South Fork of Rose Creek. Owing to the non-stationarity of the streamflow record, only the 3-year period from 2005 to 2007 was patched. The patched flows for the months February and March 2005 had to be modified to account for controlled releases of water from the Faro Creek Tailings Facility during those months.

The streamflow record of Station R7 was patched using two correlations, one representing open water conditions, and the other representing winter baseflow. The correlation on the bottom plot of Figure 3.1-9

suggests that the winter baseflows at R7 are relatively strong, at least in comparison to the winter flows observed on the large river used as the independent variable in the correlation (Ross River). If the unit baseflows (i.e., discharge per square kilometre) for the two streams were similar, then the slope of the correlation should be similar to the ratio of catchment areas of the two streams (95 km^2/7250 km^2 = 0.0131). However, the actual slope is much higher at 0.0243 which suggests the unit baseflows of the North Fork of Rose Creek are almost double those experienced in the Ross River. The existence of high winter baseflows in the North Fork is advantageous because of the contaminant load this stream receives from the waste dumps that border its lower reach.

3.1.3.3 Regional Analysis

As described in Section 3.1.2.1, Regional Analysis provides a method for estimating flows on streams at locations where no, or minimal, flow measurements have been collected. It involves preparing empirical relationships that relate a hydrological statistic to one or more catchment characteristics. These empirical relationships can be developed to predict any number of hydrological statistics from the 10-year annual minimum 7-day flow to the 200-year peak instantaneous discharge. Two types of hydrological statistics were of prime interest for the baseline hydrology study, namely: mean annual runoff and low flows. The procedures undertaken to derive the Regional Analyses for the two types of hydrological statistics were different, and are therefore described separately.

Mean Annual Runoff

Runoff is defined herein as the portion of precipitation falling on a catchment that is not subsequently evaporated. This excess precipitation is shed from the catchment via three different pathways: overland flow, interflow and groundwater. Runoff values presented in this section do not differentiate between these three pathways, but represent the total of the three components.

Based on the behaviour of precipitation examined in Section 3.1.3.1, mean annual runoff (MAR) would be expected to exhibit a dependence on elevation. The streamflow records collected by government agencies and by site personnel were employed to examine the trend between MAR and elevation. The Regional Analysis presented in this section was originally developed in 1996, as part of the preparatory work leading to the development of the first comprehensive closure plan for the Faro Mining Complex, known as the ICAP (Robertson GeoConsultants Inc., 1996). This section describes the earlier work and then presents site-specific data that were selected to check the accuracy of the original analysis.

Figure 3.1-15 is a reproduction, with a few modifications, of the graph that was used in the ICAP to examine the relationship between MAR and elevation. The vertical axis of this figure displays MAR expressed as an equivalent depth of water (i.e., the average annual runoff volume divided by the contributing catchment area). This is a convenient means of comparing runoff from catchments with vastly different drainage areas. The horizontal axis shows the variable adopted to represent the elevational characteristics of catchments, namely catchment median elevation. Median elevation is defined as the contour that divides a catchment into halves. The following sources of data were assembled to derive a relationship between the two variables on this figure:

- nineteen pairs of MAR and median elevation data provided by regional WSC and EY streamflow gauging stations (as listed in the top two sections of Table 3.1-1); and
- four pairs of MAR and median elevation values provided by four incremental catchments monitored by the WSC (as explained below and identified in the bottom section of Table 3.1-1).

The second source of data is essentially a subset of the first. Where more than one streamflow gauge was located on a river, it was possible to provide a set of MAR and median elevation values for the intervening catchment area between the gauges. For example, the runoff generated by the lower Pelly River catchment was quantified by subtracting the flows measured at Stations 09BB002 and 09BC004 from the coincidental flows at Station 09BC001. The median elevation of this incremental catchment was measured by examining only the area which lies between these three gauging stations.

Once the assembled data were plotted on Figure 3.1-15, a line was drawn through the data that was believed to represent conditions within the Anvil Creek and Vangorda Creek catchments. Positioning of this line turned out to be a reasonably straightforward task because the stations in closest proximity to the Faro Mining Complex all fell within a narrow band on Figure 3.1-15. The labels for the most representative government data are printed in red lettering.

The ICAP recommended using the following four-step algorithm to estimate the long-term average flows of the minesite streams:

- identify a point of interest on a topographic map and then draw the boundary of the catchment controlled by that point;
- measure the drainage area and median elevation of the catchment;
- enter the graph on Figure 3.1-15 at the appropriate value of median elevation and read the corresponding MAR value from the graph's vertical axis; and
- compute the product of MAR and drainage area to estimate the long-term average annual flow for the point of interest. For example, a 50 km^2 catchment with a median elevation of 1,400 m would have an estimated average annual flow of 0.48 m^3/s (i.e., Q = 304 mm/y x 50 km^2 x m/1,000 mm x 10^6 m^2/ km^2 x y/365.25 d x d/24 h x h/3600 s = 0.48 m^3/s).

The accuracy of the empirical relationship between MAR and median elevation was partially tested using streamflow data that has been collected at the Faro Mining Complex since the publication of the ICAP. The test made use of data from four streamflow gauging stations that were not employed in the development of the original relationship. Two of the stations were already introduced in the section above on data patching (X14 and R7). The other two stations are designated FDU and V1 and monitor headwater streams. The former station was established in 2007 just inside the entrance of the Faro Creek Diversion channel and monitors a 14.3 km^2 catchment with a median elevation of 1,530 m. The latter station was established in 2008 above the inlet of the Vangorda Creek Diversion and controls a catchment with drainage area of 18.7 km^2 and median elevation of 1590 m. Figures 3.1-16 and 3.1-17 present the flow data collected at FDU and V1, respectively, since 2008. To obtain estimates of MAR for these two stations, their respective daily flow records were correlated with the coincidental daily flow measurements made at Station R7 on the North Fork of Rose Creek. Given the short periods of overlap, the resulting regression equations could only provide approximate estimates of MAR for FDU and V1.

The pairs of MAR and median elevation data provided by X14, R7, FDU and V1 were superimposed on Figure 3.1-15 (see orange circles). Three of the data points lie fairly close to the original 1996 relationship. The data point provided by V1 lies well above the original MAR-elevation relationship, but this may, at least partially, be the consequence of basing the MAR value on a short period of record. Flow measurements on Vangorda Creek at a location downstream of V1 provide some evidence that the estimated MAR for V1 may be overestimated. Further details on this second set of flow data are provided in Section 3.1.4. The estimated MAR for V1 will improve as more data are collected at this new monitoring station. Taken together, the data provided by the four sets of validation data (X14, R7, FDU and V1) indicate that the original relationship between MAR and median elevation provides a reasonably accurate portrayal of hydrological conditions at the Faro Mining Complex.

As described earlier, reconstruction of the historical water balance for the Faro Mining Complex required the estimation of flows at key locations around the Faro and Vangorda Plateau mine developments for the 36-month period from January 2005 to December 2007. For an ungauged point on a receiving stream, flows were estimated by transposing the measured flow record of a monitoring station, such as R7, to the point of interest. The transposition was accomplished by scaling the measured flow record according to the ratio of estimated mean annual discharges at the ungauged and gauged locations. The estimates of mean annual discharge required for preparing the scaling ratio were derived from the four-step estimation procedure extracted from the ICAP and outlined above.

Low Flow Hydrology

Contaminant concentrations in the receiving streams at and below the Faro Mining Complex tend to be highest during periods of low flow, particularly during the winter months. This is largely due to the mismatch in flow patterns of the sources of contamination (i.e., waste dumps and tailings deposits) and the sources of ambient water (i.e., receiving streams). The flow patterns of runoff from the waste dumps and tailings deposits tend to be subdued relative to the flow patterns of the receiving streams. Because the low flow periods coincide with the highest contaminant concentrations, it was important to develop an understanding of the low flow hydrology of the Anvil Creek and Vangorda Creek catchments. This understanding was largely obtained from the preparation of a Regional Analysis of low flows. This Regional Analysis was similar to the one outlined above for estimating MAR, but had important differences. The main difference involved the use of statistical frequency analysis. The low flow study required frequency analysis whereas the MAR study did not.

A number of different statistics are commonly used to characterize the low flow regime of a stream. To get an overall picture of the range of low flows that can be expected in the local streams, empirical equations are developed in this section to estimate the following six low flow statistics:

- 2-year annual minimum 7-day flow (7Q2);
- 10-year annual minimum 7-day flow (7Q10);
- 50-year annual minimum 7-day flow (7Q50);
- 2-year low annual flow (365Q2);
- 10-year low annual flow (365Q10); and
- 50-year low annual flow (365Q50).

The first three statistics represent the average flow during the lowest part of the annual hydrograph, or more specifically the lowest seven consecutive days. The lowest flows will typically occur in the winter after a prolonged period of freezing. All of the statistics represent thresholds. For the first statistic, it can be expected that there is a 50/50 chance that the 7-day low flow for the upcoming year will drop to or below the flow represented by 7Q2. The second statistic is indicative of moderate drought conditions; the sustained flow of the stream over a 7-day period will only drop to or below this threshold once every ten years, on average. The third statistic is indicative of a severe drought; the flow in a stream is only expected to drop below the 7Q50 level once in every 50 years.

The last three statistics represent the average flow over the entire year. As was done for the 7-day low flows, it was of interest to estimate low annual flows at various degrees of severity (i.e., return periods of twio, ten and 50 years).

Preparation of the Regional Analysis of low flows entailed the following steps:

1) search Water Survey of Canada (WSC) database for streamflow gauging stations that are in reasonably close proximity to the Faro Mining Complex and that have long periods of record;
2) extract annual series of low flow events from the streamflow record of each selected WSC station for durations of seven and 365 consecutive days;
3) fit theoretical frequency distributions to the two annual series to estimate low flows for return periods of two, ten and 50 years; and,
4) identify correlations between low flow and catchment characteristics that could be used to transpose the low flow estimates at the WSC stations to points of interest on the minesite streams.

Table 3.1-9 lists the eleven stations that were selected to perform the Regional Analysis. The table also summarizes the estimated low flow statistics at each station for durations of 7 and 365 consecutive days, and return periods of two to 50 years. To facilitate comparison, the low flows have been expressed as unit discharges in units of L/s/km^2 (i.e., the absolute discharge value has been divided by the contributing catchment area).

Figure 3.1-18 examines potential correlations that can be used to estimate minimum annual 7-day flow flows at ungauged locations. The figure comprises six plots. The ones on the left side of the figure examine the relationship between 7-day low flow and mean annual runoff (expressed as an equivalent depth). The plots on the right examine the relationship between 7-day low flow and drainage area.

Abbreviations are given in the figures to identify the type of flow statistic represented by each plot. Each abbreviation comprises a number, followed by the letter “q”, followed by a second number. The first number denotes the duration of the low flow event in number of consecutive days. For example, the number 7 indicates the low flow event represents the lowest 7 consecutive days in the annual hydrograph. The lower case “q” indicates that the statistic represents a unit discharge. To obtain an absolute discharge, the value must be multiplied by the contributing catchment area. The second number in the abbreviation represents the return period of the low flow event in years.

Figure 3.1-19 explores the relationship between low annual flows, MAR and drainage area. An examination of Figures 3.1-18 and 3.1-19 reveals that drainage area is a poor predictor of how unit low flow varies amongst the eleven WSC stations. Indeed, unit low flow appears to be virtually independent of drainage area, for durations of both 7 days and 365 days. MAR, on the other hand, does help explain at least some of the variation in unit flows across the region. Wetter catchments tend to have higher unit low flows than do drier catchments. The correlations between low flow and MAR are significantly better for the 365-day duration than the 7-day duration. This is expected since MAR and the 365-day low flow events represent the identical duration. Indeed, MAR and 365q2 would represent identical flows if the series of annual flows observed at the WSC stations exactly followed the normal distribution. In reality, the true distribution of annual flow events is usually positively skewed and, therefore, the 365q2 flow rate can be expected to be slightly less than MAR.

The relationships between low flow and MAR presented in Figures 3.1-18 and 3.1-19 produced equations that estimate the low flow events in normalized units (i.e., L/s/km^2). These equations can be altered to predict absolute flow values by multiplying both sides of the equation by catchment area (A). The resulting equations are:

$7Q2 = 0.034\ A\ MAR^{0.605}$
$7Q10 = 0.030\ A\ MAR^{0.553}$
$7Q50 = 0.032\ A\ MAR^{0.481}$
$365Q2 = 0.026\ A\ MAR^{1.034}$
$365Q10 = 0.0081\ A\ MAR^{1.188}$
$365Q50 = 0.0040\ A\ MAR^{1.277}$

where, catchment area A is in km^2, the MAR is in mm and the resulting low flow is in L/s.

3.1.4 Present-Day Water Balance

The baseline hydrology of the Faro Mining Complex was documented by reconstructing the historical water balances of the Anvil Creek and Vangorda Creek catchments. The reconstruction was limited to the period from January 1, 2005 to December 31, 2007 in order to capture a period representative of present-day conditions, prior to implementation of the proposed closure plan. The hydrology of the Faro Mining Complex was reasonably stationary during this three-year period. Earlier years were excluded from the water balance analysis because several significant construction projects had been carried out at the Faro Mining Complex that impacted the surface hydrology, on at least a local level. Prior to 2005, many of the diversions at the two mine developments were upgraded to increase their efficiency, thereby reducing inflows to the open pits. In 2004, a breach was cut into the water supply reservoir, so that the flows in the South Fork of Rose Creek were no longer regulated by this reservoir.

Further construction projects were carried out in the period 2005 to 2007, however, these had relatively minor influences on surface hydrology. These projects were largely aimed at improving water quality. For example, in 2006, a pipeline was installed to convey flows from the Emergency Tailings Area (ETA) to the pond behind the Intermediate Dam. This measure was implemented to improve capture efficiency of contaminated water from the ETA and the waste dumps draining to the remnant Faro Creek channel. In

2007, a ditch was constructed to direct a small seep from the toe of the Grum Dump to an infiltration pond (Moose Pond). These two projects provided important stopgap measures to improve water quality over the short term before the final closure plan can be implemented, but were of little significance in terms of impact on surface hydrology.

For the assessment of the proposed Faro Mining Complex closure plan, baseline conditions refer to conditions as they exist today, not prior to development of the two mine developments. There are many reasons why baseline conditions would be evaluated for an environmental assessment. In the case of the Faro Mining Complex, the need to characterize baseline hydrology conditions was largely driven by the linkages between water quantity and water quality. To accurately predict the water quality that will be achieved with the proposed closure plan, it was important to first characterize the yield and seasonal distribution of runoff from potential contaminant sources, such as open pits, waste dumps and the tailings impoundment. It was equally important to estimate the yield and seasonal distribution of flows within the receiving streams. To capture information on seasonal variations of runoff, both for contaminant sources and receiving streams, the present-day water balance was constructed on a monthly time step.

No significant transfers of water exist between the Faro and Vangorda Plateau developments under present-day conditions. Accordingly, separate water balances were drawn up for the Anvil Creek and Vangorda Creek catchments. In developing the water balances, an attempt was made to use as much measured data as possible. In this regard, the period 2005 to 2007 had high utility because the program of flow monitoring at the mining complex was more extensive in this period than in the past.

3.1.4.1 Anvil Creek Catchment

Flowsheets were used to summarize the overall water balances for the Anvil Creek and Vangorda Creek catchments. The water balances of the Faro and Vangorda Plateau mine developments are complex, comprising numerous elements and flowlines. To ease interpretation of the data, the flowsheets were designed to capture only the most important features of the mine water balances. The flowsheets represent average annual flows under present-day conditions, or more specifically they represent the average of conditions that existed during the three-year period from January 2005 to December 2007.

Figure 3.1-20 presents the flowsheet developed for the Anvil Creek catchment. The flowsheet was designed to allow the reader to quickly identify sources of water contributing to the total flow at four key receiving points within the catchment, namely: North Fork at X2, Rose Creek at X14, Rose Creek at its mouth and Anvil Creek at its mouth. These locations are represented in Figure 3.1-20 as filled circles.

The basic “building block” for the flowsheets was the subcatchment area. To create a representation of the mine development without excessive detail, the Anvil Creek catchment was subdivided into a total of 10 subcatchments. The boundaries of the subcatchments were dictated by the locations of: i) the four key receiving points listed above; ii) diversion channels; and iii) the main mine elements (open pits, waste dumps and tailings impoundment). The boundaries of the 10 subcatchments are outlined on Figures 3.1-1 and 3.1-2. Table 3.1-10 provides details of these subcatchments, including drainage area, catchment median elevation and a preliminary estimate of MAR. This preliminary runoff estimate was derived from the regional relationship between MAR and median elevation presented in Figure 3.1-15. The subcatchments are

represented on the flowsheet as rectangular boxes (see Figure 3.1-20). The subcatchments are labelled with capital letters (A to J) to aid in the cross referencing of figures and tables in this report.

To complete the flowsheet, it was necessary to account for the linkages of flows amongst the subcatchments and the various receiving points. Flowlines on Figure 3.1-20 represent the flow paths judged to be of most importance because they are either associated with a large flow volume or have the potential to convey a large contaminant loading. The number shown on each flowline denotes the average annual flow in m^3/s over the three-year study period.

The estimated average annual runoff generated by each subcatchment over the three-year study period is presented as a number inside the rectangular boxes and is denoted by the variable "R". For the mine elements associated with large storages (i.e., Main Pit, Zone II Pit and the Rose Creek Tailings Facility), the rectangle boxes also include information on the net change in storage over the three-year study period. These net changes in storage are denoted by the variable "ΔS". Both R and ΔS represent the average conditions over the period January 2005 to December 2007 and are expressed in units of m^3/s. A negative value for ΔS indicates that the storage at the end of 2007 was less than the storage at the beginning of 2005.

Flowlines that represent purely groundwater flows are represented on the flowsheets as dashed lines. Solid lines denote all other types of flowlines, including purely surface flow, combinations of surface and groundwater flow, or flow contained in a pipe.

The water balances for specific elements of the Faro mine development are discussed below.

Zone II Pit

A total of four open pits exist within the Faro Mining Complex. The Zone II Pit is the smallest of them and is buried in waste rock.

This section begins by outlining the general approach used to quantify the water balances of all four open pits. It then focuses on the application of the approach to the Zone II Pit. The emphasis of the analyses for all four open pits was to estimate the seasonal pattern of inflows to the pits. This was achieved by applying the continuity equation, which can be written as:

$$I - O = \Delta S$$

where: I = total inflows to pit, including direct precipitation on pit lake, local runoff from area above pit lake and below diversions, groundwater and ditch leakage from catchments controlled by diversions and flows pumped from elsewhere in minesite;

O = total outflows from pit, including direct evaporation from pit lake, groundwater seepage and withdrawals via pumps; and,

ΔS = change in storage within the pit.

As indicated above, the water balance of an open pit can comprise numerous individual components. For the purpose of the historical water balance, it was not necessary to track all the components separately. Instead, many of the inflow and outflow components related to natural processes could be lumped together and represented as a single variable in the water balance. This variable is referred to herein as "net" inflow. It was assumed to represent the combination of three inflow components (direct precipitation on pit lake, local runoff between lake and diversion ditch, and groundwater originating from the catchment of the diversion ditch) minus two outflow components (direct evaporation from pit lake and groundwater seepage from pit). Other slight modifications to the general form of the continuity equation were required to account for special conditions that existed at some of the pits.

Site personnel kept detailed records of pit water level throughout the three-year period of interest. As a result, the net inflow rates to the open pit could be estimated with good accuracy, particularly during periods devoid of pit dewatering. The pits, in effect, acted as giant bucket and stopwatch measurements. The height-capacity curves for the pits are known and, therefore, the pit water level records could be converted into accurate estimates of equivalent storage. The pit water levels were often measured at the end of the month. In cases where this did not happen, the frequency of measurements was sufficient that linear interpolation could be used to provide a reliable estimate of the end-of-the-month water level. Based on the collected water level records, accurate estimates of monthly change in storage (ΔS) could be estimated for the 36 months adopted for the historical water balance reconstructions.

Figure 3.1-21 illustrates the reconstruction of the Zone II Pit water balance for the period January 2005 to December 2007. Since this open pit is buried in waste rock, fluctuations in storage occur within the voids of the waste rock. As a result, a slight modification was required to the method outlined above for estimating pit storage changes. The estimates generated from the height-capacity curve of the un-buried open pit were multiplied by an assumed constant fraction to estimate true fluctuations in water storage. The value of this fraction is known as the drainable porosity and can be interpreted roughly as the difference between total porosity and field capacity (i.e., the portion of water contained in voids that quickly drains by gravity from saturated waste rock as the groundwater table drops below the waste rock).

The top plot on Figure 3.1-21 presents the observed water level record within the pit, as measured from a well. The middle plot shows the measured amount of water pumped from the pit and discharged to the Main Pit. The record of pit dewatering is believed to be reasonably accurate and is based on a record of pump hours and known pump capacity.

The bottom plot shows the estimated monthly net inflows to the pit, as computed by application of the continuity equation (i.e., change in pit storage + measured pit dewatering). To prevent the calculation of negative inflow rates, a relatively small value of drainable porosity (10%) had to be adopted.

The average annual net inflow to the Zone II Pit is approximately 50,000 m^3. To reduce inflows to the Zone II Pit, an interceptor ditch (now buried) was constructed along a portion of the northern perimeter of the pit. This interceptor ditch defines a portion of the boundary of the catchment controlled by the Zone II Pit. The drainage area of the pit's catchment is approximately 0.33 km^2. Based on this catchment area, the 50,000 m^3 inflow is equivalent to a depth of 151 mm. If seepage losses from the Zone II Pit are negligible and the only source of inflows is precipitation falling on the pit's catchment, then the average annual yield of the waste

dump overlying the pit is about 151 mm. The true yield of the waste dump is less than 151 mm because the pit undoubtedly receives a portion of its inflows from groundwater originating from outside the 0.33 km^2 catchment area. This groundwater probably has two main components: i) leakage from the interceptor ditch; and ii) groundwater from areas northeast of the pit that passes below the interceptor ditch. Seepage from the Main Pit is another potential source of water for the Zone II Pit.

A groundwater study was undertaken in 2005 to estimate seepage from the Zone II Pit to the North Fork of Rose Creek (SRK, 2007a). Two estimates of seepage were made in the SRK report, one using Darcy's Law and the other using a chemical load balance in the portion of the North Fork valley alluvium adjacent to the Zone II Pit. The higher of the two estimates, provided by the former method, was used to represent conditions in the reconstructed water balance (see Figure 3.1-20). The low estimate of seepage is a quarter of the high estimate.

Main Pit

Figure 3.1-22 presents the water balance for the Main Pit for the 3-year study period. Unlike the Zone II Pit, the pit dewatering record could not be accurately estimated from pump records. Despite this, an accurate portrayal of the pit's water balance could still be developed. The main reason for this is that, in the months in which pit dewatering was undertaken, the resulting withdrawals represented the dominant component of the water balance. Thus, the change in pit storage during the month represented a large proportion of the total water pumped from the pit.

The accuracy of the water balance was improved by developing a correlation between pit inflows and the monthly flow at Station R7 on the North Fork of Rose Creek. Only inflow rates for months devoid of pit dewatering were used in the preparation of the correlation (not shown).

Preparation of the Main Pit water balance involved five main steps. Firstly, the observed pit water levels were converted into equivalent storage volumes. Secondly, the net inflows to the open pit during months without dewatering activities were estimated. This was simply done by setting the net monthly inflow for a given month equal to the change in pit storage during that month (i.e., with no outflow, inflows equal change in storage). Thirdly, the correlation mentioned above between pit inflow rate and R7 monthly average flow was derived. Fourthly, the correlation was used to estimate net inflows during periods when the pit was being dewatered (see bottom plot of Figure 3.1-22). Finally, the record of flows pumped to the Faro water treatment system was estimated by application of the continuity equation (i.e., net monthly inflow + pumped inflows from Zone II Pit - monthly change in storage). The middle plot of Figure 3.1-22 presents the estimated pit dewatering record.

The estimated average annual inflow to the Main Pit is 1.44 million m^3, excluding the small contribution from the Zone II Pit dewatering. The inflows to the Main Pit are subdued, with the average flow during the highest month (typically May) being only about three times greater than the average flow during the lowest month (typically February or March).

Faro Waste Dumps

A variety of techniques were used to estimate the amount of runoff emanating from the waste dumps at both the Faro and the Vangorda Plateau mine developments.

The most direct measurement of waste dump runoff was made for the Faro Waste Dumps overlying the old Faro Creek Channel downstream of the Main Pit. A triangular weir was established in the old Faro Creek channel some 600 m downstream of the toe of the Main Waste Dump in the fall of 2005. Owing to its location at the mouth of a small canyon, the flow of groundwater in the alluvium below the weir is probably minimal. If the groundwater bypass is indeed small, then the weir captures a very high proportion of the yield generated by the waste dumps overlying the old Faro Creek Channel. The station, designated FCS-4, was operated for just over a year. The flow record for the station is of high quality because validation data (such as staff gauge readings and bucket and stopwatch measurements) were collected on a frequent basis during the weir's operating period, including winter months. Figure 3.1-23 presents the complete stage and flow records collected at the weir. Several of the flow spikes shown in the record are due to short duration releases from the Faro water treatment system.

The reconstruction of the historical water balance required the preparation of a monthly dump release record that spanned the full period from January 2005 to December 2007. For the period October 2005 to September 2006, this was achieved by computing average monthly discharges from the observed flows at the FCS-4 weir. Before computing the monthly averages, the effect of three short-duration releases from the Faro water treatment system were removed from the record. To estimate missing data in the remainder of the three-year study period, a correlation was developed between monthly average flows at FCS-4 and coincidental monthly average flows at Station R7 on the North Fork (not shown). Figure 3.1-24 presents the resulting patched record of flows attributed to releases from the waste dumps overlying the old Faro Creek channel.

The average flow measured at FCS-4, excluding small contributions related to releases from the Faro water treatment plant, is 5.6 L/s. Using pre-mining topography as a guide for the placement of the station's catchment boundary, the drainage area controlled by FCS-4 was estimated to be 1.8 km^2. If the groundwater flow below the FCS-4 weir is indeed small, then the measured flow suggests that the average annual yield of the waste dumps overlying the old Faro Creek channel is about 98 mm. This measured yield can be compared against a climatic water balance prepared at the weather station operated on the Main Waste Dump. Given an estimated MAP of 357 mm and an estimated MAET of 229 mm, the climatic water balance indicates the average annual yield of the waste dumps should be approximately 128 mm (i.e., the difference between MAP and MAET). Three hypotheses are offered to explain the discrepancy in the two estimates. Firstly, the difference may be due to slight inaccuracies in the estimates of MAP and MAET. Secondly, the difference may be real, which could suggest that the waste dumps are still wetting up and have not yet reached their ultimate water content. Thirdly, a significant amount of groundwater may actually bypass the FCS-4 weir.

Weir FCS-4 captures much of the waste dump drainage that enters Rose Creek between water quality stations X2 and X14. To estimate drainage from waste dumps draining to the North Fork above X2, a two-

component mixing model was utilized. The model is a simultaneous solution of the following two conservation of mass equations:

QB + QD = QR

QB CB + QD CD = QR CR

where: QB = discharge from background source of water;
QD = discharge from waste dumps;
QR = discharge at water quality station in receiving stream;
CB = background concentration of tracer;
QD = concentration of tracer in discharge from waste dumps; and,
CR = concentration of tracer at water quality monitoring station.

The mixing model comprises six variables and two equations. Accordingly, if four of the variables are known (either measured or estimated), then the model can estimate the magnitude of the remaining two variables. For this application, the unknowns were QB and QD.

Dissolved sulphate was used as the tracer in the calculations. Background concentrations were based on sulphate measurements at R7, which samples a very high percentage of the background source of water (i.e., a high percentage of water that flows past X2 that is not related to the waste dumps). Table 3.1-11 documents the steps undertaken to estimate the flow-weighted average sulphate concentration of waste dump drainage.

The flows at the water quality monitoring station (QR) were estimated by transposing the monthly streamflow record for Station R7 downstream to the location of Station X2. This was accomplished by scaling the flows at R7 by the ratio of estimated average annual flows at the two stations. A scaling factor of 1.2 was adopted, based on the estimation procedure set out in Section 1.3.3.1. A check on the magnitude of the scaling factor was made using a series of spot flow measurements that have been made at X2. A correlation between these spot measurements and the coincidental flows at R7 (based on water level readings) suggested that the true scaling factor could be less than the adopted value (see top plot on Figure 3.1-25). An alternative explanation is that the adopted scaling factor is accurate and a significant amount of the North Fork flow is passing below Station X2 in the valley alluvium.

The results of applying the two-component model at X2 are illustrated in Figure 3.1-26. The estimated average annual flow from the waste dumps to the North Fork above X2 is 4.7 L/s, or 120 mm when expressed as an equivalent depth over the year. The estimated yield of the waste dumps bordering the North Fork of Rose Creek is similar to the estimated yield of the waste dumps overlying the remnant Faro Creek channel. As can be seen by referencing Figures 3.1-24 and 26, outflows from the Faro Waste Dumps are significantly attenuated. Releases from the waste dumps remain high during winter months, when flows in the receiving streams are at their lowest.

Tailings Impoundment

The water balance of the Rose Creek Tailings Facility (RCTF) comprises a large number of inflow and outflow components. The magnitude of the outflow components and some of the inflow components are known to reasonably high levels of accuracy. The largest unknown in the water balance is the magnitude and seasonal distribution of groundwater inflows to the RCTF. This analysis was aimed at improving the estimates of groundwater inflows to the tailings impoundment. To facilitate the analysis, the entire RCTF and its underlying valley aquifer were treated together as a single black box. The main outflows from this black box comprise:

- siphoned flows from the Cross Valley Dam (CVD);
- groundwater in the underlying aquifer that discharges to surface between the CVD and X14; and,
- groundwater in the underlying aquifer that remains in the alluvium at Station X14.

The sum of the last two components represents the total flow in the valley aquifer at a point below the CVD (and includes seepage through the CVD). As will be discussed later, studies have shown that the valley aquifer experiences zones of both discharge and recharge in the reach of the Rose Creek valley between the CVD and X14. As a result, the third outflow component listed above represents only a small portion of the total flow in the alluvium below X14.

The main inflow streams to the black box are:

- dewatering of Main Pit (after first being treated in the Faro water treatment facility);
- runoff from the Main Waste Dump and parts of the Intermediate and Northwest Waste Dumps;
- local runoff from incremental catchment of the RCTF, defined as area above the CVD and below the waste dumps, the Rose Creek Diversion Channel (RCDC) and the North Wall Interceptor Ditch (NWID);
- leakage from the RCDC and the NWID;
- groundwater originating on the south valley slope that passes under the RCDC;
- groundwater originating on the north valley slope that passes under the NWID; and,
- groundwater in the valley aquifer just upstream of the tailings facility.

Insufficient data are available to accurately estimate the magnitude of the last four components individually. However, the analysis undertaken here was adequate to provide a reasonably accurate estimate of the sum of the four groundwater components.

The final component of the water balance that had to be considered was storage, or more specifically monthly changes in that storage. The black box contains essentially three storages: the polishing pond behind the CVD, the pond behind the Intermediate Dam and the void spaces within the deposited tailings and the valley aquifer sediments. Site personnel maintained detailed records of water level in the two ponds, so the changes in storage within these ponds could be estimated with a high degree of accuracy. However, insufficient data were available to estimate changes in storage within the voids of tailings and alluvial sediment. The implicit assumption was made that changes in storages within the voids was negligible.

Three sources of information were used to estimate the magnitude of the outflow streams from the RCTF and its underlying aquifer. The first source was detailed records collected by site personnel on the siphon operation. These records included information on operating period, percentage opening of valve, CVD pond level and periodic current meterings of flow in channel just downstream of siphon outlet. Figure 3.1-27 presents the processed flow record for the siphon. Using the information assembled by site personnel, an empirical relationship was developed relating release from the siphon to the available hydraulic head and the percentage opening of the control valve. The hydraulic head was computed as the difference between the pond surface elevation and the elevation of the siphon's outlet. The top plot on Figure 3.1-27 shows the water level record for the pond from January 2005 to December 2007. The middle plot shows the estimated monthly outflows from the siphon based on the empirical relationship developed between discharge, hydraulic head and valve opening.

Two tests were conducted to assess the accuracy of the computed siphon flows. Firstly, a theoretical rating curve was prepared for the siphon for the case of the valve being wide open (based on pipe hydraulics). This suggested that the empirical relationship was probably overestimating the true discharge rates by about 23% when the siphon is operated with a wide-open valve. Secondly, the computed monthly withdrawals were compared with the corresponding drawdowns in the CVD pond, particularly during periods of known low inflow to the pond. This second test also indicated that the empirical relationship probably overestimates the true release rate from the CVD pond. To account for the probable overestimation, the flows generated by the empirical relationship were subsequently multiplied by a factor of 1/1.23 (i.e., they were reduced by 23% to make them consistent with the theoretical rating curve for the siphon). The corrected flows are presented in the bottom plot of Figure 3.1-27.

The second source of information for assessing outflows from the RCTF was a record of flows at a rectangular weir, known as X13, located some 100 m downstream of the toe of the CVD. The main source of water measured at this weir is discharge from the valley aquifer in the area between the CVD and X13. Figure 3.1-28 presents the stage and flow records for Station X13 for the three-year study period.

The final source of information for assessing RCTF outflows was a study entitled "Water and Load Balance Study for Rose Creek Tailings Storage Facility" (Robertson GeoConsultants Inc., 2005). This study interpreted flow and chemistry data collected during a synoptic field survey in October 2004. This synoptic study was conducted during stable low flow conditions. The following key information was extracted from the Robertson GeoConsultants Inc. report as it relates to the RCTF water balance:

- The valley aquifer continues to discharge to surface downstream of Station X13. During the October 2004 field trip, the discharge between X13 and the outlet of the RCDC was approximately 51 L/s.
- Based on interpretation of the October 2004 data, the groundwater flow in the aquifer below the CVD was approximately 107 L/s. Of this amount, approximately 24 L/s was estimated to remain in the valley aquifer at Station X14.

A range of techniques were used to estimate the inflow streams to the RCTF (including its underlying aquifer). The water balance work for the Main Pit was used to estimate the inflows from the combined dewatering of this pit and the Zone II Pit. The analysis of flows at Station FCS-4 was used to quantify inflows from the waste dumps. The flows at FCS-4 were scaled by a factor of 1.2 to account for waste dumps that

drain to the RCTF but are outside the drainage area controlled by Station FCS-4. The factor 1.2 is the estimated ratio of the planimetric area of waste dumps in the RCTF catchment to the drainage area of FCS-4.

The local runoff generated by the incremental catchment of RCTF below the waste dumps is a relatively small component. Its magnitude was estimated to be 2% of the flows measured at Station R7, based on ratio of estimated average annual flows of the RCTF incremental catchment and the R7 catchment. The Regional Analysis described in Section 3.1.3.3 was used to estimate the average annual flows for these two catchments.

The combined groundwater inflow to the RCTF (including its underlying valley aquifer) was estimated by the application of the continuity equation. Figure 3.1-29 illustrates the mechanics of applying the continuity equation. The top plot on this figure shows the combined storage of the ponds behind the CVD and Intermediate Dam. The second plot shows the monthly record of estimated combined outflows from the RCTF. The third plot presents the combined surface inflows to the RCTF, which are largely all measured. The bottom plot shows the estimated total groundwater inflows, as computed by the continuity equation (i.e., total groundwater outflows + total surface outflows + change in storage - total surface inflows). The computed groundwater inflows represent water that either recharges the underlying aquifer or eventually surfaces at the ponds. It should be noted that these estimates of groundwater inflow contain the net error in the estimates of the other components of the water balance. This error includes the storage fluctuations that occurred within the voids of the deposited tailings and the sediment of the underlying aquifer over the three-year study period. As mentioned earlier, the storage within voids was not explicitly accounted for in the water balance analysis.

The estimated average annual groundwater inflow to the RCTF and its underlying aquifer is 148 L/s. The estimated average annual inflow from all other sources (waste dumps, local runoff on incremental catchment of RCTF and dewatering of the two open pits) is 76 L/s, or about half the input from groundwater sources.

Diversions

The Faro mine development contains four main diversions. The Faro Valley Interceptor Ditch (FVID) and the Faro Creek Diversion (FCD) were constructed to facilitate development of the Main Pit. The North Wall Interceptor Ditch (NWID) and the Rose Creek Diversion (RCD) were constructed to allow the construction of the tailings impoundment within the Rose Creek valley.

Leakages from the FVID and FCD represent a significant component of the total inflow to the Main Pit. Leakage, as defined herein, encompasses water that infiltrates the bottom and sides of a ditch, together with groundwater that originates within the ditch's catchment that subsequently flows below the ditch. The combined leakage from the FVID and FCD was estimated indirectly by subtracting local runoff generated by the Main Pit's incremental catchment from the total inflow to the pit (but excluding contribution from the Zone II Pit). The local runoff comprises net precipitation on the pit's lake and runoff generated by the area above the lake and below the two ditches. The magnitude of the local runoff was estimated using the estimation techniques described in Sections 3.1.3.1 and 3.1.3.3. The estimated average annual combined leakage from the two ditches worked out to about 34 L/s, or about 20% of the total runoff generated by the catchments

controlled by the two ditches. Expressed another way, the FVID and FCD have a combined efficiency of 80%.

Insufficient data were available to estimate the efficiencies of the NWID and the RCD. As determined in the previous section, the total average groundwater inflow to the Rose Creek Tailings Facility and its underlying aquifer is substantial at 148 L/s. Owing to the large size of catchments controlled by the NWID and particularly the RCD, leakages from these two diversions must contribute a sizable proportion of the 148 L/s groundwater inflow.

Receiving Streams

The flows in the receiving streams were estimated using the records of two long-term streamflow gauging stations at the Faro mine development, namely R7 and X14. The former station is representative of natural conditions, unaffected by mining operations. The latter is located on Rose Creek downstream of all mine development and, accordingly, has been influenced to some degree by the Faro mine.

These two streamflow records were employed in two different ways to estimate the monthly flow record at ungauged locations for the period from January 2005 to December 2007. The method used in all but one case involved transposing the R7 flow record to the point of interest. The transposition was achieved by scaling the R7 flows according to the ratio of average annual flow at the point of interest to the average annual flow at R7. The estimates of average annual flow were obtained from the regional relationship between MAR and median elevation presented in Figure 3.1-15. This technique was used to characterize the runoff generated by Subcatchments A, B, I and J on Figure 3.1-20. Station R7 controls a large proportion of Subcatchment B.

Subcatchment G represents a substantial proportion of the intervening catchment between Stations R7 and X14. Accordingly, as a first approximation, the difference in flows at the two stations could be used to represent the runoff generated by Subcatchment G. This first approximation was improved by subtracting contributions from the mine development that enter the Rose Creek system between R7 and X14. Two checks were made on the estimated flow record for Subcatchment G. Figure 3.1-30 presents the results of the first check. The red line represents the flow record adopted for the historical water balance. The blue line shows what the flow record would have been if the method adopted for Subcatchments A, B, I and J had been applied (i.e., transposition of the R7 flow record). Except for May 2005, the two techniques provide similar estimates of monthly flow for Subcatchment G.

The second check made use of a series of direct flow measurements made at the inlet of the Rose Creek Diversion Channel (RCDC). This point gauges a substantial proportion of the flow generated by Subcatchment G combined with the flows from the North Fork of Rose Creek. The flow measurements at the diversion inlet were correlated with the coincidental flows at Station R7 (see bottom plot of Figure 3.1-25). This correlation suggests that the flows at the inlet of the RCDC should be approximately 2.19 times greater than the flows measured at R7. The adopted method for estimating Subcatchment G flows result in flows at the entrance to the RCDC that are in reasonably close agreement with the correlation presented in Figure 3.1-25.

As described in Section 3.1.4.1, an interpretation of a synoptic field investigation in October 2004 (Robertson GeoConsultants Inc., 2005) was used to estimate some of the outflow components for the RCTF water balance. This same investigation also provided important information on groundwater conditions at Station X14. Based on observed continued increases in flow in the reach of Rose Creek downstream of Station X14 during the synoptic study, it was determined that the alluvium at X14 was probably conveying a substantial flow. The estimate provided in the Robertson GeoConsultants Inc. report of 230 L/s was used to represent groundwater flow at Station X14 in the 2005 to 2007 historical water balance.

3.1.4.2 Vangorda Creek Catchment

Figure 3.1-31 provides the flowsheet used to represent average conditions in the Vangorda Creek catchment during the period 2005 to 2007. The conventions used in developing the flowsheet for the Anvil Creek catchment were adhered to in developing the flowsheet for the Vangorda Creek catchment. The focus of the flowsheet was to examine sources of flow at two key receiving points within the catchment: Vangorda Creek at V27 and Vangorda Creek at V8.

As with the other flowsheet, the basic building block was the subcatchment area. The Vangorda Creek was subdivided into eight subcatchments, as dictated by the locations of diversions, open pits, waste dumps, and the two key points noted above. The subcatchments are labelled with capital letters (K to R) to aid in the cross referencing of figures and tables. The boundaries of the eight subcatchments are shown on Figures 3.1-1 and 3.1-3. Table 3.1-10 provides details of the subcatchments, including drainage area and median elevation.

The flowlines shown on Figure 3.1-31 were judged to be of importance because they were either associated with a large flow rate or had the potential to convey a large contaminant loading.

Vangorda Pit

The reconstructed water balance for the Vangorda Pit is illustrated on Figure 3.1-32. Like the Main Pit, the volume of water pumped from the Vangorda Pit was not directly measured. However, since the volumes of water withdrawn from the pit represent the dominant component of the water balance, it was still possible to develop an accurate inflow record for the pit. The same method of deriving the Main Pit water balance was followed in reconstructing the Vangorda Pit water balance.

The top plot of Figure 3.1-32 presents the measured water level in the pit. As can be seen, pit dewatering took place only during one summer over the three-year study period. As a result, the water balance for this pit probably has a higher accuracy than was achieved for the Main Pit. The bottom plot on Figure 3.1-32 presents the reconstructed record of pit inflows. The net inflow rate for most months was simply set equal to the change in pit storage during the given month. For the three months where this estimation technique was not applicable, the net inflow rate was estimated using a correlation between pit inflow rate and monthly average discharge at the streamflow gauging station on Vangorda Creek (29BC003). The correlation (not shown) was based only on estimated net inflows for those months that did not experience pit dewatering.

The middle plot presents the estimated pit dewatering record. For the three months of significant pit dewatering, the withdrawal rate was estimated by application of the continuity equation (i.e., net pit inflow + dewatering of Little Creek Dam – change in pit storage). For the one month of minor pit dewatering (May 2005), the estimated dewatering rate was estimated from pump hours and the estimated average withdrawal rate over the succeeding three months.

The estimated average annual inflow volume to the Vangorda Pit is 370,000 m^3, or about 26% of the inflows to the Main Pit. This estimate excludes the flows pumped from the Little Creek Dam to the Vangorda Pit.

Grum Pit

Figure 3.1-33 illustrates the reconstructed water balance of Grum Pit. This was the most straightforward water balance to prepare because the pit was allowed to fill throughout the period January 2005 to December 2007 (see top plot of Figure 3.1-33). Indeed, no withdrawals have yet been made from the pit since the cessation of mining activities in 1998.

Because no pit dewatering occurred, it was only necessary to use a single technique to estimate net inflows for all months of the three-year study period. The net inflow for a given month was set equal to the increase in storage volume for that month.

The estimated average annual inflow to the Grum Pit is 340,000 m^3, a volume very similar to the average annual inflow to the Vangorda Pit.

Vangorda and Grum Waste Dumps

As was done for the Faro mine development, the estimation of waste dump drainage at the Vangorda Plateau required a mix of techniques. To estimate runoff from the Vangorda Waste Dump, a water balance was prepared for the collection pond that receives drainage from this dump, which is known as the Little Creek Dam (LCD). The water balance was constructed in a similar fashion as was done for the four open pits. The volumes of water pumped from the LCD to the Vangorda Pit were inferred from changes in storage within the LCD during months in which the pumping occurred. This technique can be expected to provide reasonably accurate estimates of outflow because the withdrawals were typically made in the summer when inflows to the pond are small. In this case, the change in storage over the month is virtually all attributable to the water pumped from the pond. Figure 3.1-34 presents the storage, outflow and inflow components of the LCD.

The average annual net inflow to the LCD is approximately 48,000 m^3. The LCD controls a total area of 0.72 km^2, including the contributions from the collector ditch that runs along the southern side of the Vangorda Waste Dump. The average annual net inflow volume suggests that the average annual yield of the Vangorda Waste Dump is approximately 67 mm, which is less than the estimated yields of the Faro Waste Dumps. There are several potential reasons that the yield of the Vangorda Waste Dump is lower than that of its counterparts at the Faro mine. Firstly, the collector ditch around the waste dump may be experiencing significant leakage, including groundwater flows that pass below the ditch. Secondly, the water content of the waste dump may not have yet reached a quasi-steady state. Thirdly, the oxidation processes in the waste dump may be particularly vigorous and are generating more heat than at the Faro Waste Dumps, thus causing more evaporation of infiltrated water.

For the purpose of reconstructing the historical water balance, the assumption was made that the true average annual yield of the Vangorda Waste Dump is 100 mm, or a value similar to what was observed for the Faro Waste Dumps. The difference between the assumed total yield and the water that ended up in the LCD pond was assumed to represent leakage, both from the waste dump's collector ditch and the LCD itself. These leakages are represented as dashed lines on Figure 3.1-31.

A two-component mixing model was used to estimate drainage from the Grum Waste Dump. The model was applied to the water quality monitoring station V27, located on Vangorda Creek just upstream of Shrimp Creek. As was done for Faro, dissolved sulphate was selected as the tracer. Gaps in the sulphate record at V27 were patched using a correlation between coincidental V27 and VGMAIN sulphate concentrations. Water quality data at Station V1, located upstream of the entrance to the Vangorda Creek Diversion, was used to characterize background concentrations. Missing data in the V1 record were patched using a correlation between V1 sulphate concentration and coincidental monthly average flow at Station 29BC003. The flow-weighted average concentration for the Grum Dump drainage was estimated from data collected at surface and groundwater monitoring stations located along the toe of this dump. Spot measurements of flow at V27 collected since 1993 were used to transpose the 29BC003 flow record to the V27 site. The results of applying the two-component model at V27 are presented in Figure 3.1-35.

The estimated average annual discharge from the Grum Dump is 6.3 L/s. This corresponds to an average annual yield of about 100 mm, which is comparable to the estimates of yield made for the Faro Waste Dumps.

A partial validation of the inferred Grum Dump flows was made using a record of flows collected at a triangular weir on old Grum Creek below the toe of Grum Dump. The catchment controlled by this weir is estimated to be roughly half of the total footprint of the Grum Dump. Accordingly, the flows at this weir would be expected to be roughly half of the total runoff emanating from the Grum Dump. The station was operated during the open water seasons in the period January 2005 to December 2007. Figure 3.1-36 presents the complete stage and flow records for this station. A visual comparison indicates that the flows measured at the weir are, as expected, roughly half those inferred from the two-component mixing model.

The weather station operated on Grum Dump offered an opportunity to estimate the yield of the Grum Dump based on a climatic water balance. The estimated MAP and MAET at this weather station are 369 mm and 246 mm, respectively. An estimate of the yield of the waste dump can be obtained by subtracting MAET from MAP, which works out to 123 mm. There are at least three potential reasons why the yield estimate provided by the climatic balance is higher than the estimate obtained from the two-component mixing model. Firstly, the estimate of MAP may be too high or the estimate of MAET too low. Secondly, the Grum Dump may still be wetting up and therefore is not discharging as much water as it ultimately will once the dump's field capacity has been reached. Thirdly, the sulphate concentration assigned to the waste dump drainage may be too high in the mixing model calculations, thus resulting in an underestimation of actual dump discharge.

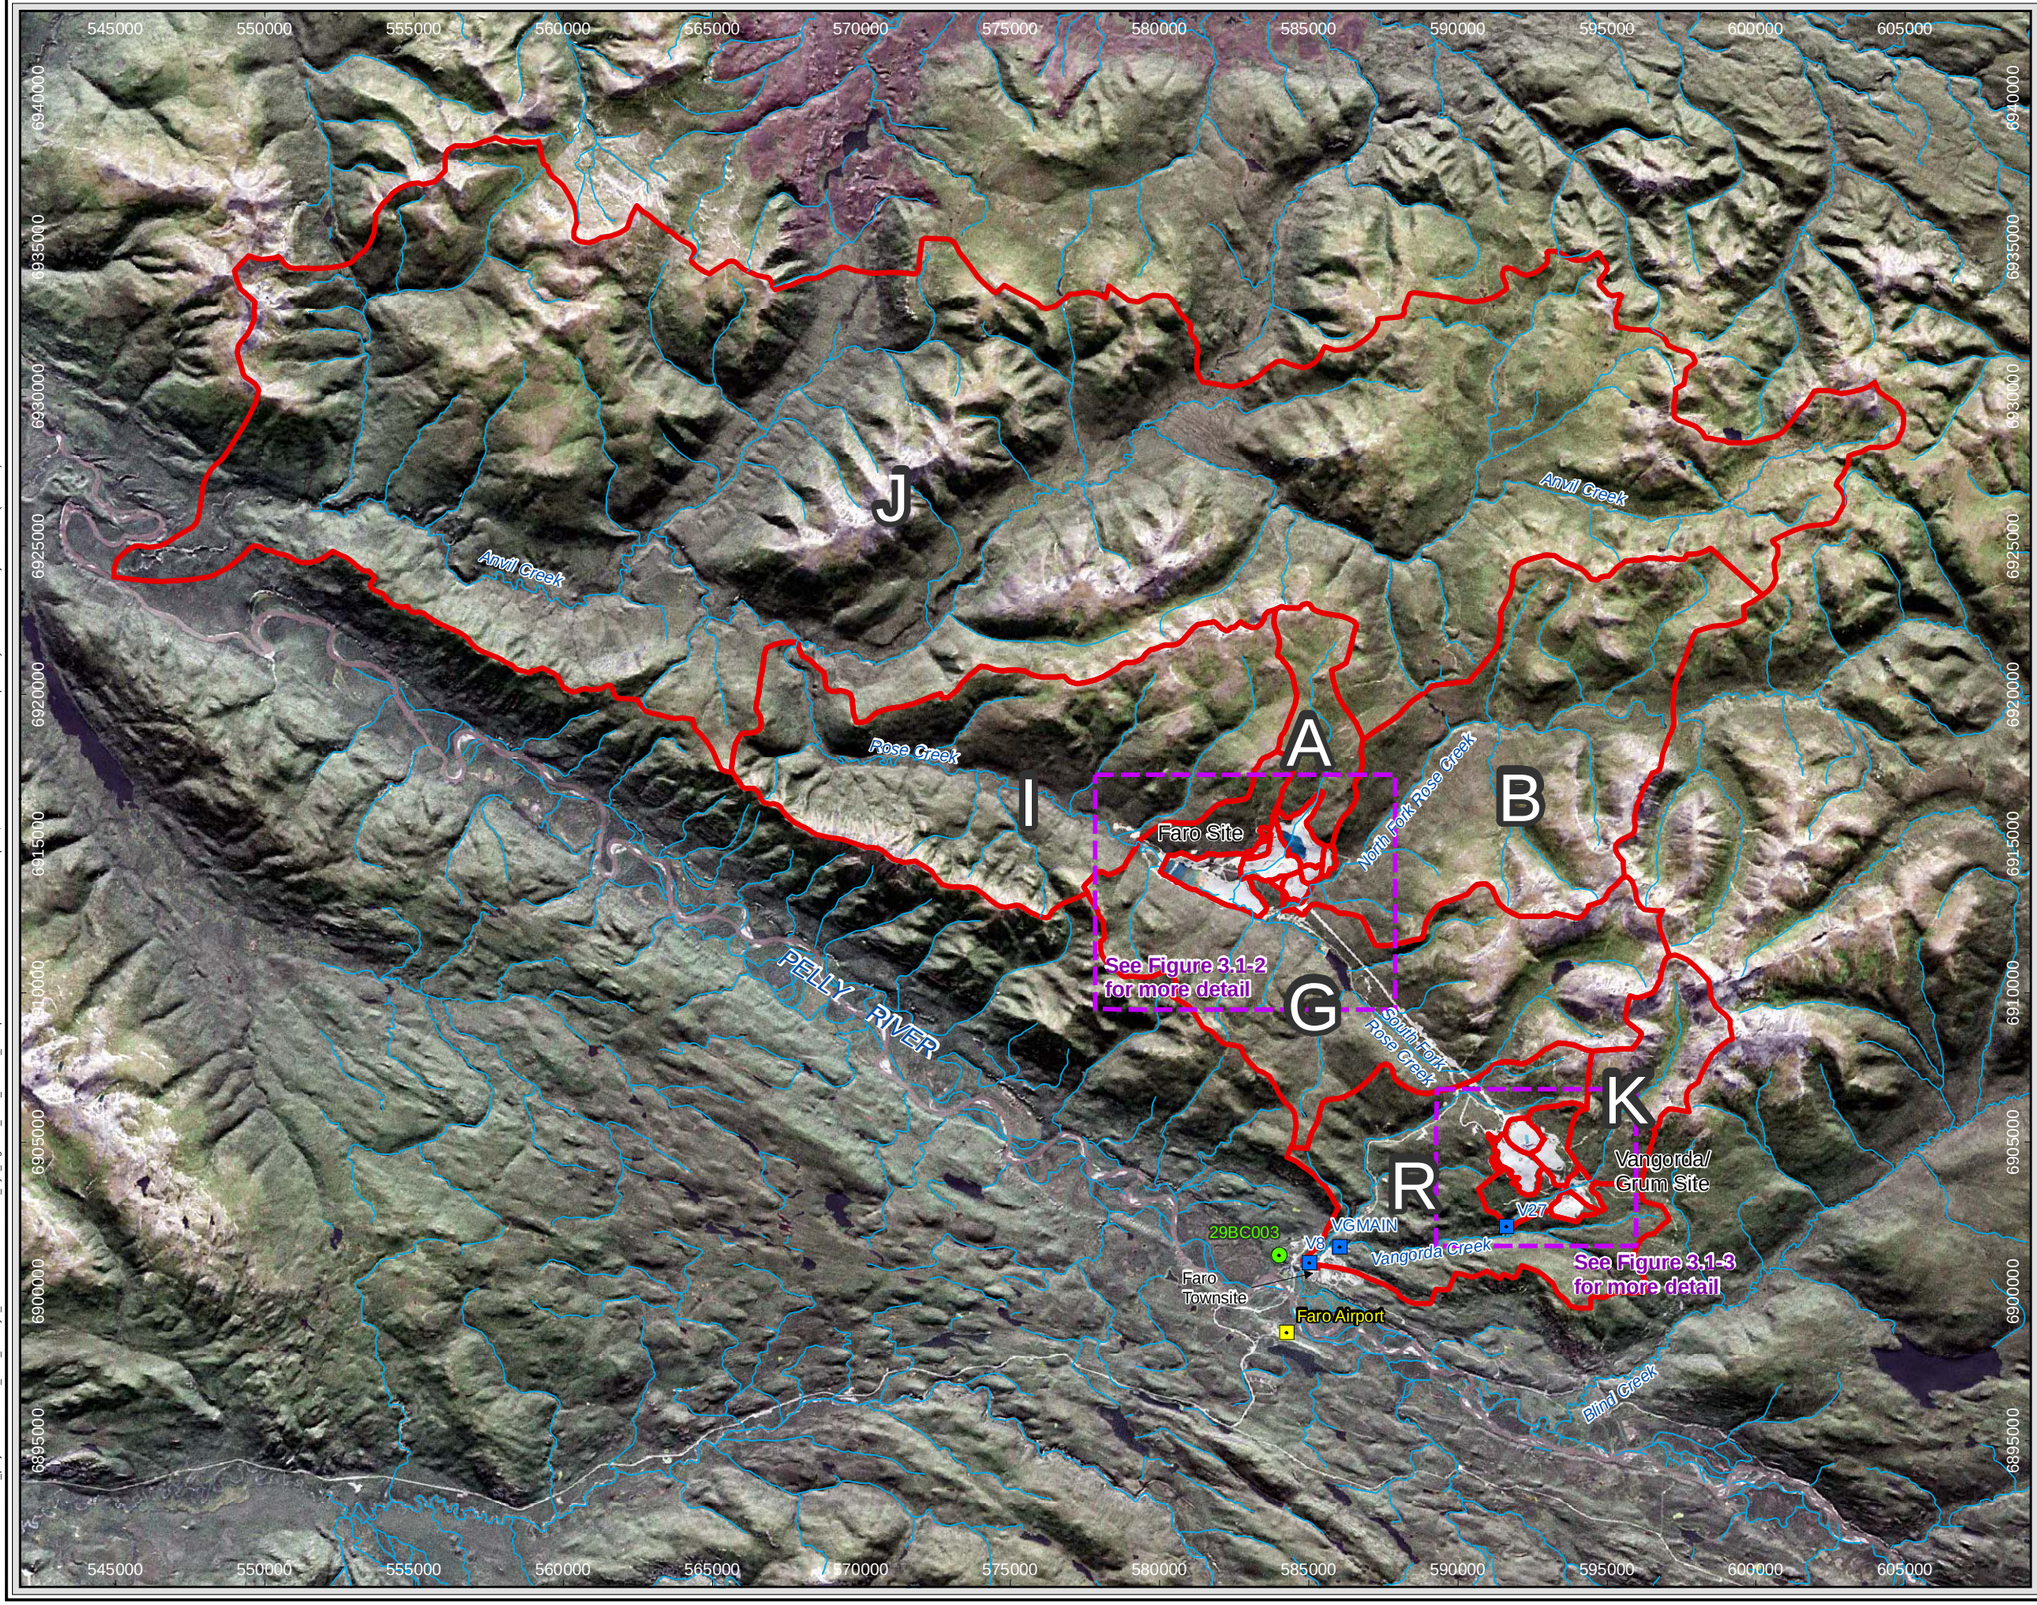
Diversions

Many diversion and interceptor ditches have been constructed at the Vangorda Plateau minesite. Three of these have had significant influence on the water balance of the mine. The Vangorda Creek Diversion (VCD) and the Vangorda Northeast Interceptor Ditch (VNEID) were constructed to facilitate the development of the Vangorda Pit. The Grum Interceptor Ditch (GID) was developed to minimize inflows to the Grum Pit.

The combined leakage from the VCD and the VNEID was estimated by following a similar approach as was used to infer the amount of leakage from the Faro Creek Diversion to the Main Pit. The estimated local runoff from the Vangorda Pit was subtracted from the estimated total inflow to the pit. Of the 370,000 m^3 of water that inflows to the pit each year on average, approximately 225,000 m^3 of this was attributed to leakages from the VCD and the VNEID. This works out to an average annual flow rate of 7.1 L/s.

The procedure outlined above was also applied to the GID for the purpose of estimating its contribution to the total inflows of the Grum Pit. In an average year, some 340,000 m^3 of water accumulates in the pit. Approximately 35% of this total, or 3.9 L/s, can be attributed to ditch leakage from the GID.

Receiving Streams



Construction of the historical water balance required records of monthly flows at key locations within the Vangorda Creek catchment spanning the period January 2005 to December 2007. For ungauged locations, this was achieved by transposing a measured record to the point of interest. The transposition was achieved in the same manner as used in the Anvil Creek catchment – the flows from the measured station were scaled by the ratio of average annual flows at the ungauged and gauged locations. Estimates of average annual flows were obtained from the regional relationship between MAR and catchment median elevation described in Section 3.1.3.3. The measured flows were provided by the government-operated gauging station on Vangorda Creek (29BC003).

The technique outlined above was used to estimate the flows generated by Subcatchments K, N, Q and R (see Figure 3.1-31). There are two pieces of evidence to suggest that the technique underestimates flows generated by the headwaters of Vangorda Creek (i.e., Subcatchment K). Firstly, as already presented in Section 3.1.3.3, a new gauging station was established in the headwaters of Vangorda Creek in 2008 (Station V1). A preliminary estimate of MAR for this station was discovered to be significantly greater than would be predicted by the relationship adopted to estimate MAR (see Figure 3.1-15).

The second piece of evidence was related to the record of spot measurements collected at V27. A correlation was performed between V27 flows and coincidental 29BC003 flows as a preparatory step in applying the two-component mixing model to Station V27 (see Section 3.1.4.2). This correlation also indicated that the flows in upper Vangorda Creek may be underestimated. The flowsheet for Vangorda Creek (Figure 3.1-31) shows the mean annual discharge at V27 to be 0.22 m^3/s. The correlation between V27 and 29BC003 flows (not shown) would suggest the flow should be higher at about 0.25 m^3/s.

Despite the evidence presented above, no alterations were made to the estimates of flow in the upper Vangorda Creek, largely because the evidence is based on either a short record (V1) or intermittent data (V27). After one or two more years of data collection at Station V1, changes to the estimated headwater flows may become warranted. If the estimated discharges in the headwaters are increased, then an offsetting decrease must be made in the estimated flows of lower Vangorda Creek. This is required so that the sum of the flows from the headwater and lower regions of Vangorda Creek are consistent with the measured flows at Station 29BC003, near the mouth of this stream.

The average annual flow at Station V8 during the period 2005 to 2007 was approximately 0.50 m^3/s. Over this same period, the measured flow in the Pelly River just below Vangorda Creek (Station 09BC004) was 210 m^3/s. Thus, Vangorda Creek contributed approximately one quarter of 1% of the flow in the Pelly River.

09BC004 - 09BA001 - 09BA002 (Middle Pelly River catchment)		1986 - 1994 [2]	9830	1200	63	202
09BB002 - 09BB001 (MacMillan R. catchment excluding headwaters)		1984 - 1995 [2]	12803	1100	115.3	284

Notes: 1) The Water Survey of Canada has not yet published official values for the catchment areas of these two new stations. The values presented in this table were measured from 1:250,000 scale topographic maps.

2) This is the period of overlap of the station records used to estimate the runoff from the incremental catchment.

Table 3.1-2 ARMC Flow Monitoring Network

Flow Monitoring Station		Period of Stage Monitoring	Drainage Area (km^2)	Control	No. of Direct Discharge Measurements	Comments
ID No.	Name					
R7	North Fork of Rose Creek above Faro Creek Diversion	1996 to present (year round)	95	Channel	57	The record of direct discharge measurements (by current meter or salt dilution) extends back to 1989, and includes measurements made during winter months.
FDU	Inlet of Faro Creek Diversion	2007 to present (open water)	14.3	Channel	6 since 2008	The baseline hydrology study only made use of the stage and discharge data collected during 2008.
X2	North Fork of Rose Creek at mine access road	2005 to 2007 (open water)	120	Channel	9	Only the direct discharge measurements were used in baseline hydrology study. The stream stage was monitored seasonally during open water.
RCDC	Inlet of Rose Creek Diversion Channel	2004 to present (open water)	197	Channel	10	Daily manual staff gauge readings are made during open water season.
FCS-4	Mouth of Faro Creek Canyon	Sep 2005 to Oct 2006 (year round)	1.8	Sharp-crested weir	18	This station monitors flow from remnant section of Faro Creek that lies downstream of Main Pit and is largely buried by waste dumps. Most of the direct flow measurements were made by bucket and stopwatch.
X5	Controlled releases from Cross Valley Dam	Water level in pond has been monitored since at least 1999 (typically on a weekly basis)	n/a	Siphon	13 in period 2005 to 2007	Site personnel maintain records of pond level, operating period of siphon, and percentage opening of siphon valve. These data, together with spot measurements of flow below siphon outlet, were used to develop an empirical relationship for estimating outflow rate from the siphon.
X13	Combined seepage from Cross Valley Dam	1986 to present (year round at weekly interval)	n/a	Sharp-crested weir	3 in period 2005 to 2008	Investigations have demonstrated that the valley aquifer continues to discharge downstream of Station X13.
X14	Rose Creek below Rose Creek Diversion Channel	1990 to present (periods of both year-round and seasonal operation)	232	Channel	121	The stage record has many gaps, due either to malfunction of monitoring equipment or seasonal operation of station. Record of direct discharge measurements extends back to 1988.
V1	Vangorda Creek above Blind Creek Road (and above inlet of Vangorda Creek Diversion)	Jun 2008 to present (open water)	18.7	Channel	7	This station is located about 120 m upstream of where the water quality samples are taken for Station V1.
n/a	Grum Creek above road crossing	2005 to 2007 (open water)	0.82	Sharp-crested weir	4	The boundary of the catchment controlled by this station is uncertain because most of the contributing area is buried in waste rock. The weir is located approx. 600 m downstream of where Grum Creek emerges from the toe of the Grum Dump.
V27	Vangorda Creek above Shrimp Creek	None	29.7	Channel	15	Spot measurements are made at this site as part of a biological and sediment monitoring program conducted on Vangorda Creek every second year.
V8	Vangorda Creek above fan apex (approx. 850 m upstream of Pelly River)	1990 to 1992, 1999 to present (open water)	90.5	Channel	59	Station V8 is located approx. 1.9 km downstream of the streamflow gauging station operated by Environment Yukon (29BC003). Owing to their close proximity, the two stations monitor very similar flow rates. The baseline hydrology study relied mostly on the data collected at Station 29BC003 because of that station's longer and more complete data record.

Table 3.1-3 Details of Regional and Site-Specific Climate Stations

Station Name	Period of Record	Elevation (m)	Mean Annual Precipitation (mm)	Authority [1]	Information Applicable to Study
Anvil	1967 - 1991	1158	368	MSC	Precipitation
Faro Airport	1978 - 2007	717	313	MSC	Precipitation
Faro Dump	Dec 2003 - 2007	1225	357	EY	Humidity/ air temperature/ solar radiation/ rainfall/ snowpack depth
Grum Dump	Dec 2003 - 2007	1220	369	EY	Humidity/ air temperature/ solar radiation/ rainfall/ snowpack depth
Mayo Airport	1925 - 2007	504	306	MSC	Humidity/ air temperature
Pelly Ranch	1951 - 2007	454	310	MSC	Pan evaporation
Rose Creek	1975-85 & 2005-07	1080	n/a	EY	Snowpack depth and density
Ross River Airport	1962 - 1994	705	264	MSC	Precipitation
Whitehorse Airport	1942 - 2007	706	261	MSC	Humidity/ air temperature/ solar radiation/ pan evaporation
Williams Creek	1994 - 2005	850	~350	EY	Humidity/ air temperature/ solar radiation

Note: 1) MSC = Meteorological Service of Canada; EY = Environment Yukon

Notes: i) For open water periods, a monthly average was only calculated for months with a maximum of 3 days of missing data. This criterion was relaxed for winter months, when flows undergo a slow recession.

ii) The flows in the winters of 1990/91 and 1991/92 include process water releases from the concentrator. Tailings deposition in the Faro Pit and process water recycle had not yet been implemented at the mine.

iii) Ice conditions can cause a significant alteration in the stream's relationship between stage and discharge, particularly during the occurrence of ice jams. Before estimating this monthly record, the computed daily flows were subjected to a screening process to identify erroneous data caused by ice conditions. However, some errors may still exist. Caution should be exercised when using the winter flows to characterize the low flow regime of Rose Creek, particularly for those periods when no or limited direct measurements are available to validate the flows computed from the pressure transducer readings.

iv) No complete months of data are available for Years 1998 and 2003.

Table 3.1-11 Estimated Flow-Weighted Average Sulphate Concentration for Waste Dumps Draining to North Fork

Item	Units	Northeast Waste Dump	Zone II Pit Waste Dump	Intermediate Waste Dump	Total
Stations used to characterize SO4-D concentrations emanating from waste dumps	n/a	NE1, NE2, W5, BH-12, BH-13 and BH-14	X26	S1, S2 and S3	n/a
Arithmetic average of SO4-D concentrations from above list of stations (C)	mg/L	508 [a]	2835	2914 [a]	n/a
Planimetric area of waste dump within catchment of North Fork (A)	km^2	0.44	0.33	0.74	1.51
Estimated proportion of waste dump effluent that reaches North Fork (f)	%	100	16 [b]	100	n/a
Effective catchment area draining to North Fork = A x f	km^2	0.44	0.05	0.74	1.23
Weighted concentration = C x A x f	$mg/L\text{-}km^2$	224	150	2156	2530
Estimated flow-weighted average SO4-D concentration	**mg/L**				**2052** [c]

Notes: a) The estimation of the average SO4-D concentration was a two step process. Firstly, an average concentration was computed for each water quality station listed in the first row of the table, using all SO4 determinations made during 2006. Secondly, an average of the station averages was determined to estimate typical quality of water discharging from the given waste dump.

b) The long-term average volume of water pumped from the Zone II Pit to the Main Pit is 1.6 L/s, based on reconstruction of this pit's historical water balance from 2005 to 2007. Based on application of Darcy's Law, the estimated seepage from the Zone II Pit to the North Fork is approximately 0.3 L/s (2005/06 Task 20e report prepared by SRK and RGC). Thus, the estimated proportion of total waste rock dump effluent discharging to North Fork = 0.3/(1.6 + 0.3) x 100 = 16%.

c) All waste dumps were assumed to generate the same average annual yield. Accordingly, effective catchment area could be used as a proxy for flow rate. To obtain a flow-weighted average concentration for all waste dumps draining to the North Fork, the concentration from each of the three waste dumps was weighted according to effective catchment area (i.e., Σ (C x A x f) / Σ (A x f)). For purpose of two-component mix model, the flow-weighted outflow concentration was assumed to remain constant year round and not exhibit an increasing trend over the period January 2005 to December 2007.

Attachment 6F-3
Fiscal Year 2012 Water Modelling Analysis Report (Section 2)

SECTION 2

Surface Water Flow Modelling

2.1 Surface Water Modelling Objectives

The FY12 objective of the SW flow modelling task was to develop a dynamic hydrological model of the FMC that would be used to provide a better understanding of the FMC hydrological characteristics and support FMC future design and investigation activities. A number of FMC design and investigative activities will be supported by the SW modelling efforts including, but not limited to:

- Stream channel diversion designs
- Regulatory-related information for the Yukon Environmental and Socio-economic Assessment Board (YESAB) project proposal
- Geochemistry and water quality evaluations
- Hydrogeology and GW interceptor designs
- Waste piles and tailings hydrology evaluations
- Water treatment evaluations
- Dam design and other major structures evaluations
- Environmental monitoring and reporting
- Revegetation and reclamation evaluations

Building on the CSM Report (CH2M HILL, 2012), the SW flow models have been used to define precipitation-runoff processes throughout the FMC. Existing physical site characteristics, meteorological data, and SW flow monitoring data were used to develop and calibrate the models. The models were then used to assist in characterizing the occurrence, conveyance, and management of SW within the FMC under varying assumptions of land use and meteorological conditions.

The main objective of the current SW flow modelling effort is to develop a calibrated tool that can be used to simulate precipitation-runoff processes from the FMC on a continuous, multiyear simulation basis. The focus of this model is to simulate the timing and magnitude of runoff events throughout the year, ranging from low-flow (i.e., base flow) conditions to peak flow conditions that occur during the spring freshet.

In addition to development of the hydrological model, the FWMT team is also currently completing hydraulic analyses of portions of the FMC, including the Rose Creek Diversion (RCD) and Cross Valley Dam (CVD). These analyses, including details related to hydraulic model development and results, are included in separate documents.

2.2 Surface Water Modelling Approach

The following tasks summarize the overall approach used to develop continuous SW flow models for the FMC:

1. Gathering and processing available information
2. Delineating regional and local FMC SW catchments
3. Developing SW flow models
4. Calibrating SW flow models

The following sections provide details regarding each of the modelling approach tasks.

2.3 Surface Water Data Sources and Review

2.3.1 Available Data and Sources

The development of a hydrological model involves three main categories of data. The first category consists of meteorological data, which are used to characterize precipitation processes including rainfall distribution and intensity, snow accumulation, and snowmelt. The second category consists of input data related to the definition of the catchment's physical characteristics, and the third category consists of flow data, which are used to calibrate precipitation-runoff processes that are derived from the first two categories of data.

Development and calibration of a hydrological model requires coincident meteorological and SW flow data. A preliminary review of available SW flow and meteorological data for the FMC indicated that the most suitable record of coincident data was available from approximately 2000 to present; therefore, compilation and analysis of data for the current SW flow model development effort focused on this timeframe, as described herein.

2.3.1.1 Meteorological Data

Meteorological data are available for two FMC stations that are operated by the site care and maintenance contractor. These stations are referred to as the Faro and Grum Dump stations, both of which were installed in 2003 and record the following parameters:

- Air temperature
- Relative humidity
- Incoming, outgoing, and net radiation
- Wind speed and direction
- Rainfall
- Snow depth
- Soil moisture
- Soil temperature and heat flux

In February 2008, instrumentation to record total precipitation (i.e., rainfall and snowfall) was added to each FMC meteorological station. Processed hourly data for the two stations; however, substantial gaps were identified in the data sets, as later sections of this report describe.

In addition to the Faro and Grum Dump stations, data were compiled from a station operated by Environment Canada at the nearby Faro Airport. Precipitation and air temperature were key parameters from this station that were used to develop the hydrological model. Figure 2-1 illustrates the locations for each of the aforementioned meteorological stations.

2.3.1.2 Surface Water Catchment Physical Data

Definition of physical catchment parameters includes data related to subcatchment area, vegetation cover, and subsurface soil conditions. These data are used to support the simulation of water cycle processes, including evapotranspiration (ET), evaporation, and infiltration. General geological mapping is available for the regional area; however, detailed information on vegetation and soil conditions for the FMC is limited, especially for the upper reaches of the regional catchment area. Available data were incorporated into the initial catchment parameterization, which formed the basis from which the calibration process was completed. Subsequent sections of this report provide details about physical catchment parameters.

2.3.1.3 Flow Monitoring Data

The following locations, shown on Figure 2-2, provide continuous flow monitoring within the Rose Creek drainage basin:

- FCD-1 at the head of the Faro Creek Diversion (FCD)
- R7 in the North Fork Rose Creek (NFRC) upstream from the FMC
- X2 in the NFRC upstream from the tailings facility

- X14 in Rose Creek, downstream from the tailings facility
- X23/FCS-1 below the Faro Valley waste rock dump (WRD)

The following locations, shown on Figure 2-2, provide continuous flow monitoring within the Vangorda Creek drainage basin:

- V1 in Vangorda Creek, upstream from the Vangorda Pit
- V8 in Lower Vangorda Creek at the footbridge
- V27 in Vangorda Creek, upstream from the confluence with Shrimp Creek

In addition to operating continuous SW flow monitoring stations, the care and maintenance staff have implemented a field program that includes collecting spot-flow measurements at various locations throughout the FMC monthly during the ice-free season. Data from this monitoring program were also incorporated into the development and calibration of the FMC hydrological models.

2.3.2 Data Review

Available physical catchment, meteorological, and flow data were reviewed in detail to determine the quality and suitability of this information for the development of the hydrological models. Observations and conclusions from this review are detailed in this subsection.

2.3.2.1 Faro Mine Complex Meteorological Station Data Review

The review of the FMC meteorological station data focused on the reported air temperature, rainfall, snow depth, and precipitation records.

Air Temperature Record

The air temperature records were reviewed from a data quality perspective, primarily to identify significant data gaps and to identify potential data errors through comparison with concurrent data recorded at the Faro Airport station. Based on this review, the air temperature data record for the Faro Dump and Grum Dump meteorological climate stations was determined to be stable and within climate normals for the region. Several significant gaps in the air temperature record were identified during this data review, primarily in the fall of 2008 and fall of 2009.

Rainfall Record

Both the Faro Dump and Grum Dump meteorological stations record rainfall. The rainfall record provided for these stations was reviewed for significant data gaps and extreme events significantly (i.e., greater than 30 percent) outside of climate normals. Outliers identified within the two records were compared with measurements recorded at the Faro Airport Station, regional climate normals, extreme events of record onsite, and records from the FMC continuous flow monitoring stations. Outliers were also compared to available reports that document extreme events at the FMC for the purposes of design work. Previous work indicates that the FMC can experience precipitation events greater than those recorded at the Faro Airport. For this analysis, events that were 30 percent greater than regional climate normals (as reported by Environment Canada at the Faro Airport Station) were flagged for further investigation. A decision was made whether to remove an outlier from the record only after further investigation and comparison with available data. This approach was deemed to be a reasonable approach for the purposes of constructing input data sets for the hydrological model. This review identified several data gaps and outliers requiring additional investigation.

Snow Depth Record

The Faro Dump and Grum Dump meteorological stations do not record snowfall in water equivalents but do record the total snow depth using an ultrasonic sensor. This record was reviewed to determine whether it was sufficient to estimate the contribution of snow to the total precipitation record at the FMC. The snow depth sensor record reports the depth of the snow pack hourly but does not report accumulated snowfall values. When processed to determine the hourly and daily accumulation of snowfall, negative values in snow depth accumulation are frequently reported. The negative values in the snow depth accumulation record were compared with the station's air temperature record to determine whether these events were potentially associated with melt events (i.e., when air temperature is greater than 0 degrees Celsius [°C]). In many cases, it

was determined that negative snow depth was not likely to have accumulated based on greater than zero temperature events. Therefore, the FWMT determined that this record contained too much variability and "noise" in the recorded data to accurately estimate the daily contribution of snow to the precipitation record.

Total Precipitation Record

Total precipitation (i.e., rain and snow) was not recorded at the FMC meteorological stations until February 2008. Total precipitation data, collected hourly between February 2008 and 2010, were obtained and reviewed. These data were processed to determine hourly and daily variations in total precipitation. Similar to the snow depth record, it was determined that negative hourly and daily precipitation totals were often included within the data set. Unlike the snow pack data, which could be influenced by melting conditions and therefore have negative values, total daily precipitation cannot be less than zero; therefore, the FWMT determined that this record could not be used for the development of the meteorological data input record.

In addition to reviewing the unprocessed meteorological data, the 2010 and 2011 FMC annual reports prepared by Denison Environmental Services (DES) were reviewed (DES, 2011, 2012a). These reports include daily total precipitation data and figures that illustrate hourly cumulative precipitation. These annual reports confirm the findings of the data review. The 2010 annual report identified that it is likely that the reported precipitation record is underestimating the total precipitation occurring at the FMC (DES, 2011).

2.3.2.2 Environment Canada Climate Database (Faro Airport Station)

A meteorological station is operated by Environment Canada at the Faro Airport. The location of this station is included on Figure 2-1. This station is located at elevation 717 metres (m), which is 508 m and 503 m below the Faro Dump and Grum Dump meteorological stations, respectively. Data from this station are available over a period between 1978 to present. To correspond with the period in which flow monitoring and meteorological data are available at the FMC, air temperature, rainfall, snowfall, and total precipitation data from the Faro Airport record, as well typical climate normals, were downloaded from Environment Canada. The data downloaded from this database are considered to be reliable because Environment Canada subjects field data to a quality control program prior to making the data available for download. The level of Environment Canada's quality review is documented within the data package.

The Faro Airport Station data set was reviewed for significant data gaps, as well as the station's suitability for filling data gaps in the FMC meteorological station data records. A large data gap in the FMC meteorological station data records was identified from 2002 to 2003, in addition to several month-long gaps. The Faro Airport record was compared to the Faro Dump and Grum Dump meteorological stations and was determined to be a suitable source for filling large data gaps within the FMC records.

2.3.2.3 Continuous Flow Monitoring Data

Continuous SW flow monitoring data were reviewed to determine their suitability for use in the hydrological model calibration. The location of the continuous flow monitoring stations is included on Figure 2-2. Table 2-1 summarizes the continuous SW flow monitoring data available and indicates years where significant data gaps exist during critical periods (e.g., spring freshet and significant precipitation events). The X marks that are highlighted in orange indicate years when gaps within the spring freshet and summer period exist, whereas rows that do not have an X mark indicate that no data are available at the given station in the given year. Rows with plain X marks indicate data that are adequate for model calibration.

2.3.2.4 Summary of Available Data

As discussed, developing and calibrating a hydrological model requires coincident records of meteorological and flow data. Based on the review of various data sources described, Figure 2-3 summarizes available coincident data.

2.4 Surface Water Model Construction

2.4.1 Surface Water Model Code Selection

Hydrological models of the FMC were developed using the United States Army Corps of Engineers (USACE) Hydrologic Engineering Center-Hydrologic Modeling System (HEC-HMS) Version 3.5 (USACE, 2010). This is a publicly available code that is widely used and is designed to simulate the precipitation-runoff processes of dendritic drainage basins. HEC-HMS is designed to apply to a wide range of geomorphic conditions and to solve a wide range of surface routing scenarios. The hydrological models were used to estimate SW runoff from the Rose Creek and Vangorda Creek drainage basins and from smaller subbasins within the FMC. Hydrographs produced by HEC-HMS will be used to forecast SW availability at downgradient locations of interest within the modelling domain.

2.4.2 Surface Water Model Domain

When developing hydrological models, the domain is defined by the overall catchment area tributary to the receiving point of interest. For the FMC, the domain is defined by flow monitoring station X14 in the Rose Creek drainage basin and by V8 in the Vangorda Creek drainage basin, as shown on Figure 2-4. Some catchment areas downstream from these monitoring stations were also delineated to account for all SW generated from the FMC. These regional basin delineations define the lateral boundaries for the SW flow models.

2.4.3 Surface Water Model Parameters

Using HEC-HMS, the FWMT developed a continuous hydrological model to simulate rainfall-runoff and snowmelt processes in both the Rose Creek and Vangorda Creek drainage basins under the existing FMC operational

conditions. The model was set up to compare runoff hydrographs at key locations in the system with available SW flow data. The calibration process involved adjusting subbasin parameters to best match the magnitude and duration of runoff events observed in the field.

The development of an HEC-HMS model includes selecting one or more meteorological models and one or more basin models. A meteorological model includes the air temperature and precipitation data, monthly ET, and snowmelt parameters that apply to a specific basin. A basin model is a physical representation of the watershed and may include elements such as: subbasins, channel reaches, storage elements, junctions, diversions, sources, and sinks. Subbasin elements are further defined by the various parameters that will affect runoff generation such as: surface and canopy losses, infiltration losses, precipitation-to-runoff transform methods, and base flow contributions. Channel reaches can be described using various geometries and hydraulic routing methods.

To analyze the FMC, two meteorological models were created: one for Rose Creek drainage basin and one for Vangorda Creek drainage basin. Four basin models were also created: one each for the Rose Creek and Vangorda Creek drainage basins during the winter period and one each for the Rose Creek and Vangorda Creek drainage basins during the summer period. The difference between the two meteorological models is reflected in the precipitation and melt-rate functions, whereas the difference between the two basin models for each mine site is related to the soil infiltration parameter.

The following subsections describe the processes applied to develop the input parameters for the HEC-HMS models. These parameters include the catchment area development, the meteorological record development (including air temperature, precipitation, evaporation and snowmelt data), and the physical catchment parameter development (including the precipitation loss parameters, runoff transform parameters, and base flow inputs).

2.4.3.1 Surface Water Catchment Development

The first step in the basin model development process was to delineate local FMC and regional catchments within the surface water model domain. Detailed light detection and ranging (LiDAR) data were available for the FMC, while only standard topographic information was available for the surrounding regional area. The elevation data for the FMC were collected at a resolution of 1 square metre (m^2) per pixel. The regional elevation data were not available at a similar resolution; therefore, the catchment development process was conducted in two stages.

LiDAR data were collected for the FMC on two separate occasions in 2012. These data provided a high-resolution data set of the FMC (1 m^2 per pixel). These data were used to develop a raster elevation data set, which was processed using the Flow Direction Spatial Analyst algorithm in ArcGIS Version 10.0. This resulted in a gridded data set that represents the flow direction from each raster cell to its steepest downslope neighbour. The flow direction data set was then processed using a Flow Accumulation Spatial Analyst algorithm to obtain a data set containing the accumulated flow in each raster cell. This process identifies likely SW drainage paths.

“Pour points,” representing known SW flow monitoring locations, were applied to the raster grid of SW flow paths. The ArcGIS tool calculated the boundaries for the area that is tributary to each pour point. The catchments were refined by repeating this process and adding or relocating pour points to reflect the known site conditions. Additional pour points were used to account for onsite conditions that may not have been reflected in the elevation data (e.g., culverts between catchments). This resulted in the delineation of a number of subdivided catchments to define onsite conditions. These were grouped together to form subcatchments reflecting the known site conditions. An attempt was made to select pour point locations and catchment boundaries that best fit the locations of continuous SW flow monitoring locations. This was done to better enable the calibration of the hydrological models using the existing SW flow records. The local catchments for the Faro and Vangorda/Grum areas are illustrated on Figures 2-5 and 2-6, respectively.

The most recent elevation model for the region surrounding the FMC predates the mining activity and is a lower resolution than the LiDAR data for the FMC. For this reason, the local FMC catchments were delineated first. The local FMC LiDAR data were merged into the regional elevation data to produce a hybrid elevation data set. This data set was processed as described in the previous section, resulting in a flow accumulation data set for the regional area, as well as the local catchments.

Pour points were selected in similar locations to those selected for the local catchment delineation exercise. In some cases, the same pour locations could not be used because of the differences in the pre- and post-mining elevations. The regional catchments were overlaid with those delineated for the FMC, and several iterations were performed until the regional catchment boundaries were optimized against the local catchment boundaries delineated earlier.

Where exact boundary matches were not made using the geographic information system (GIS) algorithms, manual adjustments were made using available topographic information and aerial photography. When combined with the catchments delineated earlier for the FMC, the final catchments represent the areas draining to pour points; these, in turn, represent continuous SW flow monitoring locations. Figure 2-7 shows the final catchments used to develop the hydrological model.

Figure 2-8 and 2-9 depict node diagrams illustrating the conceptual hydrological model development for both the Rose Creek and Vangorda Creek drainage basin model, respectively. These node diagrams illustrate the interconnection of various subbasins, as well as key routing elements included in the model.

The basin models developed for the analysis only included subbasins and channel reaches. Attenuation provided by overland storage has not been explicitly modelled by a distinct storage element. Section 2.5.4 provides a discussion supporting this decision, specifically for the Rose Creek drainage basin.

The Rose Creek model consists of eight unique subbasins covering an overall catchment area of 23,163 hectares (ha). Note that nine subbasins are included on Figure 2-5, but that Subbasin RC9 is downstream of continuous flow station X14 and is therefore not included in the current model domain. Subbasin RC1, which at 9,874 ha is the largest subbasin, was used as the main calibration subbasin for the Rose Creek model because continuous SW flow data are available at station R7. R7 is located at the downstream point of this subbasin. The discharge from the Faro Water Treatment Plant (WTP), which is a tributary to the CVD Polishing Pond, was included in the form of a constant monthly hydrograph and represents the input for Subbasins RC8a and RC8b.

The Vangorda Creek models consist of five unique subbasins covering an overall catchment area of 8,737 ha. Subbasin VC1, which is 2,007 ha, was used as the main calibration subbasin for the Vangorda Creek model because continuous SW flow data are available at station V1. V1 is located at the downstream point of the subbasin.

2.4.3.2 Surface Water Routing

A simplified approach to routing was applied to the development of the hydrological model. The following reaches were simulated in the Rose Creek model, as illustrated in Figure 2-8:

- NFRC between Station R7 and the Haul Road
- NFRC between Station X2 and the confluence with the South Fork
- Rose Creek Diversion Channel (RCDC)/Rose Creek between the confluence of the North and South Forks and Station X14

The following reaches were simulated in the Vangorda Creek model, as illustrated in Figure 2-9:

- Vangorda Creek Diversion Channel
- Vangorda Creek downstream of the Diversion Channel to Station V27
- Vangorda Creek between Station V27 and Station V8

For each reach, several cross sections were generated based on LiDAR data. From these reaches, a representative, or average cross section was developed. LiDAR is unable to penetrate water; therefore, for channels that had standing water, cross sections were extrapolated by a depth of 0.3 m below the constant plane that represents the water surface elevation. The longitudinal slope of the reach was also calculated based on LiDAR data. Cross sections are coarsely represented in HEC-HMS via eight points (i.e., distance-elevation coordinates) to include both the channel and the adjacent floodplain. A Manning's roughness coefficient of 0.03 was applied to all sections in the model.

The simplified routing approach applied to development of the HEC-HMS model is considered suitable for the current analysis because a more detailed hydraulic model will be developed in subsequent stages of the FMC project to which hydrographs generated from the hydrological model will be routed.

2.4.3.3 Air Temperature Record

Two temperature records were developed for the FMC: one based on data collected at the Faro Dump Station and another for data collected at the Grum Dump Station. The temperature record for input to the hydrological model must represent a continuous daily record for an entire calendar year. Data gaps identified during the review process were filled using several methods and a number of steps, depending on the type of data gap.

The first step was to fill gaps in the Faro and Grum Dump stations air temperature records with the air temperature recorded at the Faro Airport Station. Where there were gaps in the FMC meteorological station records, for which there was no coincident data recorded at the Faro Airport Station, data gaps were filled as follows:

1. Data gaps consisting of 1 week to 1 month of consecutive missing data were patched using average daily air temperature from the period immediately before and after the data gap period.
2. Data gaps consisting of no more than 6 consecutive days of missing data were patched using the air temperature from adjacent days keeping the trend before and after the missing data point(s). For example, if the air temperature trend is increasing before and after the missing data point, the higher of the two adjacent data points was used to fill the data gap.

Work completed by Lewkowicz and Bonnaventure (2009) investigated the influence of topography on permafrost distribution and ground surface lapse rates at various sites throughout the Yukon Territory (YT), including Faro. They found that, although summer air temperatures shows normal lapse rates close to the standard environmental lapse rate of -6.5 °C per kilometre (km), winter lapse rates were found to be inverted by as much as +11 °C per km. They concluded that air temperature trends in the YT are influenced by topography at a variety of scales, with significant seasonal differences. Given the lack of temperature data at various locations throughout the regional catchment area, combined with potential temperature lapse rate inversions, the proposed methodology of temperature record development is considered appropriate for the current model development. Figures 2-10 and 2-11 show the complete air temperature records for input to the hydrological model, indicating the data points from each source for the Faro and Grum Dump stations, respectively.

2.4.3.4 Precipitation Record

This section describes the methodology applied to the development of the precipitation data set. As with the air temperature record, the precipitation input to the hydrological model must be on a continuous daily basis for a calendar year. Because of the limitations of the rainfall and snowfall records discussed in Section 2.3.2, various methods were applied to construct a complete precipitation record for input into the hydrological model. The precipitation record consists of the rainfall and snowfall (as rainfall water equivalent) records which, when combined, represent the total precipitation on site. Two precipitation data sets were developed, one for each area of the site (Faro Dump and Grum Dump stations).

Rainfall Record

The preferred data source is data collected at the FMC meteorological stations. The data collected at the Faro and Grum stations were converted to daily rainfall totals and reviewed for data gaps, as discussed in Section 2.3.2. These gaps were filled using the daily rainfall record from the Faro Airport Station. In the *Faro Mine Complex Closure and Reclamation–Project Proposal, Current Environmental Conditions Supporting Document* (AECOM Canada Ltd [AECOM], 2009), relationships were developed between the Faro Airport Station and the Faro Dump and Grum Dump stations. These correlations indicate that the Faro Dump and Grum Dump stations receive 6.79 percent and 10.01 percent more rainfall, respectively, than the Faro Airport Station. These correlations are limited to rainfall occurring between May and September; as such, they were only applied to fill gaps in the FMC rainfall records for that timeframe. If rainfall occurred at the Faro Airport Station between October and April, the correlation was not applied, and the unchanged Faro Airport rainfall record was used to fill data gaps occurring during that timeframe. This was compared with the air temperature record to confirm that rainfall was plausible during this period based on air temperature. Figures 2-12 and 2-13 show the rainfall records developed for the Faro Dump and Grum Dump stations, respectively.

Snowfall Record

As discussed in Section 2.3.2, the Faro and Grum Dump stations do not record snowfall. AECOM (2009) compares snowpack water content at the Faro and Grum Dump stations with accumulated snowfall at the Faro Airport Station. This analysis indicated that the dumps receive about 25 percent more snowfall (as a water equivalent) than the Faro Airport. It is recognized that orographic effects and impacts of blowing snow influence snow accumulation at the FMC; however, information beyond that provided in the 2009 AECOM report is not available to better estimate such effects. Therefore, to construct a snow record at the Faro and Grump Dump stations, snow depth recorded at the Faro Airport was increased by 25 percent and applied to both stations.

The following assumptions were made while developing the snowfall (as water equivalent) record:

1. To convert the snowfall (reported in centimetres [cm]) recorded at the Faro Airport Station to water equivalents, it is reasonable to assume a snow density of 1 cm equals 1 millimetre (mm) of water equivalent.
2. Where snowfall data are missing for winter months, it is reasonable to patch the data with average-day snowfall from the period of record for the missing dates.
3. It is reasonable to assume that, when snowfall data are missing during summer months (i.e., June to September), no snowfall occurred.

Where gaps exist in the Faro Airport Station records, the average day snowfall was used to patch data gaps. Figure 2-14 illustrates the snowfall record developed for the FMC.

Total Precipitation Estimate

The rainfall and snowfall data sets developed, using the described methodology, were used to compile complete precipitation data sets for each of the two FMC meteorological stations. The precipitation data for the Faro and Grum stations at the FMC are shown on Figures 2-15 and 2-16, respectively. When these data sets were reviewed, several outliers were identified and are shown on these figures.

Outliers were identified through comparison with climate normals reported by Environment Canada for the Faro Airport Station. If an extreme event occurred that was not documented in the available site records, it was determined to be a likely outlier. Where possible, these events were compared with the available continuous flow monitoring data collected on the FMC. If a similar increase in SW flow was not reflected in the data, the event was corrected using rainfall and snowfall data from one of the nearby stations.

Table 2-2 compares daily precipitation estimates, developed as described, for the Faro and Grum areas of the FMC, with climate normals for the region as reported by Environment Canada. This table also presents the percent difference from the Faro Airport Station for each area of the FMC.

TABLE 2-2
Comparison to Climate Normals
Faro Mine Remediation Project

		FMC – Faro Area		FMC – Grum Area	
Description	**Faro Airport**	**Estimate**	**% Difference**	**Estimate**	**% Difference**
Average Yearly Rainfall (mm)	214	215	0	225	5
Average Yearly Snowfall (cm)	112	162	37	162	37
Average Total Precipitation (mm)	316	377	17	387	20
Extreme Daily Rainfall (mm)	24.8	28	11	29	14
Extreme Daily Snowfall (cm)	12.8	17	27	17	27

Notes:
Faro Airport climate normals are for 1971 to 2000.
FMC Area comparison values are for the data available between January 2000 and December 2011 (excluding 2001 and 2002).

Some differences between the Faro Airport and FMC are expected due to elevation and orographic effects. The precipitation record is considered a reasonable estimate for this modelling exercise if the total annual precipitation is within 20 percent of climate normals recorded at the Faro Airport Station. The average total precipitation is 17 percent for the Faro Dump Station and 20 percent for the Grum Dump Station. The average yearly rainfall depths for all three locations are consistent. The key difference between the Faro Airport and the FMC data sets is related to the snowfall estimate. Snowfall is expected to be approximately 25 percent greater at the FMC as water equivalent; however, because of the procedures used to patch data gaps, the total snowfall in units of cm is approximately 37 percent greater. Because the total annual precipitation numbers are within 20 percent of the climate normals, this was determined to be acceptable.

The extreme daily rainfall and extreme daily snowfall climate normals were used to determine the outliers, as previously discussed. The comparison to climate normals shown in Table 2-2 does not include the data points identified as outliers. The extreme daily rainfall for both the Faro Dump and Grum Dump stations are between 10 and 15 percent greater than those reported at the Faro Airport Station. The FMC extreme daily snowfall is approximately 27 percent greater than those reported at the Faro Airport Station.

2.4.3.5 Evapotranspiration Data

ET, expressed in terms of total depth per month, is a combination of evaporation from the ground surface and transpiration by vegetation. The monthly ET data used in the model were obtained from AECOM (2009), as summarized in Table 2-3 for the Rose Creek Model and the Vangorda Creek Model.

TABLE 2-3
Monthly Evapotranspiration Data
Faro Mine Remediation Project

Month	Rose Creek Model ET (mm)	Vangorda Creek Model ET (mm)
January	0	0
February	0	0
March	10	10
April	30	32
May	48	47
June	50	56
July	48	57
August	26	30
September	20	20
October	5	4
November	0	0
December	0	0

2.4.3.6 Snowmelt Parameters

A variety of parameters are required to define the snowpack accumulation and snowmelt processes that can be simulated by HEC-HMS. In response to the atmospheric conditions, this accumulation and melt is simulated, and the resulting liquid water available at the soil surface is available as a hyetograph for the subbasin.

The Temperature-Index method was used for snowpack simulation within HEC-HMS, which is an extension of the degree-day modelling approach. The degree-day approach typically applies a fixed amount of snowmelt for each degree above freezing. The Temperature-Index method instead allows for a dynamic computation of the melt rate based on current atmospheric conditions and past conditions of the snow pack, which improves the

representation of the ripening of the snow pack. Through use of a cold-content parameter, this method also allows for liquid water to potentially freeze as it enters the snow pack, a result of the snow pack's existing cold content. The following points describe the snowmelt model parameters according to HEC-HMS User's Manual:

- **Px Temperature (°C) = 1 °C.** The Px temperature is used to discriminate between precipitation falling as rain or snow. The discrimination temperature is usually 1 to 2 degrees above freezing.
- **Base Temperature (°C) = 0 °C.** The difference between the base temperature and the air temperature defines the temperature index used in calculating snowmelt. The melt rate is multiplied by the difference between the base temperature and the air temperature to estimate the snowmelt amount. If the air temperature is less than the base temperature, then the snowmelt is zero. Typically, the base temperature should be 0 °C or close to it.
- **Wet Melt Rate (mm/°C-day) = 4.2 mm/°C-day.** The wet melt rate is used during times of precipitation when the precipitation is falling as rain at rates greater than the rain rate limit. It represents the rate at which the snow pack melts when it is raining on the snow pack.
- **Rain Rate Limit (mm/day) = 1 mm/day.** The rain rate limit discriminates between dry melt and wet melt. The wet melt rate is applied as the melt rate when it is raining at rates greater than the rain rate limit. If the rain rate is less than the rain rate limit, the melt rate is computed as if there were no precipitation.
- **Antecedent Temperature Index (ATI) Melt Rate Coefficient = 0.98.** The ATI melt rate coefficient is used to update the ATI melt rate index from one time interval to the next. A typical coefficient value is 0.98.
- **ATI Melt Rate Function.** The ATI melt rate function defines the melt rate values to use over the range of melt rate indexes that will be encountered during the simulation. Table 2-4 presents the ATI melt rate functions used in this analysis for the Rose Creek and Vangorda Creek models. The melt rate was found to have a significant impact on the shape of the hydrograph and therefore was used as a main calibration parameter.

TABLE 2-4
Meteorological Model ATI Melt Rate Functions
Faro Mine Remediation Project

ATI (°C-day)	Rose Creek Model Melt Rate (mm/°C-day)	Vangorda Creek Model Melt Rate (mm/°C-day)
0	0.80	0.80
50	0.80	0.80
100	0.65	0.50
150	0.65	0.50
500	0.65	0.50

Cold Limit (mm/day) = 20 mm/day. The cold limit accounts for rapid changes in temperature that the snow pack undergoes during high precipitation rates. When the precipitation rate exceeds the specified cold limit, the antecedent cold content index is set to the temperature of the precipitation. If the temperature is above the base temperature, the cold content index is set to the base temperature. If the temperature is below the base temperature, the cold content index is set to the actual temperature. If the precipitation rate is less than the cold limit, the cold content index is computed as an antecedent index. A typical cold limit value is 20 mm per day.

ATI Cold Rate Coefficient = 0.84. The cold content antecedent temperature index coefficient is used to update the antecedent cold content index from one time interval to the next. A typical coefficient is 0.84.

ATI Cold Rate Function. This function defines appropriate cold contents to use over the range of cold content index values that will be encountered in a simulation. The function used was provided as a default starting point from USACE personnel (Scharffenberg, 2011, personal communication). Unlike the melt rate function, the cold

rate function was not used as a significant calibration parameter. Table 2-5 summarizes the ATI cold rate function used for the Rose Creek and Vangorda Creek models.

TABLE 2-5
Rose Creek and Vangorda Creek Meteorological Model ATI Cold Rate Functions
Faro Mine Remediation Project

ATI (°C-day)	Cold Rate (mm/°C-day)
0	1.32
50	1.32
100	1.32
150	1.32
500	1.32

Water Capacity (%) = 5 percent. The maximum liquid water capacity specifies the amount of melted water that must accumulate in the snowpack before the liquid water becomes available at the soil surface for infiltration or runoff. Typically, the maximum liquid water held in the snow pack is on the order of 3 to 5 percent of the snow water equivalent, although it can be higher.

Ground Melt (mm/day) = 0 mm/day. Heat from the ground can cause snow melt, especially if the snow pack accumulates on ground that is only partially frozen or completely unfrozen. In these cases, the warm ground is insulated by the snow pack, and heat from the warm ground will cause the snow pack to melt. It was assumed that zero ground melt occurs at the FMC.

Published literature reflects uncertainty in winter sublimation in northern environments, with estimates ranging from 10 to 45 percent (Scenarios Network for Alaska and Arctic Planning, 2011). Water balance work completed on the FMC waste dumps indicated that sublimation was insignificant (Janowicz et al., 2006, 2008). In general, sublimation is more significant in areas where snow is intercepted by canopy. Snow depth information and data required to estimate sublimation are not available for much of the overall FMC catchment area. The HEC-HMS model does not quantify sublimation specifically. However, effects of sublimation have been accounted for in the model calibration process, as discussed in Section 2.5. During the calibration process, input parameters were varied, and resultant modelled runoff hydrographs were compared to observed data. Certain parameters had a more significant effect on the calibration processes than others. Any losses due to sublimation are accounted for via “overcompensation” of one or a combination of the various calibration parameters.

2.4.3.7 Canopy Storage

Canopy storage represents intercepted precipitation that is stored in the vegetation layer, which will evaporate during storm events. The canopy storage will first consume the potential ET, and unused ET will then be transferred to the surface and soil components. Once the canopy storage is filled, the remainder of the precipitation falls to the surface storage. If there is no representation of surface storage, or if the surface storage is filled up, it falls directly to the soil.

A final effective canopy storage value of 10 mm was applied to all subbasins within the models. This was determined through a calibration process that examined values higher and lower than 10 mm. There was considered to be no initial storage percentage already used at the beginning of the simulation.

2.4.3.8 Surface Storage

The surface storage parameter represents the depression ground surface volume where water can accumulate. Precipitation fall-through from the canopy layer or direct precipitation will accumulate in the surface storage and infiltrate up to the soil capacity. Runoff occurs when the precipitation rate exceeds the soil infiltration rate and the surface storage is fully used. Precipitation residing in the surface storage can infiltrate after the precipitation stops and is subject to potential ET after the ET from the canopy layer is used.

A final effective surface storage value of 10 mm was applied to all subbasins within the models. This was determined through a calibration process that examined values higher and lower than 10 mm. There was considered to be no initial storage percentage already used at the beginning of the simulation.

2.4.3.9 Soil Infiltration Loss Method

HEC-HMS provides 12 different methods describing soil infiltration losses. Some of the loss methods are more suitable for continuous simulations (e.g., Deficit and Constant and Soil Moisture Accounting methods), whereas others are more suitable for event based simulations (e.g., Soil Conservation Service [SCS] Nurve Number and Green and Ampt methods). By design, certain loss methods require a more detailed level of information in regard to the subbasin characteristics. The absence of this information can introduce a great deal of uncertainty into the calibration and can complicate the model calibration process. For this model, the Deficit and Constant Loss method was used. The Deficit and Constant loss method is suitable for continuous simulations and requires four input parameters. The parameters required in the Deficit and Constant Loss method are the initial and maximum deficits, the constant rate, and the percent imperviousness. The initial and maximum deficits are the initial and maximum amount of water the soil can hold; both are specified as depths. The constant rate (mm per hour [mm/hr]) defines the infiltration rate when the soil layer is saturated and can be approximated by the hydraulic conductivity of the soil as a starting point. Lastly, the percent of directly connected imperviousness area is required because no loss calculations are carried out on the impervious area. A final, directly connected impervious value of 10 percent was applied to all subbasins within the models. This was determined through a calibration process that examined impervious values from 0 to 10 percent. The final soil loss parameters that were developed through calibration for each subbasin are listed in Table 2-6.

TABLE 2-6
Rose Creek and Vangorda Creek Models Deficit and Constant Soil Loss Parameters
Faro Mine Remediation Project

Model	Initial Deficit (mm)	Maximum Deficit (mm)	Constant Infiltration Rate (mm/hr)	Imperviousness (percent)
Rose Creek Model (Winter)	0	10	0.1	10
Rose Creek Model (Summer)	0	10	0.35	10
Vangorda Creek Model (Winter)	0	10	0.02	10
Vangorda Creek Model (Summer)	0	10	0.35	10

2.4.3.10 Precipitation-runoff Transform

HEC-HMS provides seven different runoff transform methods. The runoff transform methods describe how excess precipitation is transformed into point runoff in the subbasin. The available runoff transform method choices include various unit hydrograph transformations, a kinematic wave transformation, and a linear quasi-distributed method. Again, the requirement of subbasin specific parameters influenced the decision to employ the most simplified runoff transform method possible—the SCS Unit Hydrograph—because the only parameter required was a hydrograph lag time. There is discussion around the suitability of each transform method for the type of expected simulation and nature of hydrograph in the HEC-HMS User's Manual (USACE, 2010). The application of SCS Unit Hydrograph may not be entirely supported for this case; however, the model results were found to be well calibrated to the observed results. The runoff transform method and parameters also did not prove to be a very powerful calibration parameter when compared to the precipitation loss parameters discussed previously. The SCS hydrograph lag time used for all subbasins was 50 minutes.

2.4.3.11 Base Flow

There are five different options for accounting for base flow into the model. Constant monthly base flow was chosen because the availability of continuous flow data provided an opportunity to observe the actual base flow in certain subbasins. Tables 2-7 and 2-8 summarize the base flow values applied to each of the subbasins in the Rose Creek and Vangorda Creek models, respectively. The continuous flow data sets for R7 and V1 were

examined, and representative base flow values were then applied to subbasins Rose Creek RC1 and Vangorda Creek VC1. These patterns were then factored to the other subbasins according to their relative areas compared to RC1 and VC1. Note that base flow rates and monthly distributions were selected based on analysis of multiple years of low-flow data at various flow monitoring stations. These values are not adjusted annually, which could result in a potential over- or underestimation of base flow contribution during dry or wet years, respectively.

TABLE 2-7
Rose Creek Model Monthly Base Flow Estimates
Faro Mine Remediation Project

Rose Creek Model Catchments	Area (ha)	Constant Monthly Base Flow (m^3/sec)
RC1	9,874	Dec-Apr: 0.3 May-Nov: 1.0
RC2	1,589	Dec-Apr: 0.05 May-Nov: 0.16

VC5	4,352	Sept-Apr: 0.65 May-Aug: 0.87

2.4.4 Surface Water Model Initial Conditions

Initial parameter conditions were chosen as a starting point in the model prior to calibration. The sensitivity of basin model loss parameters (i.e., canopy storage, surface storage, soil loss method) and snowmelt parameters was evaluated, and if a given parameter proved to be a useful calibration parameter, it was modified during the

calibration process to a final optimized value. If a parameter did not prove to be a useful calibration parameter, it was returned to its default, or initial, condition. The final parameter values used in the Rose Creek and Vangorda Creek models were listed in Section 2.4.3. The initial conditions of the parameters that were used in the calibration process are described in this subsection.

Because limited information is available for the catchment area, the initial conditions for canopy storage and surface storage were taken as 200 mm each as an arbitrary starting point. The calibration process ultimately led to the use of canopy and surface storage depths of 10 mm each.

The soil information available for the study area (Robertson GeoConsultants Inc. [RGC], 1996) describes a mix of both well-drained and poorly drained soils. As a starting point in the calibration process for the constant soil infiltration parameter, a typical value for the hydraulic conductivity of soils was used based on a soil type that lies between the classification of a good aquifer and a poor aquifer. A good aquifer is described by clean sands and a mixture of clean sands and gravel with hydraulic conductivity ranging from approximately 16.8 to 1,697 mm/hr (5×10^{-4} to 5×10^{-2} centimetres per second [cm/sec]). A poor aquifer is described by very fine sands and mixture of sand, silt and clay, glacial till, and stratified clays, with hydraulic conductivity ranging from slightly lower than 0.01 to 16.8 mm/hr (2×10^{-4} to 5×10^{-2} cm/sec) (Chow, 1964). The calibration process ultimately led to the use of constant infiltration parameters that fall within the classification of poor aquifers (0.02 to 0.35 mm/hr or 6×10^{-7} to 1×10^{-5} cm/sec).

The initial condition for the percent imperviousness was set to 0 percent. The calibration process ultimately led to the use of a percent imperviousness of 10 percent.

It is recognized that the final calibrated values for the canopy, surface, and soil loss parameters may not be consistent with theoretical or expected values based on existing physical characteristics of the subcatchments. However, the specific combination of values derived during the calibration process produced the best match of observed versus modelled runoff hydrographs for the duration of the simulation.

The initial condition for the ATI melt rate function was used from a reference document provided by USACE personnel (Scharffenberg, 2011, personal communication). This initial melt rate function is summarized in Table 2-9.

TABLE 2-9
Rose Creek Meteorological Model Initial Conditions ATI Melt Rate Function
Faro Mine Remediation Project

ATI (°C-day)	Melt Rate (mm/°C-day)
0	1.09
50	1.32
100	2.23
150	1.77
500	1.77

The ATI melt rate function was a powerful calibration parameter, and the final calibrated values were provided in Section 2.4.3.6.

As mentioned in Section 2.4.3.1, runoff from subbasins RC8a and RC8b are represented in the form of a constant monthly hydrograph. Runoff and seepage from catchment area RC8a is tributary to the Faro Pit, whereas runoff and seepage from catchment area RC8b is ultimately captured above the Intermediate Dam. This runoff and seepage is ultimately stored in the Faro Pit or in the Intermediate Dam Pond for subsequent treatment at the Faro WTP. Discharge from the WTP is tributary to the CVD Polishing Pond. Water is discharged from the CVD Polishing Pond via a siphon equipped with a control valve. As such, direct runoff from these catchment areas was not

routed through the hydrological model. Rather, a manual hydrograph with monthly time steps was developed to represent controlled discharge through the siphon. Review of available discharge data indicates that flow through the siphon occurs through most months of the year and ranges from 0.0 to approximately 0.4 m^3/sec. For model development, an average monthly discharge estimate of 0.4 m^3/sec was applied and is considered to be a conservative (i.e., high) value for the purposes of model development. Given the relatively low flow rate associated with discharge from the CVD compared with flows coincident at the next downstream model node (i.e., the 23,163 ha X14 catchment area), it is not anticipated that the assumed siphon flow will significantly impact downstream flows from a volume perspective during peak flow events. It would be necessary to further refine this hydrograph, based on additional field data, to better estimate impacts of controlled releases on the receiving watercourse flow regime during low-flow, interevent periods.

2.4.5 Surface Water Model Boundary Conditions

The catchment delineation, described in Section 2.4.3.1 and illustrated in Figures 2-5 and 2-6, provides a no-flow boundary condition for the Rose Creek and Vangorda Creek SW flow models.

When developing hydrological models, the domain is defined by the overall catchment area tributary to the receiving point of interest. For the FMC, the domain is defined by flow monitoring station X14 in the Rose Creek drainage basin and by V8 in the Vangorda Creek drainage basin, shown on Figure 2-4.

Time series and paired data also define boundary conditions in the development of hydrological and meteorological models. For the current model development, time-series data for meteorological parameters (including precipitation and air temperature) were developed. Similarly, time-series data for base flow contribution and flow monitoring data were used. The model was run from January 1, 2004 until December 31, 2011. This period corresponds with the time when the most flow and meteorological data were available for model development and calibration.

2.4.6 Surface Water Model Time Discretization

The SW flow models were discretized to run daily time steps from January 1, 2004 until December 31, 2011. Although certain meteorological data are available hourly, some of it is only available over a 1-day period. HEC-HMS can process time-series data with time steps ranging from 1 minute to 1 day. Given that the models are developed to run continuously for multiple years, a time step of 1 day was selected for run definition. As well, given the relative times of concentrations for the catchments of the Rose Creek and Vangorda Creek models, runoff processes are better represented in terms of days rather than hours.

2.5 Surface Water Model Calibration

The intent of the calibration process was to match the simulated hydrograph peak flows and volumes as closely as possible to the observed data from the various flow monitoring locations over the years of recorded data available.

2.5.1 Surface Water Model Calibration Approach

The flow monitoring stations that were used in the calibration process, and the locations at which they are compared in the model, are summarized herein. Refer to Figure 2-2 for monitoring locations and Figures 2-8 and 2-9 for node and junction definitions, respectively.

Rose Creek Model

- **R7 NFRC above FCD:** Compared to output from node RC1 (total of 9,874 ha contributing catchment area)
- **X2 NFRC Upstream from Mine Access Road:** Compared to output from node Junction RC3, which includes flows from RC1, RC2, and RC3 (total of 12,455 ha contributing catchment area).
- **X14 Rose Creek Downstream from the RCDC:** Compared to output from node Junction RC5, which is the most downstream point in the model that includes flow from the entire catchment area (total of 23,163 ha contributing catchment area)

Vangorda Creek Model

- **V1 Vangorda Creek Upstream from the FMC and Blind Creek Road:** Compared to output from node Vangorda VC1 (total of 2,007 ha contributing catchment area)
- **V27 Vangorda Creek, Just Upstream from Shrimp Creek (DES, 2011):** Compared to output from node Junction VC1 (total of 3,025 ha catchment area)
- **V8 Lower Vangorda Creek at the Footbridge:** Compared to output from Junction VC3 (total of 8,737 ha contributing catchment area)

The calibration process started with the most upstream subbasins from each model (i.e., Rose Creek RC1 and Vangorda VC1). For each of these subbasins, continuous flow data were available at the respective discharge points. This allowed for the comparison and subsequent calibration of the subbasin-specific models. Once the subbasin parameters were appropriately calibrated for these catchments, subsequent downstream catchments were added to the models, with results compared to available continuous and spot flow data.

2.5.2 Surface Water Model Calibration Targets

For the winter models, the magnitude and duration of spring freshet was the key calibration target because this is the event that defines peak annual runoff hydrographs for the system. For the summer models, the frequency and magnitude of runoff events was the key calibration target because runoff hydrographs, in this case, are not influenced by longer-duration melt periods, as is the case with the winter models, but rather shorter duration runoff events with a more frequent return period. The shape of the hydrograph, in terms of the lag during the spring freshet, as well as during more frequent summer runoff events, was a particularly important calibration target because it dictated the volume of SW being simulated by the model annually.

2.5.3 Surface Water Model Calibration Process

After an initial sensitivity analysis was performed on parameters, those that exhibited the most influence on model results were selected for further analysis. These parameters included the ATI melt rate index function, the constant infiltration parameter, the surface storage depth, and the canopy storage depth.

The most significant effect on the hydrograph volume during the spring freshet resulted from calibrating the ATI melt rate index function value. Adjusting the melt rate values higher or lower and varying the melt rate value within the range of the ATI function itself either increased or decreased the extent of the hydrograph lag during the melt. Table 2-4 lists the final ATI melt rate index functions that best suited the simulations. The melt rate function was calibrated in conjunction with the calibration of the precipitation loss parameters because, although these parameters govern different aspects of the simulation, they interact with one other.

The most significant effect on the magnitude of peak flows resulted from varying the constant soil infiltration parameter. As mentioned earlier, two separate basin models were developed, one with the soil infiltration parameter calibrated for the snowmelt peak (which is typically the largest peak in the annual record) and one with the soil infiltration parameter calibrated to the later summer peaks. The soil infiltration parameters are presented in Table 2-6. The results of the snowmelt-calibrated model were used from the beginning of November until the end of June, and the results from the summer-calibrated model were used from the end of June until the end of October. The difference in soil infiltration parameter is intended to reflect the fact that during the snowmelt calibration period, the ground is frozen and the infiltration parameter can be expected to be lower than during nonfrozen periods of the year. During the summer calibration period, the ground has thawed, and the infiltration parameter can be expected to be slightly higher than during the frozen periods of the year. The modelling results support this reasoning; when the snowmelt-calibrated infiltration loss parameter was used, the peaks during the spring freshet were well-matched to the observed data; however, the simulated peaks in the later summer months (July through September) were much higher than those observed. Likewise, when the summer-calibrated infiltration loss parameter was used, the summer peaks were better calibrated to the observed data; however, the snowmelt peaks during the spring freshet (May through June) were much lower compared to those observed. As such, a two-model approach was developed to simulate the change in soil infiltration resulting from the change in temperature over the course of the different hydrological events. A difference was also found in the Rose Creek

model- and Vangorda Creek model-calibrated winter soil infiltration parameters, which could reflect different soil and land cover conditions between the two sites during the winter months (0.02 mm/hr versus 0.1 mm/hr [6×10^{-7} cm/sec versus 3×10^{-6} cm/sec]). The same summer-calibrated soil infiltration parameter was used for both areas (0.35 mm/hr [1×10^{-5} cm/sec]).

The modelled hydrographs at each flow station, provided in Section 2.5.4, are an amalgamation of the results from both of these models. The simulated behaviour during the potential overlap periods (end of June until early July and end of October until early November) was examined for each subbasin to determine whether the soil infiltration parameter for the snowmelt or summer period would be better suited for specific portions of this transition period. As a starting point, July 1 was initially taken as the date when the change in soil infiltration rates would occur. This remained as such for most of the years simulated, except for 2007 and 2011, where, upon examination, it appeared that there were precipitation events toward the end of June (June 25, 2007 and June 20, 2011) that were better simulated with the summer-calibrated soil infiltration parameter for these years.

Because certain years of continuous flow monitoring data are more complete than others (e.g., at times snowmelt period flow data were missing), the calibration process sometimes favoured certain years more than others. This was particularly true for the Vangorda Creek model at flow monitoring station V1. Although there are flow monitoring station V1 data available for 4 years (2008 through 2011), only the data from 2009 contains the snowmelt period of May and June; therefore, this year was relied on for the calibration process. Likewise, further downstream at station V8, although there are data available for 2008, 2010, and 2011, it is suspected that the data from 2010 and 2011 are inaccurate. As a result, only the 2008 data were used for the calibration process. The continuous 2010 and 2011 flow monitoring readings appear to be abnormally low. For verification, they were first compared to the spot-flow measurements from the 2010 and 2011 environmental monitoring reports (DES, 2011, 2012a) at the same station locations, and the values were found to agree fairly well with each other. However, the fact that the peak flow recorded at monitoring station V27 in 2011, which is located upstream of station V8, is slightly higher than that recorded at V8 (both are approximately 3 m^3/sec for the spring snowmelt peak) supports the hypothesis that the flow data in 2010 and 2011 at V8 may be compromised. Compared to V27, V8 would be expected to receive an additional 5,712 ha of catchment area; therefore, the peak flows at V8 would be expected to be higher than at V27. The model results at the location of V27 (Junction VC1) agree well with the observed data from the 2011 flow monitoring report (approximately 3 m^3/sec), whereas the modelled peak flows at the V8 location (Junction VC3) are approximately 7.5 m^3/sec.

2.5.4 Surface Water Model Calibration Results

Figures 2-17 through 2-21 compare the observed versus modelled hydrographs at flow monitoring stations R7, X2, and X14 (for the Rose Creek Model) and V1 and V8 (for the Vangorda Creek model), respectively, spanning the years of continuous flow data available for each station. Appendix A includes a separate figure for each flow monitoring station. In Appendix A, the continuous flow monitoring data are shown in black, whereas the modelled data from the winter-calibrated model are shown in green and the summer-calibrated model data are shown in orange.

As discussed, the models have been calibrated to generally match the peak flows and hydrograph volume across all years of available data. However, there are certain years where the modelled results better match the observed data as compared to others. For the Rose Creek model, years 2005, 2009, and 2011 are better calibrated to the observed hydrographs than in other years at both flow monitoring stations R7 and X14. For the Vangorda Creek model, 2009 is the best-calibrated year for V1, and 2008 is the best-calibrated year for V8.

Considering the fairly coarse resolution of the models, in terms of catchment delineation size and parameter estimation, the calibrated model appears to be adequate because it tends to achieve similar results to flow monitoring data at the most downstream end of both systems (X14 and V8, for Rose Creek and Vangorda Creek models, respectively). Nonetheless, model weaknesses include the fact that it does not succeed in replicating every event that was recorded in the continuous flow monitoring data (e.g., November 2005 and 2006 events). Further, the time lag in the spring freshet portion of the simulated hydrograph remains in general briefer than was observed. This remains true even after pushing the limits of calibration to extend it as much as possible without adversely affecting other aspects of the hydrograph. The timing of the simulated hydrograph is generally

coincident with the observed data, with the spring melt occurring on average within a few days of observed melt; however certain years match better than others. For 2005, the modelled and observed spring freshet peaks coincide well with each other around May 17. However, in 2007, the continuous flow monitoring data and spot-flow measurement data (Laberge Environmental Services [Laberge], 2007) show two peaks within the freshet period: one at the end of May (coinciding around the time of the main modelled peak) and another greater peak in early June. The model does simulate these two peaks; however, the first one is the largest, while the second peak is dampened.

It is acknowledged that base flow will vary both seasonally and annually; however, to develop a calibrated model that can be used in subsequent analyses, an average monthly base flow was applied. Because base flow varies by year, the average monthly base flow succeeded in better representing the observed base flow for certain years compared to others. For 2010, the estimated base flow is approximately double the observed base flow because this year was significantly drier than the others and experienced a smaller spring freshet. The implication of this is that, along with the base flow, the modelled events during the summer and autumn period in particular were higher than those observed.

As mentioned previously, a manual hydrograph with monthly time step was developed to represent controlled discharge from the CVD Polishing Pond. Peak flow rates from the siphon are relatively small compared with cumulative flows directly downstream in Rose Creek. Therefore, assumed discharges from the CVD Polishing Pond do not significantly impact downstream flows from a volume perspective during peak flow events. It is necessary to further refine this hydrograph, based on additional field data, to better estimate impacts of controlled releases on the flow regime of the receiving watercourse during low-flow, interevent periods.

The modelling results were calibrated against the continuous flow monitoring results and, whenever possible, the results were also compared to spot flow measurements available from other sources such as DES (2011, 2012a), Gartner Lee Limited (GLL) (2007, 2008), and Laberge (2005a, 2007). Figure 2-2 illustrates the location of the flow monitoring sites where spot readings were evaluated.

Of particular importance in the Rose Creek model was an analysis of potential attenuation effects upstream of the Haul Road Rock Drain. Based on anecdotal information, runoff appears to pool behind the rock drain during significant runoff events. Hydrographs generated from the calibrated model both upstream and downstream of the rock drain were compared to available continuous field data, as well as spot-flow measurements recorded by FMC care and maintenance operators. Based on the similarity in peak flows recorded by the continuous flow data and spot-flow measurements upstream and downstream of the Haul Road Rock Drain, as well as the general agreement between modelled and observed hydrographs from locations upstream and downstream of the rock drain, the Haul Road Rock Drain does not provide significant peak flow attenuation for events that were simulated between 2004 and 2011. To further corroborate this conclusion, the water surface elevations provided immediately upstream and downstream from the rock drain at locations NF1 and NF2 in DES (2012a) exhibit the same fluctuation over time. This suggests that the flow rates are the same over this period. In light of these observations, the model has been developed without specifically including the Haul Road Rock Drain as a separate hydraulic element. The increase in head that develops as water pools upstream of the rock drain may sufficiently maintain a constant peak flow through the structure. However, for events exceeding those that have been simulated in this modelled exercise, the rock drain would likely provide peak flow attenuation once the capacity through the porous structure was exceeded.

The spot-flow measurements in DES (2011, 2012a) typically did not coincide with significant hydrological events (such as a spring freshet or a peak summer storm). Therefore, the general comparison of these data sets to the model results was not always very telling but was nonetheless carried out. Laberge (2005a) provides more significant data because the spot-flow measurements were taken on May 11 and 12, 2005, which nearly coincides with the peak of the spring freshet (May 17, 2005). Measurements were taken at various locations along the NFRC and the RCD (at R7, X2, X14), and these were compared to both the model results and the observed continuous data, as summarized in Tables 2-10 and 2-11, respectively. Note that the nearest continuous flow monitoring station to Station RCDC4 that includes runoff from both the north and south forks of Rose Creek is X14. Although

the catchment area tributary to Station X14 is larger than that tributary to Station RCDC4, it is the most representative station to which peak flows reported by Laberge (2005a) can be compared.

2.6 Surface Water Model Application

As defined earlier in this report, the FY12 objective of the SW flow modelling task was to develop a dynamic hydrological model of the FMC that can be used to provide a better understanding of the hydrological characteristics of the FMC and support future FMC design and investigative activities. Building on the CSM Report (CH2M HILL, 2012), the SW flow models are used to define precipitation-runoff processes throughout the FMC and to assist in characterizing the occurrence, conveyance, and management of SW within the FMC under varying assumptions of land use and meteorological conditions.

The SW flow models described herein have been used to simulate rainfall-runoff processes from the FMC on a continuous, multiyear simulation basis to simulate the timing and magnitude of runoff events throughout the year ranging from low-flow (i.e., base flow) conditions up to the peak flows occurring during the spring freshet. To establish flow rates for diversion designs that exceed those produced by the freshet, a regional analysis will be used. This involves transposing flood data from regional flow gauging stations to the outlets of the respective diversion.

The SW flow models detailed in this report require further development to support the design of the SW diversion structures planned at the FMC and to support various other design activities at the FMC. The models also require further refinement to address YESAB requirements, as well as to analyze climate change scenarios. During these

efforts, the existing models will be revised to facilitate the evaluation of potential future hydrological and hydraulic stream diversion behaviour under a variety of flow conditions up to and including the probable maximum flood event (PMF). The SW flow models will be used primarily to develop stream diversion designs but will also be further integrated with the GW flow and water quality modelling efforts to support the FMRP. The following are key remedial design areas including the objective for each area:

- **FCD (East Valley).** Direct clean water around the Faro Pit and minimize seepage losses that could impact the stability of the Faro Pit walls and add to water treatment volumes.
- **North Wall Interceptor Ditch (NWID).** Remediate the existing NWID and discharge to a location below the CVD (instead of the Rose Creek Tailings Area [RCTA]).
- **Guardhouse Creek Water Management.** Intercept seepage from the mill pad and associated stockpiles and redirect this water to the Faro Pit.
- **Upgrade NFRC.** Protect the NFRC from potential sources of contamination.
- **Upgrade RCD Upstream from the Fuse Plug to PMF.** Enable the RCDC to accommodate an excess of the current 1-in-500-year flood event.
- **Breach North Fork Rock Drain.** Protect the NFRC from potential sources of contamination and restore channel.
- **Down Valley Interim Hydraulic Upgrades.** Increase the Intermediate Dam spillway capacity to pass PMF flows.
- **RCDC Fuse Plug Upgrades.** Design an RCD hydraulic structure to divert flows exceeding the 1-in-500-year flood event.
- **Upgrade of RCD Downstream of Existing Fuse Plug.** Address the freeboard inadequacy issues to enable the RCDC to pass the flow of Rose Creek on a year-round basis for all flows up to the 1-in-500-year flood event.
- **Construct New Vangorda Diversion.** Permanently realign Vangorda Creek around the Vangorda Pit to minimize leakage into Vangorda Pit and safely convey the PMF.
- **Upgrade Runoff Interceptor Ditch to Dixon Creek.** Divert uncontaminated surface runoff from the northeast side of the Vangorda to the south and into Dixon Creek via the Dixon Creek Diversion.

Associated efforts in future GW analysis and hydraulic/hydrological dam structure design tasks across the FMC will be integrated with the future SW flow modelling efforts to develop comprehensive remedial designs.

2.6.1 Surface Water Model Use and Limitations

As detailed earlier in this report, the hydrological models were developed and calibrated based on available meteorological and flow data collected at the FMC over a number of years and from additional data collected at offsite stations such as the Faro Airport Station. Modelled hydrographs compare well with those observed at the continuous monitoring stations for the duration of the analysis. However, continuous flow data were available at a relatively small number of stations, which resulted in the need to lump large catchment areas. The current SW flow models for the FMC are not sufficiently detailed to accurately develop the diversion design and stream channel upgrades. The deficiencies in the current models are based on the quality and quantity of the available data records and physical site data to adequately support model development and the current level of discretization applied to some critical basins. The proposed efforts, defined in this report, to collect additional data will facilitate further refinement and enhancement of the SW flow models. Additional flow data and site characteristics data will also allow for additional discretization of drainage catchment areas at the FMC. This additional detail will also allow for the models to be refined and the required diversion designs and stream upgrades to be better facilitated.

Water Management Supporting Technical Memoranda

Review of Pit and Pond Water Elevations Faro Mine Remediation Project

PREPARED FOR: Government of Yukon (YG)

PREPARED BY: CH2M HILL Canada Limited (CH2M HILL)

DATE: October 11, 2013

PROJECT NUMBER: 472645.09.N1.02

Overview

This technical memorandum (TM) is in response to Task Authorization Component (TAC) 009-N, Water Elevations and Peak Flows, and addresses the following objectives of TAC 009-N:

- Review the water elevations for each onsite storage reservoir or pit (e.g., Cross Valley Pond [CVP], Intermediate Dam Pond [ID pond], Faro Pit, Zone II Pit, Vangorda Pit, Grum Pit, and Little Creek Dam Pond).
- Provide recommendations regarding revised target elevations for the end of the 2013 operating season.
- Provide an updated table of target water elevations and document recommended water management changes, including the rationale for the changes.

Current Water Management

In 2012, CH2M HILL reviewed and provided updated recommendations pertaining to the 2011 Freshet Water Management Plan (WMP) (Brodie Consulting [Brodie], 2011). These recommendations were developed with the objective to limit water of deteriorated quality from migrating offsite, and to provide storage capacity, in case of extreme environmental conditions or unexpected delays to operations (CH2M HILL, 2012a). This draft TM provides recommendations based on current site conditions and site operations in FY 2012 and 2013.

Several important operational changes to water management at the Faro Mine Complex (FMC) between 2012 and 2013, including the following:

- The Faro Mill WTP was not operated in 2013
- A temporary mobile filtration system was installed and operated at the CVP
- A conveyance system was constructed to transfer water between the ID Pond and the Faro Pit, as well as between the ETA and Faro Pit (instead of conveying ETA water to the Faro Mill WTP)
- The new Zone II Pit dewatering well (CH12-Z2-PW01) began operations
- A conveyance system was constructed to transfer water from the Grum Pit to the Vangorda Pit
- The conveyance system to transfer water between Grum-V15 and the Vangorda Pit began operating

Table 1 provides target water elevations for 2013. It also describes the water management location, including the water's source and destination, the target elevation and target objective, the recommended start and end dates, contingencies, and additional comments.

YG requested CH2M HILL provide a recommendation for 2013 end-of-season target elevations, given the following unique site conditions as of September 2013:

- The Faro WTP was not operated in 2013
- The Vangorda WTP shut down for the season
- Water elevations in the Grum Pit exceeded the target levels

These conditions preclude maintaining water levels below previously established elevations for the Grum and Vangorda Pits. On October 10, 2013, YG decided to stop seasonal water transfer from the Grum Pit to Vangorda Pit based on its evaluation of relative risk associated with the Grum and Vangorda Pits.

The next section of this TM describes the GoldSim model used to inform water management targets. The remaining sections describe each management location listed in Table 1.

GoldSim Water Management Tool

A simplified model was developed from our GoldSim model v2 (CH2M HILL, 2013). The model simulates the Faro, Vangorda, and Grum Pits, as well as the CVP and ID Pond, and existing connections between these storage reservoirs along with loading from collection systems (e.g., the Emergency Tailings Area [ETA], S-wells, Zone II, and Grum-V15). The simplified model uses total monthly inflows to the storage reservoirs, plus flows from these collection systems, as boundary conditions. Inflow values were the average of a stochastic run from the GoldSim model v2, using annual precipitation data from 1978 to 2011. The model considered stochastic variability based on the historical precipitation change from average, and its output was compared with a water balance spreadsheet model to facilitate calibration.

The GoldSim model was set to run for 1 year (from September 9, 2013 until September 9, 2014) on daily time steps, and included 250 stochastic realizations. September 9, 2013, was selected as the initial date because the most recent available water level are from September 9 to September 12 (Table 2). The 250 stochastic realizations allow a range of flows to be evaluated and therefore assess potential wet, dry, and average year conditions.

Table 2 provides initial conditions and assumptions regarding storage volumes and elevations. Table 3 provides the scenarios considered to support end-of-season target water elevations. In Table 3, blue-highlighted cells with bold text indicate value(s) that changed in the scenario.

Scenario 1 provides the base case, which assumes water from Faro Pit is not treated in 2013. Although interim water treatment is planned for 2014, the simulations did not include this treatment capacity because it is not critical to developing 2013 target elevations. It assumes discharge from the CVP occurs at 13,100 cubic metres per day (m3/day) (2,400 US gallons per minute [USgpm]) via the filtration trailers and allows 14,400 m3/day (2,600 USgpm) by-pass (siphon) release until September 30, 2013. The average historical CVP elevations are used to estimate winter pond releases.

The ID Pond is dewatered at a rate of 9,800 m3/day (1,800 USgpm), which is assumed to continue until September 30, 2013. The Vangorda WTP has ceased operations for 2013; we have assumed it will start up on May 1, 2014, at 10,900 m3/day (2,000 USgpm). The scenario also assumes Grum Pit dewatering has stopped for 2013 and that when it begins again in May 2014, it will do so at 9,300 m3/day (1,700 USgpm). Grum-V15 transfers to Vangorda Pit are also assumed to have stopped in August. This scenario is the base case because it relies on the least amount of active water management intervention.

The simulated scenarios adjust individual areas of the model, one at time, to evaluate the effect different water management scenarios would have. Scenarios 2 and 3 adjust CVP water management to evaluate the effect on CVP water levels and potential winter release volumes. Scenario 2 allows the CVP water elevation to rise to the lower spillway elevation without considering winter releases, which would need to take place before the water elevation reached the lower spillway. Scenario 3 reduces the total discharge from the CVP in September to evaluate how much more winter release will be required if the CVP does not reach the target elevation by September 30. For this scenario, the assumed discharge rate from the CVP was 6,500 m^3/day (1,200 USgpm), which would correspond to the filtration capacity if one of the two mobile filtration trailers was operational and there was no siphon release. Scenario 4 evaluates continued dewatering of the ID Pond through October. This scenario helps assess whether the target elevation can be reached, and predicts the effect this additional water will have on the Faro Pit.

Scenarios 5 and 6 assess the effect continued Grum Pit dewatering would have on Grum and Vangorda Pit water levels. Scenario 5 continues pumping the Grum Pit water to the Vangorda Pit for another 20 days beginning in mid-September and Scenario 6 continues the pumping for 25 days beginning in mid-September. Scenario 7

assesses the effect of delayed Vangorda WTP operation on Vangorda Pit water levels if WTP start-up is delayed from May to June, 2014.

Figures 1 through 8 provide the scenario results, including the minimum, mean, and maximum result from the stochastic runs.

Water Management Locations

Faro Water Treatment Plant

The Faro WTP is not operational and did not operate in 2013. During the 2013 treatment season, water from the ID Pond and ETA has instead been conveyed to the Faro Pit, raising its water level.

An interim WTP is planned for operation in 2014. Interim treatment should be implemented as soon as possible, at a high enough rate to control and reduce Faro Pit water levels and the potential for increased seepage towards the Zone II Pit, the ETA, or both.

Cross Valley Pond

The CVP is part of the active water management program at the FMC. Although the Faro WTP did not discharge treated water to the CVP in 2013, the CVP still requires active management to remove water from inputs such as rainfall and seepage. In previous years, water was released from the CVP via a siphon to Rose Creek at monitoring station X5. In 2013, turbidity exceeding the discharge limit (15 Nephelometric Turbidity Units [NTU]) made it necessary to use temporary mobile filtration units that could process up to 13,100 m^3/day (2,400 USgpm). These mobile treatment units did not arrive onsite until August.

The water elevation in the CVP has historically ranged between 1,026.3 and 1,030.3 metres (m) (Denison Environmental Services [Denison], 2012; Tlicho Engineering and Environmental Services Ltd. [TEES], 2013a). The crest of the CVD is 1,033.1 m, and the lower spillway is reported at 1,030.68 m (Domingue, 2013, personal communication).

The drawdown of water in the CVP has three constraints: (1) the water quality in Rose Creek, (2) the maximum rate of daily drawdown, and (3) the ability to maintain water cover over accumulated sludge beds. The volume of releasable flow is controlled to achieve acceptable water quality in Rose Creek (particularly at X14, the surface water quality monitoring station and compliance point). BGC Engineering (BGC) recommended a maximum drawdown of 100 millimetres (mm) per day because of concerns about the Intermediate Dam's geotechnical stability (BCG, 2008).
Operational experience at the FMC indicates the water elevation in the CVP should not be lowered below about 1,027.5 m. If it is, sludge beds could be exposed and sludge particulate suspended, which may impact water quality and the ability to discharge from the CVP (Parkin, 2013a, personal communication).

The GoldSim base case scenario indicates if additional capacity in the CVP is required to accommodate spring flows, winter discharge will be required (Figure 2). The base case uses average historical water elevations in the CVP to approximate the past site operations but does not necessarily reflect the timing or magnitude of monthly winter releases. CVP winter releases could also have been simulated by setting a winter discharge target to represent site operations, but the same conclusion would have been reached: spring storage capacity can be available if winter releases occur. Site operations will determine the timing and magnitude of releases.

Based on the historical range of precipitation, and seepage inflow estimates to the CVP, Scenarios 2 and 3 predict the following results:

- Scenario 2: If the target elevation (1,027.5 m) is reached by September 30, 2013, the water elevation could reach the lower spillway after 173 days (Figure3)
- Scenario 3: If the target elevation (1,027.5 m) is not reached by September 30, 2013, and the water is only lowered to 1,028.5 m, the water elevation could reach the lower spillway after 92 days (Figure 4)

The recommended target water-level elevation in the CVP is 1,027.5 m, which provides the maximum storage capacity considering the elevation of the sludge beds: approximately 670,000 m^3 (3.18 m) of freeboard between the target elevation and the lower spillway elevation. Winter release is recommended when conditions allow.

Intermediate Dam Pond

Water and tailings are retained behind the Intermediate Dam, which is approximately 650 m long, 7 m wide, and 32 m high, with a crest elevation at 1,049.2 m (Klohn Crippen Berger Ltd. [KCB], 2012) and has a spillway elevation of 1,047.7 m (Denison, 2012). The water level in the ID Pond has historically ranged between 1,043.0 and 1,047.6 m (Denison, 2012; TEES, 2013a). In 2013, ID Pond water was pumped to the Faro Pit.

There are two constraints on the drawdown of water in the ID Pond: (1) a maximum drawdown per day of 40 mm; (2) the operations regime prescribed by KCB (2012) because of concerns about the ID's geotechnical stability (CH2M HILL, 2012b). No changes are recommended for the ID Pond target water levels.

The GoldSim base case scenario indicates that, considering accumulated winter inflows, ID Pond water levels may reach the spillway elevation if dewatering ceases on, or before, September 30. Scenario 4 suggests continued dewatering of the ID Pond at a rate of 9,800 m^3/day through October will bring the water elevation towards its target, although the target will not be reached by the end of October. Considering predicted accumulated winter inputs to the ID Pond, the water elevation is not expected to reach the spillway elevation before dewatering begins again in May 2014 (Figure 5), although the water will rise above the recommended upper elevation of 1,045.2 m, the top of the lower riprap. The Faro Pit water elevation is predicted to rise by 0.4 m, because of water being transferred from the ID Pond in October (Figure 1).

Maintaining the ID Pond's elevation at between 1,045.2 m (the top of the lower riprap) and 1,044.2 m (the bottom of the lower riprap) will limit the potential for the upstream face of the Intermediate Dam to erode. Operation outside this range could take place as a contingency measure, to prevent uncontrolled releases of ID Pond water. If the ID Pond elevation is maintained below the bottom of the lower riprap (1,044.2 m), the dam face should be monitored for erosion and will likely require maintenance in the future (i.e., erosion repair and riprap replacement). CH2M HILL (2012a) provides more discussion about this situation. CH2M HILL recommends pumping from the ID Pond while site conditions allow, to draw the ID Pond level down towards 1,044.2 m.

Faro Pit

The Faro Pit receives groundwater seepage, direct precipitation, runoff, Faro Creek Diversion seepage, and water from managed sources such as the ID Pond, the ETA, S-Wells, and Zone II Pit. From 2004 until 2012, the water-level elevation in Faro Pit was maintained between approximately 1,140 m and 1,143 m (Denison, 2012; TEES, 2013a). During the 2013 treatment season, source areas that used to go to the Faro WTP (which did not operate in 2013) went to the Faro Pit, which raised its water elevation above this range. On September 9, 2013, the Faro Pit water elevation was 1,146.1 m.

The end-of-season target elevation (between 1,140 and 1,141 m) and the maximum recommended elevation (1,144.3 m) (Denison, 2012) have been exceeded. CH2M HILL recommends dewatering activities begin at Faro Pit as early as possible in 2014, at a high enough rate to control and reduce the Faro Pit water level and the potential for seepage increases towards Zone II Pit or towards the ETA.

Emergency Tailings Area

The ETA is an area of historical tailings deposition between the Mill Building and RCTA. In previous years, water from the ETA was collected at a cut-off trench and dual sump and then pumped to the Faro WTP. In 2013, water was not initially collected at the ETA; however, as the season progressed, water was collected and pumped from the ETA to the Faro Pit via the old tailings box and a booster pump located east of the former Mill Building. There is no target elevation for the ETA, but the objective is to collect as much water as practical based on the system capacity. This will limit water of deteriorated quality from seeping downgradient to the ID Pond and the underlying Rose Creek Aquifer, and will reduce the volume of water in the ID Pond.

S-Wells and S-Wells Bypass

The S-Wells are located between the Intermediate Waste Rock Dump (WRD) and the North Fork of Rose Creek (NFRC) and consist of two parts: the S-Wells and the S-Wells Bypass (or Shallow Interception Trench). There were no changes to water management for the S-Wells in 2013. CH2M HILL (2012a) provides additional details about this system.

Zone II Pit

The Zone II Pit is located directly southeast of the Faro Pit and northwest of the NFRC. The Pit was mined in the late 1970s and early 1980s and subsequently filled with about 40 million tonnes of unclassified waste rock from mining operations at other areas at the FMC (Robertson Geoconsultants Inc. [RGC], 1996). The Zone II Pit base is at an elevation of about 1,094.5 m (RGC, 1996) and the current surface topography is at an elevation of about 1,166 m. If water rose above 1,128 m, it would spill over the buried rim and seep toward the NFRC. Between the base of the Zone II Pit and an elevation of 1,128 m, the backfilled Pit has about 480,000 m^3 of storage capacity, assuming 30 percent porosity of the backfilled waste rock (SRK, 2007). In 1991, a pumping well was installed to manage the water level and limit water from migrating towards the NRFC. In 2012, a replacement pumping well (CH12-Z2-PW01) was added. The water-level elevation at Zone II Pit has been managed at approximately 1,107 m and has ranged between about 1,103 and 1,111 m since October 2010 (Denison, 2012). However, this elevation leaves a hydraulic gradient between the groundwater elevation in the Pit and the stage elevation of the NFRC (about 1,096 m). The expired water licence (QZ03-059) required the groundwater elevation in Zone II Pit to be maintained lower than 50 metres below ground (mbg), or 1,116 m.

X26 (Zone II – Old Well)

X26 was not used to dewater the Zone II Pit in 2013. The well is still used to monitor the water elevation in the Zone II Pit. CH2M HILL (2012a) provides additional details about this pumping well. Table 1 does not provide a target elevation for this location.

CH12-Z2-PW01 (Zone II – New Well)

During the summer of 2012, CH2M HILL oversaw the drilling and installation of CH12-Z2-PW01. This well extends to a total depth of 77.4 mbg, with a screened interval between 1,091.7 and 1,114.0 m and a sump extending below 1,091.7 m to the end of the hole at 1,088.6 m (CH2M, 2012c). The lithology consisted of waste rock to a depth of approximately 69.45 mbg (1,096.5 m) (i.e., within 2 m of the reported base of the Pit). The purpose of this well was to replace X26 and allow the groundwater levels within the Pit to be managed so they are lower than those previously achievable. The objective of this deeper well was to lower the groundwater elevation below the stage elevation of the NFRC, to reverse the hydraulic gradient. CH2M HILL understands the water conveyance system installed at this location consists of an insulated high-density polyethylene (HDPE) pipeline, heat-traced for year-round operation. According to the 2011 WMP (Brodie, 2011), the pipeline is positioned to discharge water at 30 m below the surface of the Faro Pit lake. The recommended target elevation for the water level in Zone II Pit is at or below 1,096 m. Groundwater collection should continue from Zone II Pit year-round.

Faro Valley Dumps

The Faro Valley Dumps refers to an area of ponded water along the alignment of the original Faro Creek Channel, upstream from the Faro Valley WRD on the north–northeast side of the Faro Pit. There were no changes to water management for the Faro Valley Dumps in 2013. CH2M HILL (2012a) provides additional details about the system.

Grum Pit

The Grum Pit receives groundwater seepage, direct precipitation, runoff, and Grum Northeast Interceptor Ditch seepage. The Adaptive Management Plan (AMP) threshold level to trigger a response to rising water levels (1,210.8 m) was surpassed in October 2011. The trigger and maximum water elevation was set under AMP Event 6 (Gartner Lee Limited [GLL], 2005) to manage water level increases in the Grum Pit, which was a requirement of the expired water licence (QZ03-059).

This is the first year water elevations in the Grum Pit have been actively managed. The objective is to prevent water of deteriorated quality from reaching downstream receptors and to provide additional storage capacity to

retain water received in the Grum Pit. In August 2013, water transfer from Grum Pit to Vangorda Pit began (TEES, 2013b).

SRK (2009) indicated the overflow elevation to be 1,232.3 m, which is the lowest elevation of the Pit walls in the Grum Slot, located at the southern end of Grum Pit. The maximum recommended elevation, 1,213.4 m, allows storage capacity for a 1-week probable maximum flood before the water reaches the contact elevation of the overburden and bedrock (at 1,216 m) near the Grum Slot (Denison, 2011a). The permeability of the overburden above the bedrock contact was estimated to be about $5x10^{-4}$ metres per second (SRK, 2009). The 2011 Annual Review, AMP Report (Denison, 2012) suggests a revised maximum pit water elevation between 1,214.3 and 1,216.1 m, considering potential hydraulic containment south of the Pit (CH2M HILL, 2012a provides additional discussion). This suggested elevation range is based on the storage capacity between this range of elevations and the elevation of the potential hydraulic containment, as well as the estimated volume of water that could drain to Grum Pit during an extreme precipitation event or breach of the Grum Northeast Interception Ditch.

Observed groundwater elevations in the monitoring wells installed in the Grum Slot are higher than the water elevation in Grum Pit. This condition could contain the water within Grum Pit. However, groundwater elevations in the Grum Slot monitoring wells fluctuate seasonally and there are limited monitoring locations. As a result, there is uncertainty about the effective level of hydraulic containment provided by groundwater under the Grum Slot. Continued dewatering of the Grum Pit would slow the steadily rising water levels, so the water level could be managed to remain below the overburden/bedrock contact. Maintaining the water level below an elevation of about 1,213.4 m will limit potential seepage and provide storage capacity during an estimated 1-week probable maximum flood (Denison, 2011a). Given the water elevation in Grum Pit in mid-September, the water elevation cannot be lowered below 1,213.4 m during this operating season.

The base case scenario (Figure 6) indicates if no additional water is transferred from the Grum Pit to the Vangorda Pit, the Grum Pit water elevations will stay above the overburden/bedrock contact until about a month after transfers begin in 2014. Scenarios 5 and 6 estimate the Grum Pit water level if additional pumping takes place starting in mid-September2013 for 20 and 25 days, respectively (Figure 6). These scenarios consider winter accumulations and suggest that pumping down Grum Pit water levels for another 20 days in 2013 at a rate 9,300 m^3/day (to an elevation of about 1,215 m) will maintain the water elevation below the overburden/bedrock contact until May 2014 (Figure 6). Pit water above the documented overburden/bedrock contact could allow seepage, and less storage capacity would be available in case of an extreme rainfall event or if the interceptor ditch was breached.

On October 10, 2013, YG decided to stop seasonal water transfer from the Grum Pit to Vangorda Pit based on its evaluation of relative risk associated with the Grum and Vangorda Pits. Hence, the decision on the end-of-season water elevation has been made for the Grum Pit.

Grum Sulphide Cell Sediment Control

In 2010, an engineered cover was placed over the Grum Sulphide Cell (GSC) to limit infiltration, and in 2011, a series of surface water management upgrades were completed to improve this remedial measure. Before 2010, runoff from the GSC discharged to Moose Pond, along with runoff from areas upgradient of the Pond. Moose Pond discharges to Vangorda Creek (Denison, 2012). CH2M HILL (2012a) provides additional details about the system.

In 2013, a ditch along the north and east perimeters of the GSC was constructed to intercept and redirect runoff generated in the catchment upstream of the GSC. These two ditches direct the collected water to Vangorda Pit.

Grum V15 Seep and Grum Creek Seeps

Seepage from the Grum WRD surfaces at V15 and Grum Creek, downgradient from the waste rock pile on the southeastern side. If such seepage is not otherwise collected, it discharges to Moose Pond, west of Vangorda Creek, after V15 and the Grum Creek intersect at the Grum weir. After the high runoff conditions in 2011, a seepage collection system was constructed to manage peak spring runoff conditions and constituents of concern in seepage from the Grum WRD. The pumping system at V15, located east of the Grum WRD, consists of

an insulated and heat-traced, 76-mm HDPE pipeline, a power supply, and pumps (Denison, 2011b). The system can redirect seepage from the Grum WRD (V15, Grum Creek, or both) to the Vangorda Pit all year.

In 2013, the V15 conveyance system was operated to transfer water collected from V15 and Grum Creek to Vangorda Pit. However, the conveyance system is not operated year-round. When it is not operated, discharge flows to Moose Pond (Parkin, 2013b, personal communication). The V15 and Grum Creek have no target elevation; however, the target objective is to limit water of deteriorated quality from seeping to downstream receptors (i.e., Vangorda Creek).

Vangorda Pit

Vangorda Pit receives groundwater seepage, direct precipitation, runoff, and Vangorda Creek Diversion seepage, along with water from managed sources such as the Little Creek Pond and the GSC Pond. In 2013, additional sources were placed in Vangorda Pit, including Grum Pit water, discharge collected from V15 and the Grum Creek, and discharge collected in the ditch around the northeast perimeter of the GSC and from dewatering the sludge ponds. There is uncertainty around the timing and magnitude of transfers to Vangorda Pit for these new sources, which are not fully accounted for in the GoldSim model. The water-level elevation in Vangorda Pit has averaged near 1,085 m since 2004, and has ranged between 1,074.6 and 1,094.1 m (Denison, 2012, TEES 2013a). Based on water levels from 2010 to 2012 (Denison, 2012), water elevations in the Vangorda Pit appear to have been lowered to 1,083 m or lower at the conclusion of dewatering activities. They were then allowed to rise throughout the fall and winter, reaching about 1,088 m in the spring.

In 2012, TEES lowered the Pit water elevation to 1,076.8 m at the end of August and stopped dewatering activities (TEES, 2013a). The water elevation was at 1,081.6 m on October 1 and reached 1.084.4 m by early May. The water elevation peaked around mid-June at 1,088.8 m. The water level exceeded the maximum recommended water elevation of 1,091.8 m once in 2008 and once in 2009. Since then, as a result of annual pumping, the water level appears to have been maintained below the maximum recommended level (Denison, 2012). At the maximum recommended water level in the Vangorda Pit (1,091.8 m), which was the limit in the now expired water licence QZ03-059, there is about 3 Mm^3 of storage capacity in case of diversion failure or an extreme storm event.

The base case scenario (Figure 7) suggests water elevations will be below the maximum recommended level, until the Vangorda WTP starts up in May 2014. This considers winter water accumulation and assumes no additional water is actively transferred to the Vangorda Pit in 2013. The base case scenario predicts the May 1, 2014 Pit water elevation will reach between 1,084 and 1,086 m.

Scenarios 5 and 6 evaluate the Grum Pit transfers assuming the Vangorda WTP will not operate for the remainder of 2013. The scenarios estimate the Vangorda Pit water levels considering additional pumping in 2013 for 20 and 25 days beginning in mid-September, respectively (Figure 7).These scenarios suggest the Vangorda Pit water elevation in spring 2014 will be below the maximum recommended level if the end-of-season elevation is below 1,086 m. If Vangorda Pit receives water from Grum Pit until mid-October, its elevations on May 1, 2014 will range from approximately 1,087 m and 1,089 m. However, Vangorda Pit water levels will continue to rise with spring inflows (natural and transfers).

Scenarios 5 and 6 suggest a 2013 end-of-season elevation in Vangorda Pit of 1,086 m or lower accommodates inflows below the 1,091.8 maximum recommended water level, if dewatering of the Vangorda Pit begins on May 1, 2014. The final water elevation will depend on the timing and magnitude of inflows (natural and transfers), as well as the start-up date of the Vangorda WTP in 2014.

Scenario 7 suggests even if no additional water is transferred from the Grum Pit to the Vangorda Pit in 2013, the maximum recommended water level may be exceeded if the Vangorda WTP does not start until June 1, 2014 (Figure 8).

As discussed previously, on October 10, 2013, YG decided to stop seasonal water transfer from the Grum Pit to Vangorda Pit based on its evaluation of risk. This decision effectively determines the end-of-season water elevation for the Vangorda Pit. Dewatering activities should begin at the Vangorda Pit in 2014, as soon as practical, and should continue until the storage capacity is restored.

Little Creek Pond

The Little Creek Pond collects runoff and seepage from the Vangorda WRD via a seepage collection ditch. There were no changes to water management for Little Creek Pond in 2013. CH2M HILL (2012a) provides additional details about the system.

Sheep Pad Ponds

The Sheep Pad Ponds are located south of the Grum Overburden Pile. They collect runoff from upslope areas, and discharge to the lower portion of the Vangorda Creek Diversion (KCB, 2012). There were no changes to water management for Sheep Pad Ponds in 2013. CH2M HILL (2012a) provides additional details about the system.

Vangorda Watering Hole

The Vangorda Watering Hole is understood to be located in the original Vangorda Creek Channel, upstream from the Vangorda Creek Diversion. Since 2002, a sump at this location has collected runoff from the local catchment and pumped it to the Vangorda Creek Diversion (Denison, 2011C). There were no changes to water management for Vangorda Watering Hole in 2013. CH2M HILL (2012a) provides additional details about the system.

Vangorda Waste Rock Dump

A seepage collection ditch along the southern and western basal perimeter of the Vangorda WRD collects and redirects seepage toward Little Creek Pond. There were no changes to water management for Vangorda WRD in 2013. CH2M HILL (2012a) provides additional details about the system.

Summary and Recommendation

The 2013 water elevation targets (see Table 1) were established to limit water of deteriorated quality from migrating offsite, and to provide potential storage capacity in case of extreme environmental conditions or unexpected delays to operations. Changed site conditions and facility operations were also considered when providing recommendation on target elevations.

The target water elevations should be reviewed annually to address changing site conditions and varying environmental factors.

Tables

TABLE 1

Faro 2013 Water Management Targets

Faro Mine Remediation Project

Management Location		Target Elevation (m)	Target Objective	Start	End	Contingency	Comments
Source	Destination						
Cross Valley Pond	Release at X5 or via mobile treatment system to Rose Creek	1,027.5 m	Maximum achievable drawdown of water level until 1,027.5 m Transition to inflow equals outflow once water elevation at target *Limitations* *+ WQ criteria at X14* *+ Max drawdown of 100 mm/day* *+ Lowering below 1,027.5 m exposes sludge beds*	As early as practical per seasonal site constraints	Cease as required based on seasonal constraints	See site emergency response plan	1,027.5 m provides 3.18 m of freeboard (~670,000 m^3 of storage) between the target elevation and the lower spillway elevation (1,030.68 m). This provides an estimated average of 173 days of water accumulation based on the historical range of precipitation and seepage inflow estimates to the CVP, before the water elevation reaches the spillway elevation (i.e., from October 2013 until the end of March 2014). Winter release, as conducted in previous years, should be performed when conditions allow.
Intermediate Dam Pond	Faro Pit (pump to)	Between 1,044.2 and 1,045.2 m	This range is recommended to prevent erosion of the dam face. [a] *Maximum drawdown 40 mm/day*	As early as practical per seasonal site constraints	When target level reached	See site emergency response plan	It is recommended that the water level elevation be maintained as practical between elevations 1,045.2 m, which is the top of the lower riprap, and elevation 1,044.2 m, which is the bottom of the lower riprap, as per the 1991 as-built drawings. Operation outside this range could be performed as a contingency measure to prevent uncontrolled releases of IP water; however erosion monitoring should occur and future maintenance on the dam face will likely be required.
Faro Pit	None currently available	1,141 m	Target end of season water level elevation is 1,141 m, however it is not possible to achieve this elevation in 2013.	As early as practical per commissioning of interim water treatment plant.	Cease as required based on seasonal constraints	None currently available	Faro WTP not currently operational. During the 2013 treatment season IP and ETA water have been placed in Faro Pit raising the water level. Recommended that interim treatment be implemented as soon as possible in 2014 at a rate high enough to control and begin to reduce Faro Pit water level and therefore potential increases of seepage towards Zone II Pit and/or towards the ETA.
Emergency Tailings Area (ETA)	Faro Pit (pump to)	N/A	Collect as much water as practical based on system capacity.	Commence collection as early as practical per seasonal site constraints	Cease collection as required based on seasonal constraints	If problem is encountered, repair system as soon as practical.	
S Wells	Faro Pit (pump to)	N/A	Target objective is to limit bypass of water of deteriorated quality from reaching the receiving environment. Pump to sump to be conveyed to Faro Pit.	Year-round operation		If problem is encountered, repair system as soon as practical.	Capacity of pumping system should be evaluated
S Wells bypass (Shallow Aquifer Interception Trench)	Faro Pit (pump to)	N/A	Target objective is to limit seepage bypass from reaching receiving environment. Pump to main sump to be conveyed to Faro Pit.	As needed to prevent seepage into NFRC		If problem is encountered, repair system as soon as practical.	Capacity of pumping system should be evaluated
X26 (Zone II - Old Well)	Faro Pit (pump to, surface)	-	-	-	-	-	Replaced by CH12-Z2-PW01
CH12-Z2-PW01 (Zone II - New Well)	Faro Pit (pump to, depth)	1,096 m	Target objective is to limit the hydraulic gradient and thus seepage of water of deteriorated quality from the Zone II Pit from reaching the NFRC and underlying alluvial aquifer.	Year-round operation		If problem is encountered, repair system as soon as practical.	Target elevation lowered from 1,103 m to 1,096 (approximate stage elevation of NFRC to the east) to utilize new well screened depth.
Faro Valley Dumps	Faro Creek Diversion Channel	-	-	-	-	-	[b]Water quality does not meet criteria to enable active water management from this location
Grum Pit	Vangorda Pit (pump to)	-	Target end of season water level elevation is not possible to achieve in 2013. [c]AMP trigger: 1,210.8 m; [c]AMP maximum elevation: 1,213.4 m [b]2011 AMP review suggests increasing maximum level to between 1,214.3 and 1,216.1 m.	As early as practical given site constraints	When target level reached	See site emergency response plan	Pit water elevation above the documented overburden/bedrock contact at 1,216 m allows possible seepage and there is a decrease in storage capacity in the case of an extreme rainfall event or breach of interceptor ditch. On October 10, 2013, YG decided to stop seasonal water transfer from the Grum Pit to Vangorda Pit based on its evaluation of relative risk associated with the Grum and Vangorda Pits. Hence, the decision on the end-of-season water elevation has been made for the Grum Pit.

TABLE 1

Faro 2013 Water Management Targets

Faro Mine Remediation Project

Management Location		Target Elevation (m)	Target Objective	Start	End	Contingency	Comments
Source	Destination						
GSC sediment control	Vangorda Pit (pump to)	N/A	Prevent unacceptable water from entering the receiving environment.	When water starts flowing into lined storage pond at toe of GSC	As allowed by pond inflows	Unlined 9,000 m^3 storage pond located to southwest of lined storage pond	-
Grum V15 Seep and Grum Creek Seep	Vangorda Pit (pump to)	N/A	Collect as much water as practical based on system capacity.	Year-round operation		-	[d]TEES reports that the system was shutdown in August. "Normal" flow volumes currently report to Moose Pond. High spring flows will be pumped to Vangorda Pit.
Vangorda Pit	Vangorda/Grum WTP	-	Based on operational experience, the target end of season water level elevation is 1,083 m, or lower, however, it is not possible to achieve this elevation in 2013. Recommended maximum water level is 1,091.8 m, which is consistent with the limit in the expired water licence (QZ03-059) and provides about 3 Mm^3 of storage capacity in the event of diversion failure or an extreme storm event.	As soon as practical per seasonal site constraints	When target level reached	See site emergency response plan	Additional 2013 inputs to Vangorda Pit include Grum Pit, Grum-V15 transfers and runoff collected by the perimeter ditch around the northeast portion of the GSC. On October 10, 2013, YG decided to stop seasonal water transfer from the Grum Pit to Vangorda Pit based on its evaluation of risk. This decision effectively determines the end-of-season water elevation for the Vangorda Pit. Vangorda WTP operation should begin as soon as practical per seasonal site constraints in 2014 to restore storage capacity.
Little Creek Pond	Vangorda Pit (pump to)	1,108 m	Target elevation is 1,108 m; however, the operational management level since 2010 has been 1,106.5 m. Maintain minimum 3 m freeboard; Licence limit is 1,111.8 m	When water starts flowing in Vangorda rock pile collection ditch	When target level reached; historically, fall freeze-up	See site emergency response plan	[e]September 19, 2013 TEES reports that operations shut down for season. Elevation reached 1,107.9 m.
Sheep Pad Pond	Vangorda Creek (siphon)	N/A	Produce water of sufficient quality for discharge to Vangorda Creek.	When water starts flowing in Grum overburden ditch	As allowed by pond inflows	See site emergency response plan	-
Vangorda - Watering Hole	Vangorda Creek Diversion	N/A	Intercept run-off and reduce the volume of water entering Vangorda Pit by pumping into the Vangorda Creek Diversion.	As early as practical given site constraints	As required by inflow volumes	See site emergency response plan	-
Vangorda Waste Rock Dump	Little Creek Pond (via seepage collection ditch)	N/A	-	-	-	-	-

Response to Objective 5 of Task Authorization Component 009-D Water Management Support, Faro Mine Remediation Project

PREPARED FOR: Kaori Torigai/Government of Yukon (YG)

PREPARED BY: CH2M HILL Canada Limited (CH2M HILL)

DATE: September 4, 2012

PROJECT NUMBER: 436662.09.D4.OA

Overview

This technical memorandum (TM) is submitted in response to Task Authorization Component (TAC) 009-D, Water Management Support. This TM addresses the following objective of TAC 009-D:

- Review rates of infilling/storage capacity for Vangorda Pit.

This TM provides a review of existing data and work previously completed regarding Vangorda Creek Diversion (VCD) flow regimes. The calculations and conclusions contained herein are based on elevations reported by Denison, and these assumptions need to be confirmed by field surveys, scheduled for completion in early September 2012. This review of existing information included a discussion with Pat Bryan (independent consultant) to clarify previous work he completed for YG. The estimated time required for Vangorda Pit to fill under average conditions (base case), during the June 2012 high flow event, and under extreme flow events is provided.

This evaluation was completed through the review of existing historical data and reports pertaining to pit water level fluctuations; runoff arising from a range of hydrological conditions, including extreme rainfall events; and accounting for the VCD failure and water treatment plant (WTP) failure. Failure of the WTP is included in this scenario since dewatering of the pit would be suspended. Under large storm events, this volume of water would be relatively minor compared to discharge from a diversion breach. Calculations on time required to fill the Vangorda Pit in the event of a failure of the VCD is provided based on work performed by Pat Bryan (date unknown).

On June 8, 2012, CH2M HILL was notified that water flow in the VCD exceeded the design capacity and water was pooling above the drop structure (Figure 1). At that time, YG requested CH2M HILL provide an estimate of the time required for the Vangorda Pit to fill in the event of a breach of the diversion channel. An email summary produced by CH2M HILL was provided to YG on June 8, 2012, which concluded that Vangorda Pit would be expected to fill with water within days in the event of a failure of the FCD during an event with peak flows sustained at 10 cubic metres per second (m^3/s) (the design flow of the diversion).

Vangorda Pit

Vangorda Pit is approximately 1,150-metres (m) long by 350-m wide and 150-m deep from the crest of the pit walls to the deepest point of the pit (SRK, 2010a). The lowest elevation of the surrounding pit walls where water would first overflow from the pit during an uncontrolled rise in water level is indicated to be at an elevation of 1,130 metres above sea level (masl) at the original Vangorda Creek channel on the northwest side of the pit (SRK, 2006). However, in the *2011 Annual Environmental Monitoring and Activities Report* (Denison, 2012), the maximum water level elevation before overflow from the pit would occur is indicated to be about 1,122 masl. This elevation was also used in the work by Pat Bryan and will be considered the maximum water level elevation throughout this TM to be conservative. Vangorda Pit receives groundwater seepage, direct precipitation, runoff, and VCD seepage, along with water from managed sources, such as the Little Creek Pond, the GSC Pond, and V15/Grum Creek (the V15 system has yet to be operated). Average annual inflows to Vangorda Pit have been

reported as 500,800 m^3 between 2005 and 2009 (Denison, 2010), 350,000 m^3 in 2010 (Denison, 2011), and 384,000 m^3 in 2011 (Denison, 2012). The average annual flow to Vangorda Pit between 2005 and 2011 is estimated as 462,600 m^3 (14.7 litres per second [L/s]).

Water level elevations in the Vangorda Pit between 2005 and 2012 recorded by Denison are shown in Figure 2. The water level elevation in Vangorda Pit has averaged near 1,085 masl and has ranged between 1,074.6 and 1,094.1 masl since 2005 (Denison, 2012). Based on 2010 and 2011 groundwater levels reported by Denison (2012), water surface elevations in Vangorda Pit appear to be lowered to 1,083 masl at the initiation of dewatering activities, and are then managed below approximately 1,088 masl throughout the summer (Denison, 2012). At the maximum recommended water level in Vangorda Pit (1,091.8 masl), which was the license limit in the expired water licence QZ03-059, there is about 1.6 million cubic metres (Mm^3) of water contained in the pit (SRK, 2006). About 4.6 Mm^3 of storage capacity is available at the final overflow elevation at about 1,122 masl, which is about 1.2 Mm^3 less storage than is indicated to be available at 1,130 masl (SRK, 2006). At the average water level elevation in Vangorda Pit (about 1,085.8 masl) (Denison, 2012), Vangorda Pit contains about 1.5 Mm^3 (SRK, 2006). For the current analysis, the approximate available storage capacity is calculated by subtracting the volume associated with the maximum recommended water surface elevation of 1,091.8 masl (1.6 Mm^3) from the volume available at the approximate capacity of pit (4.6 Mm^3) according to Denison.

Vangorda Creek Diversion Channel

To limit runoff from entering Vangorda Pit, the approximately 1,200-m-long VCD was constructed in 1991 around the northern perimeter of the pit (SRK, 2010b). Since that time, upgrades and maintenance to the VCD have occurred, but the design and alignment has not changed (SRK, 2010a). The alignment of the VCD is shown in Figure 3 (Figure 5.11 in RGC, 1996).

In June 2004, a storm event occurred with a magnitude equivalent to the estimated 100-year return period event that resulted in damage to the conveyance system and nearly overtopped the VCD dam at the head of the diversion (SRK, 2010b). An overflow spillway was installed in the VCD dam in 2005 to redirect water into Vangorda Pit if this water level is reached again.

As indicated by SRK (2010b), the VCD consists of the following components:

- Headworks comprising an 8-m-high earth dam and a 1.5-m-diameter culvert within the dam which directs the water into an 800-m-long, 2,400-millimetre (mm)-diameter, half-round, corrugated steel pipe (CSP) culvert section
- A plunge pool or stilling basin located at the end of the culvert sections
- A 3,000-mm-diameter drop-box structure, a 2,000-mm CSP culvert, and a 1-600-mm outfall culvert conveying the discharge from the plunge pool beneath the Haul Road and back into Vangorda Creek
- Two 1,000-mm-diameter culverts at the headworks provide an emergency spillway to the Vangorda Pit for events that exceed the 100-year event

The flume structure (2,400-mm-diameter CSP) was designed to accommodate the 1:100-year storm event, with a peak instantaneous flow of 10 m^3/s (SRK, 2010b). The water level in the flume is expected to rise to a maximum depth of 0.73 m during this peak discharge (SRK, 2010b). The water level in the flume in June 2012 (Figure 1) appears to reach the top of the half-round CSP culvert in places; therefore, it is assumed that the June 2012 event was greater than a 1:100-year event; however, the flow in the diversion is not known.

Infilling of Vangorda Pit

The report titled *Candidate Method for Selecting Design Flood Events for Faro Creek and Vangorda Creek Closure Diversions* by Pat Bryan (date unknown) was reviewed to understand how quickly the Vangorda Pit is expected to fill under extreme flood events. Note that CH2M HILL has not reproduced the work performed by Pat Bryan; we are only reporting his results.

In this work, an average discharge in litres per second per square kilometre (L/s/km^2) for a number of consecutive days based on five return periods is presented from a regional analysis (Table 1). This work generated estimates of average flow for a range of consecutive days and for a range of return-period storm events. Based on regional analyses performed on 15 stations in Yukon and Alaska, Pat Bryan determined that unit flow values (that is, L/s/km^2) were independent of the catchment area. Therefore, the Salcha River near Fairbanks, Alaska with a watershed area of approximately 5,618 km^2 was selected to represent the 20.9-km^2 VCD and pit lake catchment. At the time of the analyses, the data available for the Salcha River covered a 56-year period of record. Table 1 from Bryan (date unknown) provides average discharge rates normalized to the catchment area for various return periods and flow periods generated from the Salcha River dataset by multiple hydrological frequency analyses.

TABLE 1
Average Discharge over Consecutive Days
Faro Mine Remediation Project

Return Period (years)	Average Discharge in L/s/km^2 for the Following Number of Consecutive Days											
	1	**2**	**3**	**5**	**7**	**10**	**15**	**30**	**60**	**90**	**183**	**365**

1,000	469	381	345	280	228	192	155	109	69	57	38	19

(Bryan, date unknown)

The values presented in Table 1 are average discharge rates normalized to the catchment area for the indicated number of consecutive days and for various return periods. Based on correspondence with Pat Bryan (2012), it is understood that for the 1-day average discharge (Column 2), the maximum average daily flow for each year in the period of record from the Salcha River is used as input to the frequency analyses. For consecutive-day periods, the average daily flows from each consecutive-day period in a year (for example, using the 7-day period, Day 1 to 7, 2 to 8, 3 to 10…359 to 365) were first produced; then, the maximum of these average daily flows over the number of consecutive days was selected for each year within the period of record, which were used as the input for the frequency analyses. The procedure was similar for other consecutive-day periods. The 365-consecutive-day period used the annual average daily flow for each year in the period of record from the Salcha River as input to the frequency analyses to predict the average discharge normalized to the catchment for various return periods.

The volume of water that would be generated for each return period from discharge over the indicated number of consecutive days was calculated for the Vangorda Pit catchment at approximately 20.9 km^2 (Table 2).

TABLE 2
Calculated Volume of Flood-Generated Water
Faro Mine Remediation Project

Return Period (years)	Calculated Volume of Water Generated by Flood - Mm^3 Following Number of Consecutive Days

Notes: Bold values indicate, for each return period, the closest volume approaching the available capacity in the pit.

The flood volumes reported in Table 2 were used to estimate the time required to fill the approximate 3 Mm^3 capacity of Vangorda Pit in the event that all water was directed from the diversion to the open pit. For each return period, the closest volume approaching the available capacity in the pit is highlighted in bold in Table 2.

Base Case

The estimated time required for Vangorda Pit to fill with water under the base case scenario is presented in this section. The base case scenario considers average flow conditions and failure of the diversion (or drop box) which results in all flow from VCD being directed to Vangorda Pit.

Based on the 2-year return period event for annual flow, 8 $L/s/km^2$ (Table 1), the annual flow in the VCD is approximately 5 Mm^3. Therefore, assuming a storage capacity in Vangorda Pit of 3 Mm^3 (4.6 Mm^3 at 1,122 masl minus 1.5 Mm^3 at 1,085 masl), in the event of a breach of the diversion channel that was left unrepaired, the pit would fill within approximately 220 days.

June 2012 Event

The estimated time required for Vangorda Pit to fill with water under the estimated flow conditions experienced during the spring freshet in June 2012 is discussed in this section. Flow data is not available for the VCD; therefore, the peak instantaneous flow rate and the duration or overall volume of runoff arising from this runoff event is unknown. Rob Wren (TEES, 2012) indicates flows in the diversion were elevated beginning early in the morning on Friday, June 8, 212, and receded by about Sunday, June 10, 2012. Because insufficient flow records are available, it is not possible to accurately estimate how much of the pit would have filled if the diversion had failed at the beginning of this event.

As noted, following a rain-on-snow event in 2004 which resulted in an estimated 1:100-year event, an overflow spillway was installed behind the headworks dam, which directs flow to Vangorda Pit. Therefore, even without breaching the diversion channel under flow conditions greater than the 1:100-year event, discharge should still be directed to Vangorda Pit. However, based on discussion with TEES (2012), the water elevation behind the headworks dam did not reach a level to initiate flow through the overflow spillway during the June 2012 event. It is uncertain whether this has to do with an issue with the design or construction of the overflow spillway, or is a reflection on the size of the event.

Extreme Event

Bryan reports that the estimated time to fill the 3-Mm^3 capacity in the Vangorda Pit is about 1 week (7 days) for an extreme 1,000-year flood event scenario (Table 3). Based on flood volumes estimated by Bryan for a flood event with a recurrence interval of 100 years, it would require about 16 consecutive days of sustained flows to generate this volume. Additional time would be required for lower-magnitude and shorter-duration flood events.

TABLE 3
Estimated Time Required to Fill Buffer Storage after Breach of Diversion
Faro Mine Remediation Project

Pit Name	Number of Days Required to Fill Pit during Peak of Flood with Return Period of:				
	2 years	**100 years**	**200 years**	**500 years**	**1,000 years**
Vangorda Pit	90	16	12	9	7

(Bryan, date unknown)

The following assumptions were stated in the Pat Bryan report (italicized text):

> *The time estimates presented in Table 4 [*Table 3*] are associated with a number of assumptions. Some of these assumptions would result in an underestimation of the actual amount of time available to repair a breach. The following two assumptions have that effect.*
>
> - *The breach is assumed to occur in the early stages of the flood event. In reality, a large proportion of the flood waters would likely have been successfully conveyed around the open pit before the breach actually developed.*
> - *Upon development of the breach, the full flow of the stream is assumed to report to the open pit. However, the diversion may still be partially functional and continue to convey a portion of the flood waters around the open pit.*
> - *The following two assumptions could potentially result in an overestimation of the time available to repair the diversions.*
> - *The sample of floods provided by the Salcha River streamflow record were assumed to be a good representation of the overall population of floods that could potentially occur in the region of the mine. However, it is possible that the true population is more skewed than suggested by the 56 years of data collected at the USGS station. This would result in true flood volumes that are greater than estimated in Table 2 [Table 1], particularly for the return periods of 500 and 1000 years.*
> - *The flood volumes were assumed to be relatively insensitive to a stream's long term mean annual runoff (MAR). This is probably a good assumption for the shorter durations (say up to 7 days). However, for the longer durations the flood volumes probably show some relationship with MAR. The Salcha River catchment is somewhat drier than the catchments controlled by the diversions (261 mm vs. approx. 350 mm). Thus, the flood volumes presented in Table 2 [Table 1] for the longer durations may underestimate the true amount of water that would be generated by the diversion catchments. This effect is expected to be relatively small.*

The following assumptions have been applied to the current calculations prepared by CH2M HILL:

- The maximum available storage volume of 3.0 Mm^3 is based on the assumption that the pit is already at its maximum recommended water surface elevation of 1,091.8 masl.
- The maximum water surface elevation (overflow elevation) is assumed to be 1,122 masl according to Denison (2012), which results in approximately 1.2 Mm^3 less available storage as compared to the maximum water surface elevation of 1,130 masl reported by SRK (2006).

Water Treatment Plant Failure

In the event of a failure of the WTP, dewatering activities to maintain the water level to the desired elevation would cease, and the volume of water that would normally be processed by the WTP would accumulate in Vangorda Pit. The estimated volume of water which would be pumped from the pit to the WTP over four durations of WTP downtime at an assumed rate of 10,900 m^3/day (that is, the approximate operating capacity of the Vangorda/Grum WTP [Denison, 2011]) is presented in Table 4. If the WTP was inoperable for 30 days, there would be about 327,000 m^3 of water which would accumulate in Vangorda Pit; this is approximately equal to 11 percent of the pit storage capacity (Table 4).

TABLE 4
Estimated Volume which could not be removed from Vangorda Pit in the Event of WTP Failure
Faro Mine Remediation Project

Duration of WTP Failure (days)	Volume which would Not be Processed during this period (m^3)	Percent of Available Vangorda Pit Storage (%)
5	54,500	0.02
10	109,000	0.04
15	163,500	0.05
30	327,000	0.11

In consideration of an event which resulted in additional water being stored in Vangorda Pit, the time required to process the accumulated water was estimated (Table 5). The following steps were taken. A volume of accumulated water as a percentage of the total storage volume in Vangorda Pit was used to estimate a duration required to complete treatment. The portion of annual average inflow to the pit over this duration was then estimated based on annual average inflow of 462,600 m^3 (1,267 m^3/day). The estimated time required to treat the revised total volume (i.e., accumulated volume and portion of annual average inflow over the treatment duration) was then calculated. Approximately 31 days would be required to remove and treat 300,000 m^3 of accumulated water in the event that 10 percent of the current storage capacity was filled. Approximately 307 days would be required to remove and treat 3 Mm^3 of accumulated water. It is clear that very long durations would be needed to treat large volumes of water spilled into the pit, requiring treatment over the winter or over multiple summer seasons.

TABLE 5
Estimated Time Required to Treat Accumulated Volumes
Faro Mine Remediation Project

Volume of Accumulated Water as percent of Total Storage Volume (%)	Volume of Accumulated Water (m^3)	Initial Estimated Time required to Treat (days)	Estimated Annual Inflow during this Period (m^3)	Revised Total Volume to Treat (accumulated and portion of annual average inflow) (m^3)	Estimated Time Required to Treat Total Volume (days)

Assumed WTP capacity		10,900	m^3/day		

Vangorda Pit Summary and Recommendations

In summary, if the VCD were to breach at the initiation of sustained peak flows equal to the design capacity of the VCD (i.e., 10 m^3/s), there appears to be a danger of the Vangorda Pit reaching the water level elevation at which overflow would occur in a short time span (days to weeks) if all the water is directed towards the pit. In the event of a breach of the VCD while the water elevation in Vangorda Pit is at or below 1,085 masl, the pit has the capacity to store approximately 3 Mm^3 of runoff before reaching an elevation from which discharge would occur (1,122 masl). Based on flood volumes generated for an estimated flood event with a recurrence interval of 100 years, it would require several days (about 16 consecutive days) of sustained flows to generate this volume. For an estimated flood event with a recurrence interval of 1,000 years, it would require about 1 week of sustained flows to generate this volume. Remedial measures would need to be implemented rapidly to prevent uncontrolled discharge from the pit. It is uncertain if repairs could be made in this time frame.

Based on this information, CH2M HILL recommends that in the short-term, the VCD be monitored closely, including implementation of a continuous flow monitoring program on this channel. Also, diversion failure modes should be identified and an emergency response plan be developed and ready to implement. In the event of a breach, the diversion should be re-established as soon as practicable, and before the water elevation approaches an elevation of 1,122 masl. The specific design return-period event or peak flow rate that is to be used for ultimate diversion design (level of service) is to be defined, and in the longer-term, the VCD should be upgraded to accommodate these defined events.

SECTION 1

Introduction

The purpose of this report is to describe the baseline conditions and trends for groundwater resources across the Faro Mine Complex (FMC). Understanding groundwater conditions and trends is integral to the prediction and interpretation of potential effects on key Valued Components (VCs), including water quality and fish habitat. The environmental effects assessment for the Faro Mine Interim Works does not identify groundwater as a VC because past mining activity at the site precludes use of onsite groundwater for future uses. However, the indirect effects of changes in groundwater quality and flows have been considered in evaluating effects on the other VCs.

This report is divided into two main sections. Section 2, Methods, defines the overall study area of the baseline analysis, describes the groundwater data and information sources necessary to conduct the analysis, and describes the analysis methods.

Section 3, Results, describes the results of the baseline characterization for groundwater. This section contains a brief description of the geologic and hydrogeologic setting and a more detailed description regarding groundwater quantity across the site. In addition, a discussion of surface water and groundwater interaction is provided to understand how and where surface water might be affected by groundwater discharge. Groundwater quality is also discussed in detail to assess the potential effect of contaminated groundwater on the surface water VC.

SECTION 2

Methods

Groundwater baseline conditions were characterized using various data sources and tools, as described in the following section. In general, information presented in previous environmental reports and historical groundwater monitoring data were used as a starting point for characterizing baseline conditions. The data were reviewed and used to construct a calibrated groundwater flow model for a portion of the site. Groundwater quality trend graphs were also used to develop a better understanding of the baseline groundwater quality conditions at the site, and how these conditions have changed over the past decade or more.

2.1 Study Area

The study area for groundwater resources is generally defined as the aquifers underlying the Faro Mine Area and the Vangorda/Grum Area. The aquifer systems that may potentially be affected by mine operations fall entirely within the surface water drainages that encompass the Faro Mine Area and the Vangorda/Grum Area. Groundwater flowing downgradient from the mine areas quickly discharges to surface water drainages (Rose Creek or Vangorda Creek); therefore, subsurface flow of mine-related contaminants through the aquifer system will be limited, and no extensive downgradient groundwater effects from mine operations are anticipated. For these reasons, a study area encompassing the mine areas will provide appropriate characterization to support the environmental effects assessment for relevant VCs.

The groundwater baseline local study area can be sub-divided into two distinct areas. The first is the Faro Mine Area, which generally covers the topographic drainage area upgradient from surface water station X14 on Rose Creek and includes the Rose Creek Tailings Area (RCTA), Zone II Pit, Emergency Tailings Area, and S-Wells area (see Figure 6G-1). The second is the Vangorda/Grum Area, which covers the entire topographic drainage area upstream from surface water station V27 on Vangorda Creek (see Figure 6G-2). Based on current information, all mine-affected groundwater in the Faro Mine Area will report to surface water at downstream locations along Rose Creek, and mine affected water in the Vangorda/Grum Area will report to several surrounding creeks including Vangorda Creek, AEX Creek and the West Fork of Vangorda Creek. Sources of Data and Information

Data and information sources for the evaluation of groundwater resources baseline conditions include the following:

- Information provided in previous environmental reports for the study area: a literature review and data compilation was completed to extract relevant information for this evaluation.
- Historical field monitoring data for groundwater levels and groundwater quality performed by various consulting firms, collected over the past decade or more and summarized in the reports described in the previous bullet or downloaded from a site-wide database of site water quality data from the various field events (emLine database) (Denison Environmental Services [DES], 2012a).
- Topography for pre-mining and post-mining surfaces from a combination of 10-metre (m) and 30-m digital elevation models, light detection and ranging data, and more detailed topographic mapping performed in 2012.
- Previously developed groundwater flow model of the RCTA (Robertson GeoConsultants, Inc. [RGC], 2006).
- Newly developed groundwater flow models of the Faro Mine Area (CH2M HILL, 2013).
- Field-acquired data from well construction and development activities and aquifer testing efforts.
- Photographs from site visits.

2.2 Data Analysis Methods

The characterization of baseline conditions primarily consisted of a detailed data compilation and literature review. Descriptions of local geology and hydrogeology from previous reports were reviewed and incorporated into this analysis. Hydrographs from historical groundwater level surveys were used to estimate changes in groundwater elevations and general groundwater flow patterns. Groundwater quality trend graphs from historical groundwater quality sampling and testing were used to estimate changes in chemical loading to groundwater as well as contaminant migration patterns. The review of groundwater quality data resulted in an estimation of levels of groundwater quality effects that have occurred within various subareas across the FMC and are used to understand the existing conditions at the site.

The magnitude of groundwater flow through the aquifer system present within the Rose Creek drainage basin was estimated using the following calibrated groundwater flow models:

- North Fork of Rose Creek (NFRC) subarea model, including NFRC, Zone II Pit and Outwash, and S-Wells areas
- Rose Creek Alluvial Aquifer (RCAA) subarea model, including the RCTA and the Cross Valley Dam (CVD) areas

The two groundwater flow model grids each mathematically represent a 262-square-kilometre (km^2) area encompassing a portion of the Rose Creek drainage basin. The locations of the lateral model domain boundaries shown in Figure 6G-3 were selected to coincide with natural hydrological features, such as watershed boundaries and streams, to help establish a regional hydrological framework around the subareas of interest. The model domains are discretized horizontally into grid-block (i.e., cell) spacings ranging from 10 to 100 m. The finer cell spacings (10 m) are located in the two general subareas of interest:

- **NFRC Subarea.** This subarea is of interest because of elevated concentrations of constituents of interest between the Faro Pit and NFRC, north of the RCTA (see Figure 6G-4).
- **RCAA Subarea.** This subarea is of interest because of the tailings situated upgradient from the proposed CVD SIS, which has been identified as the last line of defence for capturing contaminated groundwater before it migrates to downgradient receiving waters (see Figure 6G-5).

Cell spacings were refined in two separate model grids, as opposed to both subareas within one model grid, to avoid excessively long runtimes that would have resulted from having such refinements in one model grid.

The development of these two models is described in the *Fiscal Year 2012 Water Modelling Analysis Report* (CH2M HILL, 2013). For the Vangorda/Grum Area, the estimation of groundwater flow rates is more qualitative, as no groundwater models exist for this area and historical field data are sparse. Therefore, no quantitative analysis has been done to date to identify the amount of groundwater that flows through this area. Alternatively, pit water levels and extraction rates were used to estimate the magnitude of interaction of groundwater with the pit lakes. Measured groundwater elevations were also used to generally assess the direction of groundwater flow in the area.

SECTION 3

Results

The groundwater baseline characterization results are grouped into four sub-sections: (1) Geologic and Hydrogeologic Setting, (2) Groundwater Quantity, (3) Groundwater and Surface Water Interaction, and (4) Groundwater Quality.

3.1 Geologic and Hydrogeologic Setting

The following section provides a brief description of the surficial and bedrock geology and a summary of the geologic and hydrogeologic setting. A more detailed description is provided in the Conceptual Site Model report (CH2M HILL, 2012). Hydrogeology is described in terms of general groundwater flow and observed groundwater elevations, general subsurface properties such as hydraulic conductivity (permeability), and typical pumping well capacities in the project area.

3.1.1 Geologic Setting

The FMC is located on the Vangorda Plateau, a northwest-to-southeast-oriented upland area surrounded by the Anvil Range along the northern edge and Rose Mountains along the southern edge. The area is typical of a mountainous region that has been influenced by multiple past glaciations, consisting of broad, U-shaped valleys, rounded hills, and rough mountain peaks and deposits of glacial till and glaciofluvial materials. The FMC is north of a regionally dominant structural feature, the northwest-trending Tintina Fault (Trench), which separates the older sedimentary rocks deposited into a marine environment on the edge of the older continental craton and the more recent accretion terranes (Smith et al., 2004). Bedrock geology, including the main regional formations and faults, is shown on Figure 6G-6.

The Faro deposit, a lead-zinc massive sulphide deposit, is located in the Mount Mye Formation and consists of phyllites and schists. There are several faults bisecting the ore body that provide possible structural control for groundwater flow, as do other planes of weakness and deformation that are likely to be the most permeable pathways in the crystalline rock. This Cambrian-age formation is greater than 2,000 m thick. Mineralogical analyses suggest that, typically, the rocks of this formation contain between 0 and 4.8 percent total sulphur, with an average of 0.25 percent. A thin veneer of glacial till originally overlaid the Faro Pit and the surrounding south-facing hill slope (RGC, 1996). Faro Creek Valley to the northeast of the pit and the former Faro Creek Channel southwest of the pit contain thicker deposits of colluvium and fluvial deposits, indicated to be up to 100 m thick northwest of the pit and thinning to about 10 m south of the pit (RGC, 1996).

The Grum and Vangorda deposits are located in the Vangorda Formation, which consists predominantly of calcareous phyllite and calc-silicate rocks banded with meta-igneous greenstone and chloritic phyllite, carbonaceous phyllite, and minor limestone (AECOM, 2009). Up to 100 m of till overburden overlaid the Grum deposit; the overburden thinned out to less than 40 m in the northeastern and southeastern portions of the pit (RGC, 2006). The Grum deposit intersects the Mount Mye Formation at its base.

Similar to the Faro deposit, the Grum and Vangorda deposits have large-scale fault structures that provide possible permeable groundwater flow paths. This Cambrian/Ordovician formation is approximately 1,000 m thick. Mineralogy of the Vangorda Formation indicates the phyllites commonly contain 10 to 30 percent calcite and 1 to 2 percent sulphide minerals in the form of pyrite and lesser amounts of pyrrhotite (RGC, 1996).

The surficial geology in the FMC and the surrounding area is influenced by its glacial history, mountainous terrain, and past and current fluvial regime. Glacial till, glaciofluvial deposits, colluviums, and alluvium overlie much of the area. The anthropogenic overburden consists of mined materials, including the waste rock piles and tailings deposits. Typical of surficial geology present in mountainous areas, hilltops and upland areas have exposed bedrock or thin coverings of colluvium. On valley side slopes, deposits of colluvium and till increase in thickness towards the base of the valley, with valley bottoms containing thicker deposits of colluvium, till, and fluvial deposits. Surficial geology deposits in the valley bottoms are complicated by fingering or layering of fan

and outwash deposits, which were subsequently incised. Review of the surficial geology maps suggests the following (Gartner Lee Limited, 2008; RGC, 1996):

- Upland areas such as Mount Aho, Mount Mye, and the Rose Mountains are generally exposed bedrock or are covered in colluvium.
- Valley bottoms, including South Fork Rose Creek, North Fork Rose Creek, Vangorda Creek, and Faro Creek, comprise fluvial materials and glaciofluvial materials.
- Broad side hills and areas adjacent to river valleys are frequently composed of blanket or veneer glacial deposits.
- Till materials are predominantly identified surrounding all three open pits.
- Glaciofluvial deposits are identified in isolated pockets throughout the project area.
- Few organics are identified in the vicinity of the FMC (locations mapped are distal to mine components).

Figures 6G-7 and 6G-8 show the surficial geologic information (Bond, 1999) mapped for both the Faro Mine Area and Vangorda/Grum Area, respectively.

The FMC is located in the discontinuous permafrost Zone of the Canadian arctic and valley bottoms. North-facing slopes and forested areas may contain year-round frozen sediments at depth. On the Vangorda/Grum side, drilling at the Little Creek Dam identified discontinuous permafrost at about 11 m below ground surface; the vertical extent is unknown (SRK Consulting Engineers and Scientists [SRK], 2010b). About 300 million tonnes (154 million cubic metres [m^3]) of waste rock are located in areas adjacent to the three open pits. Surrounding the Faro Pit, there are about 30 separate waste rock piles containing segregated and nonsegregated waste rock spread over a footprint of 3.4 square kilometres (km^2) (RGC, 1996; SRK, 2010a).

South of the Faro Pit, is a secondary pit, the Zone II Pit, from which 6.8 million m^3 of material was removed and subsequently backfilled with rock removed during mining operations. Immediately to the west and south of the Grum Pit, there are about 28 million tonnes (14.4 million m^3)[1] of waste rock covering 1.48 km^2 of surface area. This includes a sulphide cell covering a surface area of about 0.28 km^2. This waste rock is underlain by thin colluvium and low-permeability bedrock. South and southwest of the Vangorda Pit, there are approximately 16 million tonnes (8.2 million m^3) of waste rock occupying about 0.4 km^2 of area. In addition, there is a 5,900-tonne (11,400-m^3) stockpile of the fines of the oxidized ore or baritic fines (RGC, 1996).

The 55 million tonnes (28.6 million m^3) of tailings in the RCTA generally exhibit a coarser-grained fraction on the northern edge of the Original and Second Impoundments, grading to finer-grained fraction to the south. In the Intermediate Dam (ID) Impoundment, tailings grade from coarse to fine from east to west. The thickness of the tailings increases towards the centre of RCTA—reaching about 25 m thick—and thin to zero towards the edges. Stratigraphy and geology underlying the RCTA may be important for containment and potential attenuation processes. Surficial geology underlying the tailings consists of sand and gravel of fluvial and glaciofluvial origin with till deposits identified along the edges of the valley but pinch out towards the central portion. Within the coarse-grained fluvial and glaciofluvial material are areas of interlayered fined-grained silts and clays typical of backwater areas or glaciolacustrine deposits. Underlying bedrock appears to be from the Vangorda Formation and consists of phyllite and bands of marble and is intruded by the Anvil Batholith. It was noted that the bedrock, where exposed, appears to weather readily (RGC, 1996).

The Emergency Tailings Area (ETA) contains about 123,000 tonnes (63,800 m^3) of tailings deposited into the former channel of Faro Creek. Tailings thickness varies between about 6 and 20 m and overlies the former Faro Creek Channel materials and calcareous phyllite of the Vangorda Formation (SRK, 2010b).

[1] Refined quantity estimates are in progress.

3.1.2 Hydrogeologic Setting

As is typical in mountainous environments, the upland mountain areas act as groundwater recharge areas and the valley bottoms as groundwater discharge areas. Locally, there may also be recharge to underlying aquifers from streams or rivers. In areas where low-permeability confining units are located, artesian conditions may be prevalent.

Pre-mining regional groundwater flow within the Faro Mine area likely mirrored the topographic gradient with flow oriented from the highlands towards the valley bottoms. This suggests the pre-mining groundwater moved south/southwest from Mount Aho and adjacent mountains in the north towards the Rose Creek Valley; and on the opposite side of the valley, north-to-northwest flow would be expected from the Rose Mountains towards Rose Creek. Between the Faro Mine Area and Vangorda/Grum Area, there is a surface drainage divide, which is assumed to be coincident with a groundwater flow divide. From this local topographic high, groundwater flow is expected to follow the gradient of Rose Creek and travel northwest to west toward the RCTA.

On the Vangorda/Grum side, pre-mining groundwater flow is assumed to have followed the topographic gradient and flowed from the mountains around Mount Mye in the north to northeast towards the Town of Faro and the Pelly River in the southwest. Mining activities have changed the landscape (e.g., generating new surface topography with open pits and waste rock piles, fracturing rock faces, and ponding water behind dams) and are actively controlling groundwater (i.e., depressurization of pit walls, groundwater capture via pumping wells and altering recharge patterns with diversion channels), which influences the direction and quantity of groundwater flow. Factors controlling the pre-mining groundwater flow regime are expected to be regionally similar post-mining, but in local areas, groundwater flow would be altered.

Figures 6G-9 and 6G-10 show generalized post-mining groundwater flow directions for the Faro Mine and RCTA, and the Vangorda/Grum Area, respectively.

3.1.2.1 Faro Mine Area Hydrogeology

Surrounding the Faro Pit, four hydrostratigraphic units are potentially present based on a review of geological data predominantly to the south and southeast of the Faro Pit (RGC, 1996):

- A thin, low-permeability layer of till overburden
- An overburden/weathered bedrock contact unit where permeability (hydraulic conductivity) is reported to be higher
- A bedrock horizon with a low-permeability unit of phyllite and schist but with some higher-permeability areas associated with schist with diorite intrusions and fractured/faulted bedrock
- The former Faro Creek Channel northeast and southeast of the Faro Pit

In general, the Faro Pit is expected to act as a groundwater sink. However, the operation of the groundwater extraction well in the Zone II Pit may result in some limited outflow from the southeastern portion of the Faro Pit. This outflow is likely captured by the extraction well and subsequently treated. The water level within the Faro Pit is actively managed by pumping, creating a local groundwater sink, potentially resulting in flow into the pit from most directions. Groundwater discharge to the pit occurs mainly from the natural former Faro Creek Channel and overburden/bedrock contact, whereas seepage from bedrock is limited except via limited faults and fractures (AECOM, 2009). The schematic cross section depicted on Figure 6G-11 shows the groundwater movement between the Faro Pit and the RCTA (refer to Figure 6G-9 for the cross-section location).

Faro Waste Dumps are expected to be largely unsaturated, with infiltrating precipitation collecting within topographic low areas of the pre-mining topography (such as former stream channels). However, based on the presence of seeps associated with the waste dumps, many with low pH and high sulphate and zinc concentrations, these waste dumps are a key source of surface water contamination. Depending on the subcatchment in which a particular waste rock pile is located, seepage from the waste rock piles surrounding the Faro Pit potentially report to Faro Pit, Zone II Pit, NFRC, Old Faro Creek, Guardhouse Creek, or Rose Creek Valley

(RGC, 1996). The schematic cross section depicted on Figure 6G-12 shows the groundwater movement between the Faro Pit and the Zone II Outwash (refer to Figure 6G-9 for the cross-section location).

Zone II Pit water elevations were historically managed to remain at a level no greater than 1,113 m (SRK, 2007). Since October 2010, the Zone II Pit water levels ranged between 1,103 and 1,111 metres above mean sea level (masl) (DES, 2012a). Following the installation of the new Zone II extraction well in 2012, the Zone II Pit target elevation was changed to allow for maintenance of groundwater levels within the Zone II Pit well below the stage of NFRC (which is approximately 1096 m). Maintaining Zone II Pit water levels below the NFRC stage ensures that seepage from the Zone II Pit will not flow toward and subsequently discharge into the NFRC. The new well was first used in June 2013, and Zone II Pit water levels were drawn down to about 1,098 m by late August 2013.

The NFRC area includes the Zone II Outwash and S-Wells areas, which are located between the Faro Waste Dumps and the NFRC. The stratigraphy within the Zone II Outwash and S-Wells areas consists of alluvial/outwash materials overlying bedrock. In locations towards the valley margins, till material may be present and form a low-permeability confining unit.

In the area of the S-Wells, a shallow aquifer unit of sand and gravel is underlain by low-permeability till with an underlying deeper aquifer of sand and gravel overlying weathered bedrock. The shallow unit has high water levels, which suggests that it is perched. The low permeability unit consists predominantly of fine-grained materials that appear to be laterally continuous but likely inter-finger with coarser grain materials. This unit represents a confining layer (with lower-permeability sediments of variable thickness) for the underlying deep aquifer, which includes deeper sand and gravel materials overlying bedrock. The bedrock in the S-cluster area consists of schist of the Mount Mye Formation and is defined as calcareous schist to calcareous silicate (AECOM, 2009).

The shallow sand and gravel layer in the vicinity of the S-Wells has been interpreted to consist of sediments from a pre-mining surface drainage that is now covered by the Intermediate Waste Dump. This aquifer is about 20 to 30 m wide and 3.5 m thick, and is characterized by hydraulic conductivity values ranging from 10^{-5} to 10^{-4} metres per second (m/s) (SRK, 2009a). The deep aquifer is around 350 m wide, has an average thickness of 15 m, and is characterized by hydraulic conductivity values of 10^{-6} to 10^{-4} m/s (SRK, 2009a). According to SRK's 2008 groundwater investigation (2009), the shallow aquifer pinches out near the NFRC and only the deep aquifer is present beneath the creek.

The following three hydrostratigraphic units have been identified in SRK's 2009 groundwater investigation (2010b) in the upper portion of the NFRC:

- A permeable alluvial deposit of variable thickness between 5 and 20 m
- An underlying lower-permeability phyllite bedrock unit
- A colluvium and till unit towards the valley margins (a low-permeability unit between the alluvial deposit and bedrock, which is not present in the central portion of the valley [SRK, 2010b]). Discontinuous permafrost has also been identified at shallow depths.

Groundwater flow in the NFRC valley is towards the southwest, aligned with valley orientation (AECOM, 2009). The gradient is estimated to be 0.02 metres per metre (m/m), consistent with the gradient of the NFRC (SRK, 2010b). The potentiometric surface adjacent to the upper end of the NFRC is shallow, with the water table identified within 2 m from the surface in wells installed in sand and gravel (SRK, 2010b). Groundwater levels in the Zone II Outwash area are up to 5 m below ground surface (AECOM, 2009) and appear relatively stable. Groundwater levels exhibit very little variation, less than 1 m seasonally and less than 2 m spatially, within the Zone II Outwash itself within the alluvial aquifer. Water levels within S-Well monitoring wells installed in till, overburden, and bedrock were within 10 m of ground surface. Seasonal variation of the potentiometric surface has typically been less than 1 m (AECOM, 2009).

The ETA is located in the former Faro Creek Channel, downstream from the Faro Pit. A prominent feature in this area is a 6- to 20-m-thick low permeability tailings unit overlying an alluvial/weathered bedrock unit of sand and gravel with higher permeability. This alluvial/weathered bedrock unit appears to thin from about 5 m near the waste dumps to about 1 m down-valley. Lower-permeability competent bedrock (calcareous phyllite of the Vangorda formation) provides the foundation (SRK, 2010b; AECOM, 2009). A significant groundwater and surface water source to the ETA is the upgradient waste dumps and associated seeps (including seep location X23, which is surface expression of the groundwater flow traveling along the Faro Creek Channel). At the ETA, groundwater elevations tend to fluctuate seasonally within a range of about 2 m. AECOM (2009) noted rapid responses in groundwater elevations in the area to snowmelt.

Key findings from review of the site characterization studies at the Faro Mine Area can be summarized as follows:

- The Faro Pit is generally considered a groundwater sink, except for limited outflow because of pumping at the Zone II Pit.
- Faro Waste Dumps are expected to be largely unsaturated with infiltrating precipitation but constitute a key source of surface water contamination.
- The stratigraphy within the Zone II Outwash and S-Wells areas consists of alluvial/outwash materials overlying bedrock.
- Groundwater flow in the NFRC valley is towards the southwest, aligned with valley orientation, and with a gradient assumed to be 0.02 m/m.
- Groundwater levels in the Zone II Outwash area are up to 5 m below ground surface and appear relatively stable with very little variation.
- Water levels within S-Well monitoring wells installed in till, overburden, and bedrock were within 10 m of ground surface. Seasonal variation of the potentiometric surface has typically been less than 1 m.
- At the ETA, groundwater elevations tend to fluctuate seasonally within a range of about 2 m.

3.1.2.2 Rose Creek Tailings Area Hydrogeology

The RCAA system is a classic fluvial depositional system deposited by Rose Creek and its tributary, the NFRC. The alluvial aquifer is composed of a heterogeneous mixture of silt, sand, gravel, and cobbles. The alluvial deposits are thickest near the centre of the valley, aligned with the ancestral thalweg of Rose Creek, with the thickest deposits around 50 m. Before tailings deposition, Rose Creek was flowing in a meandering stream channel that crossed the valley floor and was fed by several smaller streams that drained the hillsides of Rose Creek Valley. The water table of the underlying valley-fill aquifer was very close to the stream level, indicating a good hydraulic connection between the stream and the groundwater that flowed in the permeable valley sediments (RGC, 1996). Following the onset of mining operations, tailings were deposited over the alluvial valley-fill deposits to a maximum thickness of about 25 m. The greatest thicknesses of tailings were deposited in the Original and Second Impoundments, with thickness diminishing toward the edges of the valley (RGC, 1996).

Available stratigraphic information obtained primarily from the SRK 2009 groundwater investigation (2010b) below the CVD suggests there are up to four hydrostratigraphic units within the RCTA, as summarized in the following bullets.

- The tailings form a low-permeability unit overlying the central portion of the valley that ranges from approximately 250 m wide at the CVD to 800 m wide in the central portion of the valley, with a maximum thickness of about 25 m.
- An overburden unit (valley-fill) composed of highly permeable fluvial and glaciofluvial sand and gravels with thicknesses of up to 50 m towards the central portion of the valley, thinning towards the valley edges.
- A less-permeable glacial till unit underlying the overburden unit that can reach up to 25 m thick towards the valley edges and pinches out in areas towards the middle of the valley (SRK, 2010b).

- Phyllite and schist bedrock forming an underlying lower-permeability hydrostratigraphic unit.

The fluvial deposits are characterized in some areas by extremely high hydraulic conductivities, but also a high degree of heterogeneity. Hydraulic information collected downstream from the CVD supports this hypothesis. The boring log for pumping well PW-1, located in the central portion of the Rose Creek Valley, indicates the presence of numerous intervals of clean sand and gravel layers. In contrast, wells farther to the north, closer to the valley margin, indicate a stratigraphic section dominated by silty sand or gravel with only a few limited layers of clean sand and gravel. Productivity of wells completed in the "well-washed" sand and gravel deposits is very high, with wells capable of pumping in excess of 31.5 to 38 liters per second with very limited drawdown (less than 5 m). The permeability of the other lithologic units present (till, weathered bedrock, and bedrock) are orders of magnitude lower than the fluvial sediments, and therefore play a minor role in the bulk movement of groundwater through the aquifer system.

The pre-mining (1967) water levels were about 1.5 to 3 m below ground surface, and the horizontal gradient down-valley was about 0.011 m/m (RGC, 1996). No temporal trends in groundwater elevation data are apparent (AECOM, 2009). These data suggest a fairly low-gradient, unidirectional flow system typical of meandering stream valleys. In contrast, a static groundwater-level survey of the RCTA in the vicinity of the ID and CVD, performed on September 2006 (RGC, 2006), shows significant complexity in the groundwater flow field because of the presence of the ID, the CVD, and the Rose Creek Diversion (RCD).

Groundwater levels in the aquifer at the toe of the CVD Pond are significantly lower than the water level in the Polishing Pond. Similarly, the groundwater levels in the aquifer at the toe of the ID are significantly lower than in the ID Pond. According to RGC (2006), the groundwater flow field suggests that the Polishing Pond and the ID Pond are "underdrained" because of the large contrast in permeability between the pond sediments/tailings and the underlying aquifer material.

Vertical hydraulic gradients measured in multi-level wells installed within the RCTA indicate the presence of downward gradients between the tailings and the underlying alluvial deposits, suggesting that either contaminants mobilized because of infiltration of precipitation through the tailings or that contaminants entering the tailings through discharge from the ETA could be carried downward and discharged into the underlying RCAA. Additional vertical hydraulic data indicate that gradients within the RCAA are upward between the deepest alluvial deposits and the more shallow portions of the alluvial system. These data suggest that regional groundwater flow moves laterally towards the valley-fill deposits and discharges upward into the more permeable alluvial horizons before migrating downgradient (down valley) with the alluvial flow system.

In 2005, RGC conducted drilling and aquifer test activities at the toe of the CVD (RGC, 2006). Aquifer tests were conducted with a sustained pumping rate of about 2,400 litres per minute from the central well (RGC-PW02) for 24 hours and at about a rate of 1,800 litres per minute from the northern most well (RGC-PW01) for 56 hours. Results from these aquifer tests indicated hydraulic conductivity for the RCAA between $5x10^{-4}$ and $7x10^{-4}$ m/s.

The *Water and Load Balance Study for Rose Creek Tailings Storage Facility* (RGC, 2005) presents scenarios of sulphate and zinc loading to Rose Creek based on current and future conditions and assuming alternatives for remediation. Simulations were based on the review of site characterization studies of the tailings and underlying aquifer materials, as well as historical monitoring data for surface water and groundwater quality.

The following are key findings from review of the site characterization studies:

- Seepage sources to the RCAA include the tailings, Faro Creek seepage (from the ETA) upstream from the RCTA, and seepage from the CVD Pond and ID Pond.
- The average groundwater velocity in the RCAA was estimated to range between about 0.03 and 2 metres per day (m/day), based on an average hydraulic conductivity of $1.2x10^{-4}$ m/s for the RCAA.
- Seepage from the RCD was estimated to take place at about 200 litres per second (L/sec) between the ID and the end of the diversion.

- The area between the CVD and X14 in Rose Creek represents a major groundwater discharge Zone (with an estimated combined flow of 83 L/sec).
- Rose Creek remains a gaining stream downstream from the confluence with RCD, where it returns to its natural streambed; groundwater discharge into Rose Creek between X14 and station RC1 (Next Creek) is estimated to flow up to 200 L/sec.
- In the summer of 2012, CH2M HILL performed additional aquifer tests at existing and new monitoring wells along the CVD. The data collected during these aquifer tests were used to calibrate the RCAA Subarea groundwater model. Modelled horizontal hydraulic conductivity values resulted in the following:
  - Northern Rose Creek Valley near the CVD (alluvium): 5 to 50 m/day
  - Basal till in the CVD area: 0.01 to 0.1 m/day
  - Slope till in the CVD area: 1 to 3 m/day
  - Bedrock in the CVD area: $2x10^{-3}$ m/day

Results show that the RCAA area has high permeability and would allow for the effective operation of a groundwater extraction system to intercept contaminated groundwater before it travels downgradient.

3.1.2.3 Vangorda/Grum Area Hydrogeology

Similar to the Faro Pit, the area around the Grum Pit has a low-permeability overburden (glacial till) unit overlying low-permeability bedrock. A second confined (limited extent) overburden unit, called the Thalweg aquifer, may also be present. This is composed of high-permeability sands and gravels, about 20 to 30 m thick. Above the bedrock contact, a permeable unit of unknown extent may also be present and may be connected to the Thalweg aquifer (RGC, 1996). Investigations to the south and west of Grum Pit reported in the 2009 groundwater investigation (SRK, 2010b) typically identified calcareous phyllite of the Vangorda Formation underlying silty to sandy glacial till in both areas. Three hydrostratigraphic units were identified as consisting of a surficial silt, sand, and gravel unit; weathered bedrock; and competent bedrock (SRK, 2010b). The schematic cross section depicted on Figure 6G-13 shows the groundwater movement between the Grum Pit and the Vangorda Waste Rock Dump (refer to Figure 6G-10 for the cross-section location).

West of the Grum Waste Dumps, Grum Creek and several tributaries drain towards Vangorda Creek. Generally, alluvium material is found over till material with varying degrees of sand, gravel, and clay. Weathered bedrock, transitioning to competent bedrock, provides the foundation. The thicker overburden and fluvial sediments of the Grum Creek area have been interpreted to provide the greatest conduit for groundwater movement. At one borehole in the Grum Creek area, two permeable water-bearing units were observed above the bedrock: a coarse-grained gravel and boulder layer and a sand and silt unit, separated by a low-permeability silt layer (RGC, 1996). Although limited data are available, a confined aquifer, overlain by an unconfined aquifer, was identified at depths below approximately 12 m. Lateral extents, recharge, or discharge zones for the confined aquifer are unknown (SRK, 2006). Drainage from the Grum Waste Dump is anticipated to predominately flow towards the south/southeast, particularly in thicker overburden materials of Grum Creek and associated smaller tributaries (RGC, 1996).

Similar to the Grum Pit area, three hydrostratigraphic units appear to be identifiable in the Vangorda Pit area. However, at Vangorda, there is an overlying confining, low-permeability overburden composed of silty, sandy glacial till (about 30 m thick) that sits atop a saturated sand and gravel unit overlying weathered bedrock that transitions into competent and lower-permeability calcareous phyllite. Several fault zones have been identified in the bedrock (RGC, 1996).

Similar to the Grum Creek area, the greatest conduit for groundwater movement away from the Vangorda Waste Dumps is expected to be via sediments underlying the Vangorda Creek area. Typically, overburden consisting of compact silty and sandy glacial till overlies a more permeable basal sand and gravel unit. Underlying this unit is the low permeability calcareous phyllite bedrock of the Vangorda Formation (RGC, 1996). In the investigated areas of Vangorda Creek Valley, fluvial sediments up to about 20 m thick offer greater permeability. A confining unit of low-permeability till with silty to sandy composition overlies more permeable

sand/weathered bedrock. Thickness of each unit varies but, combined, they are not typically greater than 30 m (SRK, 2010b).

In general, water levels downgradient of the Vangorda/Grum Pits exhibit about 1 m of seasonal fluctuations. Groundwater in the alluvium appears deeper (about 7 to 10 m below ground surface) and shallower in the overburden (about 2 to 6 m below ground surface). Water levels reported for the bedrock are relatively stable, about 7 m below ground surface (AECOM, 2009).

Key findings from review of the site characterization studies at the Vangorda/Grum Area can be summarized as follows:

- The area around the Grum Pit includes three hydrostratigraphic units: a surficial silt, sand, and gravel unit; weathered bedrock; and competent bedrock.
- Drainage from the Grum Waste Dump is anticipated to predominately flow towards the south/southeast, particularly in thicker overburden materials of Grum Creek and associated smaller tributaries.
- At Vangorda, an overlying confining, low-permeability overburden composed of silty, sandy glacial till (about 30 m thick) sits atop a saturated sand and gravel unit overlying weathered bedrock that transitions into competent and lower-permeability calcareous phyllite.
- The greatest conduit for groundwater movement away from the Vangorda Waste Dumps is expected to be via alluvial deposits underlying the Vangorda Creek area.

3.2 Groundwater Quantity

The two calibrated groundwater flow models for the Rose Creek Drainage Basin, as described above and in the *Fiscal Year 2012 Water Modelling Analysis Report* (CH2M HILL, 2013), were used to estimate groundwater flow rates through the Faro Mine area and the RCAA. The groundwater flow modelling domain is shown in Figure 6G-3. The Rose Creek Drainage Basin groundwater models use meteorological and hydrological data, along with drainage basin and aquifer characteristics, to compute groundwater flows and groundwater elevations (heads) throughout the modelled domain under assumed hydrogeological and operational conditions. Modelled potentiometric surfaces for each of the six model layers in the areas of interest are shown in Figure 6G-14. This figure shows that the groundwater flow at the site recharges the RCAA before continuing further downstream along Rose Creek. Modelled depths to groundwater are shown on Figure 6G-15 and vary from about 75 m below ground surface at the waste dumps to less than 10 m at the Mill Building area, the ETA, and the Impoundments. Groundwater balances for the Faro Mine Area and the RCTA are provided in the following subsections. A calibrated groundwater flow model does not currently exist for the Vangorda and Grum areas. No quantitative analysis has been done to date to identify the amount of groundwater that flows through this area. As an alternative, pit water levels and extraction rates were used to estimate the magnitude of interaction of groundwater with the pit lakes. Measured groundwater elevations were also used to generally assess the direction of groundwater flow in the area.

3.2.1 Faro Mine Area

The NFRC model was used to compute a steady-state groundwater balance in an approximately 4.2-km^2 area encompassing the Northeast Rock Dump, NFRC, Zone II Pit and Outwash, and S-Wells areas (see Figure 6G-16). Table 6G-1 lists the components of the combined modelled groundwater balance for Model Layers 1 through 6 in the NFRC model subarea. These data indicate that approximately 20 L/sec of groundwater flows through the NFRC.

TABLE 6G-1
Modelled Groundwater Balance in the NFRC Model Subarea
Faro Mine Interim Works

3.2.2 Rose Creek Tailings Area

The RCAA model was used to compute a steady-state groundwater balance in an approximately 4.6-km^2 area encompassing the RCTA, the CVD, and an area downstream from CVD slightly below the confluence of the RCD with the Rose Creek Channel (see Figure 6G-16). Table 6G-2 below lists the components of the combined modelled groundwater balance for Model Layers 1 through 6 in the RCAA model subarea. These data indicate that approximately 211 L/sec of groundwater flows through the RCAA.

TABLE 6G-2
Modelled Groundwater Balance in the RCAA Model Subarea
Faro Mine Interim Works

Groundwater Inflow Component	Groundwater Inflow Rate (L/sec)	Groundwater Outflow Component (L/sec)	Groundwater Outflow Rate (L/sec)
GW Recharge from Precipitation	2	GW Pumping	0
GW Recharge from Streams	134	GW Discharge to Streams	147
GW recharge from Ponds and Pit Lakes	0	GW Discharge to Ponds and Pit Lakes	0
Subsurface Inflow	75	Subsurface Outflow	15
		GW Discharge to Drains	49
Total GW Inflows	**211**	**Total GW Outflows**	**211**

Notes:
Values are rounded to the nearest L/sec.

3.2.3 Vangorda/Grum Area

Before development of Grum Pit, a small lake existed at this location, representative of a pre-mining water table (RGC, 1996). The Thalweg aquifer along the north-northeast portion of the pit provides recharge to the pit. Groundwater flow is estimated to be in a predominately southerly direction. Between 1990 and 1995, approximately 1.5 million cubic metres per year (m^3/yr) of water was pumped from the Grum Pit for dewatering during mining operations; of this, about 900,000 m^3/yr was estimated to be from aquifer storage (RGC, 1996).

Since mining operations and pit pumping ceased, the Grum Pit water level elevation has risen. On average, the Grum Pit water level rate of increase has been about 3 metres per year (DES, 2012b). In 2011, the pit gained approximately 464,084 m^3/yr of water (DES, 2012b). Since 2004, the average annual increase in water gained by the Pit has fluctuated between less than 300,000 m^3/yr in 2006, 2007, and 2010, to more than 500,000 m^3/yr in 2008 and 2012. The decreased rate of water flow to the pit (compared to during mining conditions) may indicate a reduction in groundwater infiltration as the pit water level has increased. Decreased groundwater discharge to the pit under these conditions would be expected because of the reduced magnitude of the hydraulic gradient driving groundwater flow into the pit. The rate of groundwater discharge to the pit likely fluctuates throughout the year, as groundwater levels and pit levels vary.

The Vangorda Pit water level elevation averages 1,085 masl and had ranged between 1,074.6 and 1,094.1 masl since 2004 (DES, 2012a). Seasonal pumping maintains Vangorda Pit as a groundwater sink. The amount of water pumped from Vangorda Pit ranged from none to 925,678 m^3/yr between 2002 and 2010 (an average of 580,903 m^3/yr, or 746,875 m^3/yr if the years with zero pumping are excluded (2006 and 2007)—this means that the following year, higher pumping rates are needed to address 2 years of storage) (DES, 2011). In this particular case, pumping volumes are not an accurate gage of natural inflow volumes to the Pit, because of the contribution from other sources such as pumping from Little Creek Pond as well as some inflow from the Sheep Pad Ponds during freshet in many years.

Groundwater flow is expected to be toward the south/southwest, predominately sourced from the sand and gravel units associated with Vangorda Creek and its associated small tributaries. As the water level in the pit is retained below surrounding groundwater elevations (as it will be for the long term), flow may be received from all directions. During mining, total groundwater discharge to Vangorda Pit averaged between 350,000 m^3/yr from 1992 to 1993 and about 220,000 m^3/yr from 1994 to 1995. Post-mining estimates of discharge to Vangorda Pit from deep groundwater discharge along structural features in bedrock is estimated at less than 100,000 m^3/yr (RGC, 1996).

3.3 Groundwater and Surface Water Interaction

Knowledge of surface water/groundwater interaction is somewhat limited across the site because of the limited number of data available to support the characterization of the nature of stream-aquifer interaction at the site. Ongoing and planned studies are being conducted to determine locations where groundwater discharges to surface water, or where groundwater is replenished by surface water seepage into the subsurface.

3.3.1 Faro Mine Area

Groundwater discharge to the Faro Pit occurs mainly from the natural Old Faro Creek Channel and overburden/bedrock contact, whereas seepage from bedrock is limited except via limited faults and fractures (AECOM, 2009).

Groundwater flow beneath the ETA is expected to discharge in the form of seeps south of the mine road or discharges to the Old Faro Creek channel in the historic Faro Creek Valley upon which the ETA sits or it will travel southwest in the overburden/weathered bedrock unit and flow to the RCAA beneath the RCTA. The horizontal hydraulic gradient in the ETA has been estimated as 0.05 m/m (SRK, 2010b). Old Faro Creek gains significantly along its length, with much of the groundwater contributions to the stream likely occurring between X23 and the mine access road (SRK, 2006).

Before tailings deposition, Rose Creek was flowing in a meandering stream channel in the valley floor. Rose Creek was fed by several smaller streams that drained the hillsides of Rose Creek Valley. The water table of the underlying valley-fill aquifer was very close to the stream level indicating a good hydraulic connection between the stream and the groundwater flowing in the permeable valley sediments. Depending on local conditions, groundwater was either discharging into Rose Creek or was being recharged by the stream (RGC, 1996).

Groundwater levels are elevated beneath the ID Pond and CVD Pond (Polishing Pond) because of vertical leakage from the impoundments. This condition results in the development of significant upward gradients within the alluvial aquifer just downgradient from the CVD and the presence of an associated groundwater

discharge area in that location. One location in the central portion of the valley was observed to have artesian conditions (SRK, 2010b). Groundwater elevation data in the alluvium aquifer downgradient from the CVD indicate groundwater is within 5 m of the ground surface. Groundwater contours also indicate elevated groundwater levels on the south side of the valley in the vicinity of the CVD, suggesting that leakage from the RCD is recharging the aquifer system in this vicinity. Observed stratification of groundwater quality in this area, with higher sulphate concentrations observed in the northern portion of the aquifer and lower concentrations to the south, support the hypothesis that RCD leakage is occurring in this area and providing cleaner diluted water to the southern portion of the aquifer.

Additional field work using streambed piezometers was being completed by CH2M HILL in the fall of 2012 below the CVD and in the summer of 2013 on the NFRC. Preliminary results suggest that the NFRC is gaining upstream and in the vicinity of Zone II Outwash (see Figure 6G-17). In addition, preliminary results also confirmed gaining conditions along Rose Creek downstream from the CVD (see Figure 6G-18). These conditions suggest that subsurface contamination could readily be discharged into the surface water system in these areas.

3.3.2 Vangorda/Grum Area

At the upper end of Vangorda Creek below the Vangorda Pit, limited data suggest groundwater levels are higher than the creek levels in both the overburden and bedrock, indicating a gaining creek (SRK, 2010b). No other field work has been performed to date to be able to estimate the groundwater and surface water interaction in more detail.

3.4 Groundwater Quality

This section describes the current distribution of groundwater contamination. The data will be used to evaluate the areas of highest groundwater contamination and assess the chemical breakthrough of constituents of concern such as zinc and sulphate. Chemical time series plots for selected locations throughout the study area are shown in Attachment 6G-1.

Groundwater quality at the site is changing and evolving as a result of the ongoing geochemical processes within mine-impacted areas. The three main contributors of contaminant load to groundwater are as follows:

- The waste dumps: the Northeast Waste Dump, Northwest Waste Dump, Main Waste Dump, Intermediate Waste Dump (including the infilled Zone II Pit)
- The three open pits: the Faro, Grum, and Vangorda pits (including discrete inputs into the pits--that is, pit walls, seepage interception systems [SIS], and surface runoff)
- Tailings: ETA and RCTA

The following paragraphs present mine-related water contamination information for known impacted areas of the FMC, while the following subsections summarize the current observed chemical loading and contributors to groundwater quality degradation at the various sites of interest.

Metal attenuation can be a result of adsorption to natural organic matter or to secondary oxyhydroxides, or coprecipitation of secondary mineral phases. This attenuation may act to retard the migration of trace metals away from the waste dumps within the shallow groundwater system, especially in the early stages of seep development when pH is near neutral, but zinc and sulphate are elevated. Sulphate is a relatively conservative and abundant constituent that generally is a good indicator for acid rock drainage. Zinc is used as an indicator metal representing several other trace metals that are released during acid rock drainage production because of its more consistently higher concentrations making the analytical measurements and trends more reliable. Given this source material, zinc is the best indicator of trace metal breakthrough from sulphide mineral sources because of its higher concentrations and higher mobility compared to other metals such as cadmium. For the purposes of this discussion, the relative levels of contamination are categorized according to the concentrations listed below for use in illustrating figures and differentiating areas of impact within the text. These categories are based on zinc and sulphate concentrations (and further described in the conceptual site model [CH2M HILL, 2012; AECOM 2009]):

- Not impacted or minimally impacted: sulphate ≤ 40 milligrams per litre (mg/L) and zinc ≤ 0.05 mg/L.
- Slightly impacted: sulphate > 40 mg/L and ≤ 400 mg/L or zinc > 0.05 mg/L and ≤ 0.5 mg/L.
- Moderately impacted: sulphate > 400 mg/L and ≤ 4,000 mg/L or zinc > 0.5 mg/L and ≤ 5 mg/L. This corresponds to sulphate and zinc concentrations one order of magnitude greater than the "slightly impacted" range.
- Highly impacted: sulphate > 4,000 mg/L or zinc > 5 mg/L. This corresponds to sulphate and zinc concentrations one order of magnitude greater than the "moderately impacted" range.

In general, spring samples collected during the influence of freshet tend to show lower concentrations, except in years when the freshet comes too late or too early relative to the sampling event. By contrast, samples collected in summer and fall tend to show the highest concentrations.

3.4.1 Faro Mine Area

Groundwater quality for the Faro Mine Area is described for each major area of interest in the following subsections. Figures 6G-19 and 6G-20 show the overall water quality effects at the Faro Mine Area for alluvial wells and bedrock wells, respectively.

3.4.1.1 Faro Pit

Faro Pit water quality is highly impacted with moderate sulphate concentrations (less than 1,000 mg/L) and high zinc concentrations (above 5 mg/L) for data reviewed between 1998 and 2012 (DES, 2012b). Contaminated water from the S-Wells SIS and from the Zone II Pit are currently pumped to Faro Pit. Seep water flowing to Faro Pit (discharging from the Faro Waste Dump) ranges in water quality from not impacted to highly impacted, as shown in Figure 6G-21. Sulphate levels in Faro Pit water have remained steady while zinc concentrations have steadily increased over the last decade (see Attachment 6G-1). The most current field sampling results show that seepage from the Main Waste Dump at X23 continues to deteriorate as sulphate, manganese, and dissolved metals concentrations increased and seepage became more acidic (RGC, 2013).

3.4.1.2 North Fork of Rose Creek

The North Fork of Rose Creek Valley is a typical alluvium-filled fluvial valley that runs along the southeastern margin of the FMC. The Faro Creek diversion discharges Faro Creek flows into the NFRC just upstream from the Northeast Waste Dump From this point, the creeks flows to the southwest at the base of the Northeast and Intermediate Waste Dumps and flows beneath the Haul Road through the North Fork Rock Drain. The creek then continues past the S-Wells area, eventually joining the South Fork of Rose Creek before entering the RCD. The two most extensively studied areas with the NFRC Valley are the Zone II Outwash area and the S-Wells area. Numerous wells have been installed in both locations to characterize the alluvial thickness, depth to bedrock, groundwater flow patterns, and groundwater quality. Wells also exist in other areas of the valley, usually in close proximity to the NFRC. Groundwater quality has been substantially impacted in both the Zone II Outwash and S-Wells areas because of subsurface migration of mine-affected water from waste dumps in the Zone II Pit area and from the Intermediate Waste Dump, respectively. Field investigations conducted in 2013 suggest that the NFRC is a gaining stream along the majority of its length between its confluence with the Faro Creek Diversion and the North Fork Rock Drain. These conditions suggest that groundwater contamination in the vicinity of the stream represent a viable pathway for contaminants of concern to enter the stream system and degrade surface water quality. To address this concern, a seepage interception system has been installed at the S-Wells site that consists of a shallow permeable trench and a series of deeper weathered bedrock extraction wells. Recent groundwater quality data also indicate that sulphate and zinc concentrations are increasing in groundwater at the base of the Northeast Waste Dump, suggesting that this area may also represent a conduit for metals loading to the NFRC.

Zone II Pit and Outwash Area

Groundwater flows from the waste dumps west of the Zone II Outwash area. Groundwater in the waste-rock-filled Zone II Pit is managed (pumped) to mitigate potential seepage from the pit to the Zone II Outwash area. As

discussed above, groundwater contamination in the vicinity of the Zone II area may travel along two potential pathways: groundwater contamination could discharge to NFRC, in which case it would likely bypass the RCAA through the RCD, or it may travel as subsurface underflow, resulting in continued loading to the RCAA. Leakage from the NFRC or RCD to the RCAA might also represent a possible pathway for contaminant loading to the groundwater system.

Water in the Zone II Pit (well X26) is highly impacted. Sulphate concentrations have been more variable than zinc concentrations since 2008, however, both sulphate and zinc concentrations within the pit continue to increase. Zinc and sulphate loads collected from the Zone II Pit were 5.8 tonnes per year (tpy) and 184 tpy, respectively, in 2011. Between July and September 2012, loads collected from the pit were approximately 3 tpy of zinc and 134 tpy of sulphate. Contaminant concentrations at X26 tend to be lower in the spring when meteoric water inputs are greater. Several seeps are present in the vicinity of the Zone II Pit on the Faro Pit side of the waste dump, but no seeps locations are noted at the toe of the waste dump in the immediate vicinity of the Zone II Outwash. There are seeps observed both downgradient and upgradient from the Zone II Outwash areas (RGC, 2012).

The Zone II Outwash area surface water and groundwater monitoring locations are shown on Figures 6G-22 and 6G-23. In the alluvial aquifer, two wells are highly impacted, five wells are moderately impacted, one well is slightly impacted, and one well is not impacted. In the bedrock aquifer, four out of five monitored wells are moderately impacted and one is highly impacted. Most groundwater both in the shallow and bedrock aquifers in the Zone II Outwash is moderately impacted, with some highly impacted groundwater near the toe of the waste dump (locations BH2, BH6, and BH8). Concentrations have generally remained stable or show gradual increasing trends in Zone II Outwash wells over the monitoring period (see Attachment 6G-1). Monitoring wells to the north of Zone II Outwash have had substantial mine-related contamination increases in recent years. The *2012 Groundwater Quality Review* (RGC, 2013) suggests that the breakthrough of more highly contaminated groundwater might occur in this area from the toe of the Intermediate Waste Dump to the west.

S-Wells Area

Contaminated groundwater daylights both as seeps along the Intermediate Waste Dump face to the north of the S-Wells area and also flows south toward NFRC within alluvial, weathered bedrock, and bedrock aquifers. Groundwater contamination in this area discharges to NFRC and could contribute loading to the RCAA as leakage from the NFRC or RCD. The 2008 S-Cluster groundwater investigation (SRK, 2009) concluded “the plume of contaminated groundwater [in the S-Wells area] is likely moving underneath the NFRC in permeable materials and discharging to the NFRC at indeterminate locations.” The S-Wells groundwater monitoring locations are shown on Figures 6G-24 and 6G-25.

In general, groundwater in the S-Wells area is moderately to highly impacted, with some slightly impacted alluvial and overburden locations on the far eastern portion of the site. The shallow groundwater system generally has the highest contamination, with 11 out of 21 wells classified as highly impacted (and 8 wells classified as moderately impacted). Groundwater contamination does extend into the bedrock as well, with highly impacted groundwater detected in one bedrock well (SRK-08-SPW2) and moderately impacted groundwater detected in the remaining bedrock wells (RGC, 2012).

An SIS was constructed in 2009 to intercept contaminated groundwater flowing from the Intermediate Waste Dump before it reached NFRC. It consists of three parts (RGC, 2012):

- A shallow rock-filled interceptor trench located in the shallow aquifer (overburden) with one pumping well (SRK08-PW3).
- Two pumping wells (SRK08-SPW1 and SRK08-SPW2) screened in the deeper bedrock aquifer. Only one well typically operates because the other well contains high iron concentrations.
- Surface water interception via a rock drain at the toe of the Intermediate Waste Dump. Water is diverted to the shallow aquifer interceptor trench.

S-Wells SIS water is pumped to the Faro Pit and currently operates year-round (RGC, 2012). Zinc and sulphate loads in 2011 captured by the S-Wells SIS were 21.3 tpy and 300 tpy, respectively. Between May 2012 and December 2012, 17.8 tonnes of zinc and 272.5 tonnes of sulphate were captured at the S-Wells SIS.

Groundwater quality in wells classified as slightly to moderately impacted have relatively stable concentration trends. However, some wells along the southern toe of the Intermediate Waste Dump continue to deteriorate gradually (SRK05-SP1A/B and SRK05-SP2). Groundwater quality in the till unit, located to the west of the SIS, also continues to degrade (this water is not captured by the SIS). Groundwater quality in the bedrock aquifer is improving overall as a result of pumping the S-Wells SIS bedrock wells (see Attachment 6G-1). However, operation of the shallow aquifer interceptor trench of the S-Wells SIS has not made a noticeable impact on shallow groundwater quality (RGC, 2012).

Northeast Rock Dumps Area

The Northeast Rock Dumps are located to the northeast of the Zone II Pit and southeast of the Faro Pit and cover an area of about 0.51 km^2, with a maximum elevation of 1,290 masl. The “near pit” dumps are located immediately to the south and southwest of the pit, just north of the Main and Intermediate Dumps, and cover an area of 0.2 km^2, with a maximum elevation of 1,200 masl (RGC, 1996). Groundwater quality at areas in the vicinity of the Northeast Waste Dumps can be summarized as follows:

- Areas downgradient from the Northeast Waste Dump: Three well pairs (BH12A/B, BH13A/B, and BH14A/B) are located at the toe of the Northeast Waste Dump and are screened mainly in weathered bedrock and deeper bedrock (Figure 6G-26). Groundwater conditions in this area have worsened substantially over the last 10 years (see Attachment 6G-1), and zinc concentrations up to about 10 mg/L have been detected at the well pair closest to Zone II (BH14A/B; highly impacted). The well pairs located farther northeast have moderate groundwater effects. Mine-related contamination is expected to increase in this area and additional investigation is required to evaluate the extent of contamination (RGC, 2012).
- NFRC upgradient from Northeast Waste Dump: Three wells are located near NFRC upgradient from Northeast Waste Dump (P09-UN1 through P09-UN3) and are screened in alluvial sediments or weathered bedrock (Figure 6G-27). The area is characterized by sulphate concentrations less than 200 mg/L and zinc concentrations up to 1 mg/L. The moderate contamination effects shown in this area are a result of mine-impacted groundwater flow from the Northeast Waste Dump (RGC, 2012).

3.4.1.3 Emergency Tailings Area

The ETA has some of the highest contaminated groundwater and surface water in the Faro Mine Area and represents a major source of contaminant loading to the RCAA (AECOM, 2009). The ETA seep, surface water, and groundwater monitoring locations are shown on Figures 6G-28 and 6G-29. The *Anvil Range Mining Complex 2005 Seepage Investigation at the Emergency Tailings Area* (SRK, 2006) concluded that a significant contaminant load discharged to the Faro Creek Canyon and Rose Creek Valley from the ETA. Flow monitoring and sampling completed in 2005 and 2006 along Faro Creek below the ETA indicated that the total zinc load discharged from the ETA (surface flow and subsurface seepage discharging downstream from the mine access road) ranged from about 35 to 80 tpy (RGC, 2007). The contaminated seepage is a combination of surface flow originating as toe seepage from the Main Waste Dump and groundwater flow from the waste dump through highly permeable alluvial sediments from the Old Faro Creek. The ETA tailings also contribute significantly to the groundwater and surface water contaminant loading (SRK, 2006). Seeps discharging to the ETA at the base of the Main Waste Dump, which form flowing surface water across the ETA in Old Faro Creek and Mill Canyon Creek, are highly impacted and show increasing contaminant load trends as evidenced by the water quality at X23 (Figure 6G-28).

Surface water and groundwater quality in the ETA have increasing trends for acidity, sulphate, and zinc, and this trend is expected to continue (see Attachment 6G-1). Seepage from the Main Waste Dump has become noticeably more acidic over the last 3 years, suggesting ongoing ”breakthrough” of ARD products and a decline in the buffering capacity of the Main Waste Dump waste rock and ETA alluvial soils (RGC, 2012). Groundwater seepage from the ETA expresses downgradient from the mine access road. In 2006, an interim SIS was constructed at the southeast end of the ETA (just downgradient from the mine access road) to collect surface

water runoff and seepage (from two prominent seeps). The SIS operates during the ice-free seasons, and collected water is pumped to the Faro Water Treatment Plant or the Faro Pit. The ETA SIS intercepted an estimated 31.2 tpy of zinc and 488 tpy of sulphate in 2011 and an estimated 86 tpy of zinc and 940 tpy of sulphate in 2012. Seepage not intercepted by the SIS was observed discharging directly to the Faro Creek Canyon. Overburden and weathered bedrock groundwater quality and surface water quality downstream from the ETA is highly impacted (locations P09-ETA2 and FCS-4), and the seasonal operation of the ETA SIS does not appear to be improving this condition. However, groundwater in deep bedrock downgradient of the ETA does not show indications of mine-related contamination based on data from monitoring well P09-ETA1 (RGC, 2012).

Background groundwater quality concentrations can be estimated from wells located far away from the waste rock dumps and with unimpacted water quality conditions. Based on a review of available groundwater quality data, well TH86-17 appears to be an accurate indicator of background groundwater quality (Figure 6G-27). This well is located in the alluvial aquifer upstream from the RCTA. Sulfate concentrations at this well have been stable between 10 and 20 mg/L for the last decade. Zinc concentrations have been consistently below 0.02 mg/L, sodium concentrations below 5 mg/L, and pH has been neutral.

3.4.2 Rose Creek Tailings Area

Generally, low metals bearing groundwater from the south and southeast flows to the RCTA, and Faro-Mine-contaminated groundwater flows to the RCTA from the north, with a significant portion of contamination associated with the Faro Creek Canyon. Locally, the tailings contribute to groundwater contamination in the RCTA as well. The extensive leakage of clean water from the RCD (south of the RCTA) has a major influence on the spatial water quality trends in the RCAA, especially further downgradient near the CVD. There is a significant spatial trend from south to north of not impacted groundwater transitioning to moderately impacted groundwater in the western half of the RCTA. This section provides summary information on the water contamination in the RCTA.

3.4.2.1 Impoundments

Groundwater in the Original and Second Impoundment area ranges from not impacted to highly impacted, with the highest sulphate and zinc concentrations in the tailings. Higher concentrations are generally observed in groundwater in the northern portion of the RCAA likely because of contaminant discharges from the Faro Creek Canyon. The Original and Second Impoundment groundwater monitoring locations are shown on Figure 6G-30. The upper portions of the underlying alluvial aquifer are highly-impacted. The highest sulphate and zinc concentrations are detected in tailings porewater in the southeastern (multilevel wells P03-01 and P03-03) and northwestern (multilevel well P03-06) areas of the Second Impoundment. Zinc concentrations tend to be highest near the interface of the sand and gravel RCAA and the overlying tailings. Groundwater contamination in the far southeast section of the impoundment areas is thought to be mainly a result of direct tailings-related contamination (RGC, 2012).

There are continued increases in contamination in the alluvial aquifer near the mouth of Faro Creek Canyon (multilevel well P03-06), which is a primary flow path for contamination from the Faro Mine Area to the RCTA (see Attachment 6G-1). The increased contamination near well P03-06 may also be a result of either increased waste dump- and ETA-related contamination or seepage from the coarse tailings beach of the Original Impoundment (Figure 6G-30). Contamination in the alluvial aquifer is also increasing within the central portion of the Second Impoundment. The increase in contamination may indicate that the neutralizing capacity of the aquifer is being exhausted in this area (AECOM, 2009).

Groundwater in the Intermediate Impoundment area ranges from not impacted to highly impacted as well, with the highest sulphate and zinc concentrations in the tailings. Sulphate and zinc concentrations are very high in shallow tailings porewater and have been relatively stable for the last 10 years. In contrast, alkalinity and pH have decreased substantially since 2009, indicating a breakthrough of the acid front in the Intermediate Impoundment area. Concentrations in the RCAA are gradually increasing in the Intermediate Impoundment, and seepage from the coarse tailings beach of the Second Impoundment and input from the Faro Creek Canyon are

likely sources. Concentrations are expected to increase until they are similar to conditions observed in the Second Impoundment (RGC, 2012).

3.4.2.2 Toe of Intermediate Dam

Groundwater in the RCAA at the toe of the ID is moderately impacted in the alluvium and till, as shown in Figure 6G-31. Concentrations of mine-related contaminants have generally increased since 2001 in this area, and seepage from the coarse tailings beaches of the upgradient impoundments and input from the Faro Creek Canyon are likely sources. Conditions are expected to deteriorate in the coming years as the groundwater contamination front in the RCTA progresses. Groundwater in the southern portion of the area is generally less contaminated than in the northern portion because of the inflow of clean groundwater leaking from the RCD to the south. However, concentrations in this area do show a significant increasing trend for sulphate, iron, magnesium, and manganese. It is believed that the mine-related total dissolved solids (TDS) plume front has reached this area (RGC, 2012).

3.4.2.3 Toe of Cross Valley Dam

Groundwater in the RCAA on the southern edge of the Rose Creek Valley, downgradient from the CVD, remains only slightly impacted by mine-related groundwater contamination, as shown on Figure 6G-31. Contamination concentrations increase from south to north at the toe of the CVD, as expected based on clean water inputs from the RCD. Groundwater contamination in the northern area has higher sulphate and magnesium concentrations, indicative of the leading edge of the TDS plume. Concentrations of sulphate and metals are gradually increasing in shallow groundwater along the north side of the valley downgradient of the CVD, but zinc concentrations remain low (less than 0.05 mg/L) (RGC, 2012) (see Attachment 6G-1). Groundwater in bedrock at the toe of the CVD follows similar trends from south to north across the valley, as shown in Figure 6G-32. Bedrock groundwater in the north portion of the valley (P09-C1) is moderately impacted because of elevated sulphate and zinc concentrations. However, in the central portion of the valley (well P09-C2), bedrock groundwater is not impacted (RGC, 2012).

Groundwater farther downgradient from the CVD (wells X16A/B) are not impacted. However, the well pair upgradient from this location (X17A/B) has had increases in mine-related contamination since 2008, which is likely to continue. This water is now within the slightly impacted range, indicating continued movement of the leading edge of the TDS plume front down the valley (RGC, 2012). The deeper Well X17B exhibits distinct seasonal variations with highest concentrations observed in the spring. This may be because of upwelling of deep groundwater from underlying bedrock, or might indicate that tailings impacted groundwater is flowing beneath the CVD (AECOM, 2009).

3.4.3 Vangorda/Grum Area

Most groundwater monitoring locations in the Vangorda/Grum Area are between the toes of the waste dumps and Vangorda Creek, as shown in Figures 6G-33 and 6G-34. In general, the Vangorda/Grum Area is characterized by low-permeability materials with some higher permeability alluvial material associated with current and former stream channels. Therefore, seepage from waste dumps is expected to follow preferential flow paths.

3.4.3.1 Grum Pit and Waste Rock

Wells installed in the overburden and bedrock south of the Grum Pit suggest hydraulic containment of the pit lake because water levels in both wells were similar to the water level in Grum Slot, an area of standing water south of the pit (SRK, 2010b). The Thalweg aquifer appears to be hydraulically connected to the standing water in the Grum Slot (RGC, 1996).

Grum Pit is expected to be a groundwater sink (groundwater flows to the pit) and is not considered a source of contamination to the Vangorda Creek drainage as long as the water is kept contained. The pit water quality is considered highly impacted, based on elevated zinc concentrations. One well pair is located on Grum Waste Dump (P09-GS1A/B), as shown on Figures 6G-33 and 6G-34. Groundwater quality in the overburden is classified as highly impacted (based on zinc concentrations), and groundwater in the underlying bedrock is classified as moderately impacted in this area (based on sulphate concentrations). The high zinc concentrations in the

overburden may be related to in situ leaching of mineralized waste rock in the area, but contamination may be influenced by seepage from the Grum Waste Dump (RGC, 2012).

At the southeast and western toes of the Grum Waste Dump and within Grum Creek, seep and shallow groundwater data indicate slight to moderate effects on groundwater quality from the Grum Waste Dump and seepage from Moose Pond. Groundwater quality appears to be greatly influenced by recharge events. The sulphate and other TDS plume parameters have migrated into the Vangorda Creek Valley and do extend beyond specific drainage channels, but zinc concentrations are still low in the area (typically less than 0.05 mg/L) (RGC, 2012).

Weathered bedrock and bedrock at the toe of the Grum Waste Dump generally have slightly impacted groundwater with less sulphate than the overburden (RGC, 2012).

According to RGC's 2012 Groundwater Quality Review (2013), groundwater quality in the shallow overburden soils to the south, southwest, and west of the Grum Waste Dump continues to gradually deteriorate (see Attachment 6G-1). Currently, contamination is limited to conservatively transported species, such as sulphate and manganese, and deeper groundwater near the bedrock-overburden interface in this area is still unimpacted by waste rock seepage. Concentrations are typically lowest during the spring freshet (May) and highest during the summer months.

3.4.3.2 Vangorda Pit and Waste Rock

Vangorda Pit is expected to be a groundwater sink and is not considered a source of contamination to the Vangorda Creek drainage if the pit is maintained at or below its current water level (RGC, 2012). The pit water quality is highly impacted based on elevated zinc concentrations. Sulphate and zinc concentrations at the surface of Vangorda Pit have been steadily increasing since 2000.

Groundwater in monitoring wells and seep collection wells located both within the Vangorda Waste Dump and at the toe of the waste dump is generally moderately to highly impact. Sulphate and TDS constituents in shallow groundwater downgradient of the Vangorda Waste Dump have been increasing, even in areas downgradient of the till berms installed in the waste dump to reduce seepage, while zinc generally remains low (less than 0.12 mg/L). The highest zinc concentrations are detected in more permeable alluvial sediments (associated with preferential flow paths) and have recently increased near the northwestern toe of the Vangorda Waste Dump (RGC 2013).

Little Creek Pond, located northwest of the Vangorda Waste Dump on Little Creek, holds water from the Vangorda Waste Dump seepage collection system, which is pumped to Vangorda Pit. Seepage from Little Creek Dam, where Vangorda Waste Dump seepage is collected, appears to have slight effects on downgradient water quality toward Vangorda Creek (RGC, 2012). The sulphate and zinc concentrations of surface water in Little Creek Dam have steadily increased since 2004 (see Attachment 6G-1). However, the alluvial aquifer and bedrock wells in the vicinity of Little Creek Pond are considered slightly impacted with neutral pH (see Figures 6G-33 and 6G-34).

Weathered bedrock and bedrock at the toe of the Vangorda Waste Dump have slightly impacted groundwater with less sulphate than detected in the overburden (RGC, 2012).

EXECUTIVE SUMMARY

The Faro Mine Complex (FMC) was formerly owned by the Anvil Range Mining Corporation, which produced lead and zinc concentrates that were extracted for lead, zinc, silver, and gold. Mine operations were terminated in April 1998 and the site went into receivership. Site Care and Maintenance responsibilities are being managed by contractors acting on behalf of the Government of Yukon (YG), while efforts continue towards development of the final scope and implementation of the overall Faro Mine Remediation Plan (FMRP). In the meantime, YG seeks authorization for 10 years of interim site management and maintenance activities. This document has been prepared to support the assessment under the Yukon Environmental and Socio-economic Assessment Act (YESAA), specifically summarizing current surface water quality and aquatic ecosystem conditions.

Habitat

The FMC occupies portions of both the Rose Creek and Vangorda Creek watersheds. Both creeks are tributaries to the Pelly River, which is a major tributary to the Yukon River. Several physical alterations to stream courses have occurred over time around the FMC to accommodate mine features; these include several stream diversions and numerous road crossings, with some of the latter resulting in barriers to fish passage. Common features among most reaches of the Rose-Anvil Creek and lower Vangorda Creek systems include boulder and cobble substrate, with boulders and pools providing in-stream cover for fish.

Water Quality

Water quality data for the FMC from 2008 through 2012 indicate that concentrations of a variety of non-metals and metals are elevated in surface waters relative to the typical range of background (reference station) concentrations. Alkalinity, conductivity, hardness, sulphate, total dissolved solids, calcium, cobalt, magnesium, nickel, sodium, strontium, and zinc occur at concentrations above the background range in approximately half or more of samples collected downstream of the Vangorda/Grum Area (V8) and the Faro Mine Area (X14). Concentrations of non-metal analytes are below those expected to have adverse effects on aquatic biota.

Despite contaminant contributions from the Vangorda/Grum Area, and likely also the landslide across West Vangorda Creek, metal concentrations in lower Vangorda Creek

(V8) rarely (≤ 15% of samples) exceed guidelines for protection of aquatic life and median concentrations are usually less than half the guideline values. Water concentrations of several metals (cadmium, cobalt, iron, lead, manganese, zinc) are above guidelines in up to one-quarter of samples collected at NF1, on the North Fork Rose Creek (NFRC) upstream from the Haul Road, but zinc is the only mine-related metal that exceeds guidelines at stations between NF1 and Rose Creek station X14, just downstream of the Faro Mine Area. Cobalt and manganese are also found at concentrations above water quality guidelines for protection of aquatic life in up to 40% of samples collected at X14, but median concentrations for all metals other than zinc are below the guidelines. Water quality guidelines are infrequently exceeded at stations farther downstream in Rose Creek (R4) and Anvil Creek (A1) indicating that mine related effects on biota, if any, are likely localized around the Faro Mine Area. Mine-related effects on water quality do not extend into the Pelly River.

Sediment Quality

Arsenic, lead, manganese, and zinc concentrations tend to be elevated in sediment samples collected at mine-exposed areas relative to sediment quality guidelines. However, the survival and growth of the invertebrate *Hyalella azteca* were not affected in 14-day laboratory tests of sediments collected from mine-exposed areas. Mine-related contaminants tend to be associated with fine sediment particles; however the aquatic environments around and downstream from the FMC are typically moderately to swiftly flowing, with sediments composed of particles that are mainly sand-sized or larger. Therefore, sediment exposure to mine-related contaminants represents a relatively minor pathway for potential effects to aquatic biota to mine-related contaminants.

Periphyton

Periphyton communities were characterized in 2009 along the NFRC and the RCD. The group of photosynthetic bacteria known as Cyanophyta dominated the communities in the NFRC just downstream from the confluence with the Faro Creek Diversion, but a shift to diatom (Bacillariophyceae)-dominated communities occurred closer to the Haul Road and continued downstream throughout the RCD. *Achnanthes minutissima* made up roughly 44% (4 – 72%) of the diatom assemblage at all stations and was more abundant downstream than upstream of mine-related influences. *Achnanthes*, especially *A. minutissima*, is generally considered tolerant of a wide variety of environmental conditions and, in other studies, has been observed in streams affected by mining or metals. Data

regarding the tolerance to mine-related disturbance of diatom species other than *A. minutissima* are generally sparse or lacking in the published literature.

Benthic Invertebrate Communities

Benthic invertebrate surveys conducted annually between 2007 and 2010 indicated that communities are dominated by organisms in the mayfly (Ephemeroptera), stonefly (Plecoptera), and caddisfly (Trichoptera) groups, as well as midges (chironomids). Most communities in streams adjacent to and downstream from mine-related disturbances at the FMC are similar to communities in local reference areas uninfluenced by mining. Exceptions are communities along lower NFRC and in Rose Creek immediately downstream from the Faro Mine Area where modest differences from reference communities have been evident in some studies.

Fish

Slimy sculpin (*Cottus cognatus*), Arctic grayling (*Thymallus arcticus*), Chinook salmon (*Oncorhynchus tshawytscha*), burbot (*Lota lota*), round whitefish (*Prosopium cylindraceum*) and longnose sucker (*Catostomus catostomus*) have been reported in surface waters around and downstream from the FMC. Within the Rose-Anvil Creek system, slimy sculpin tend to be most abundant, followed by Arctic grayling. Both species appear to utilize surface waters around the Faro Mine Area year-round, although some Arctic grayling migrate to the Pelly River for overwintering. Although juvenile Chinook salmon have occasionally been observed in the Rose Creek system near the FMC, the Rose-Anvil Creek system has been classified as having low to moderate suitability for Chinook salmon spawning and adults have rarely been observed in surface waters around the FMC. Blind Creek, to the east of Vangorda Creek, is a local stream that provides more important habitat for salmon. Downstream of the Vangorda/Grum Area, in lower Vangorda Creek, juvenile Chinook salmon are typically the most abundant fish because this area provides valuable rearing habitat for juveniles that move in from the Pelly River and other tributaries.

Culverts and rock drains associated with road crossings have isolated fish populations in upper NFRC and upper SFRC from populations in the rest of the Rose-Anvil Creek system. Also, a culvert on West Vangorda Creek and a waterfall on the main stem of Vangorda Creek have prevented upstream migration so that fish are only found in the lower reach of Vangorda Creek.

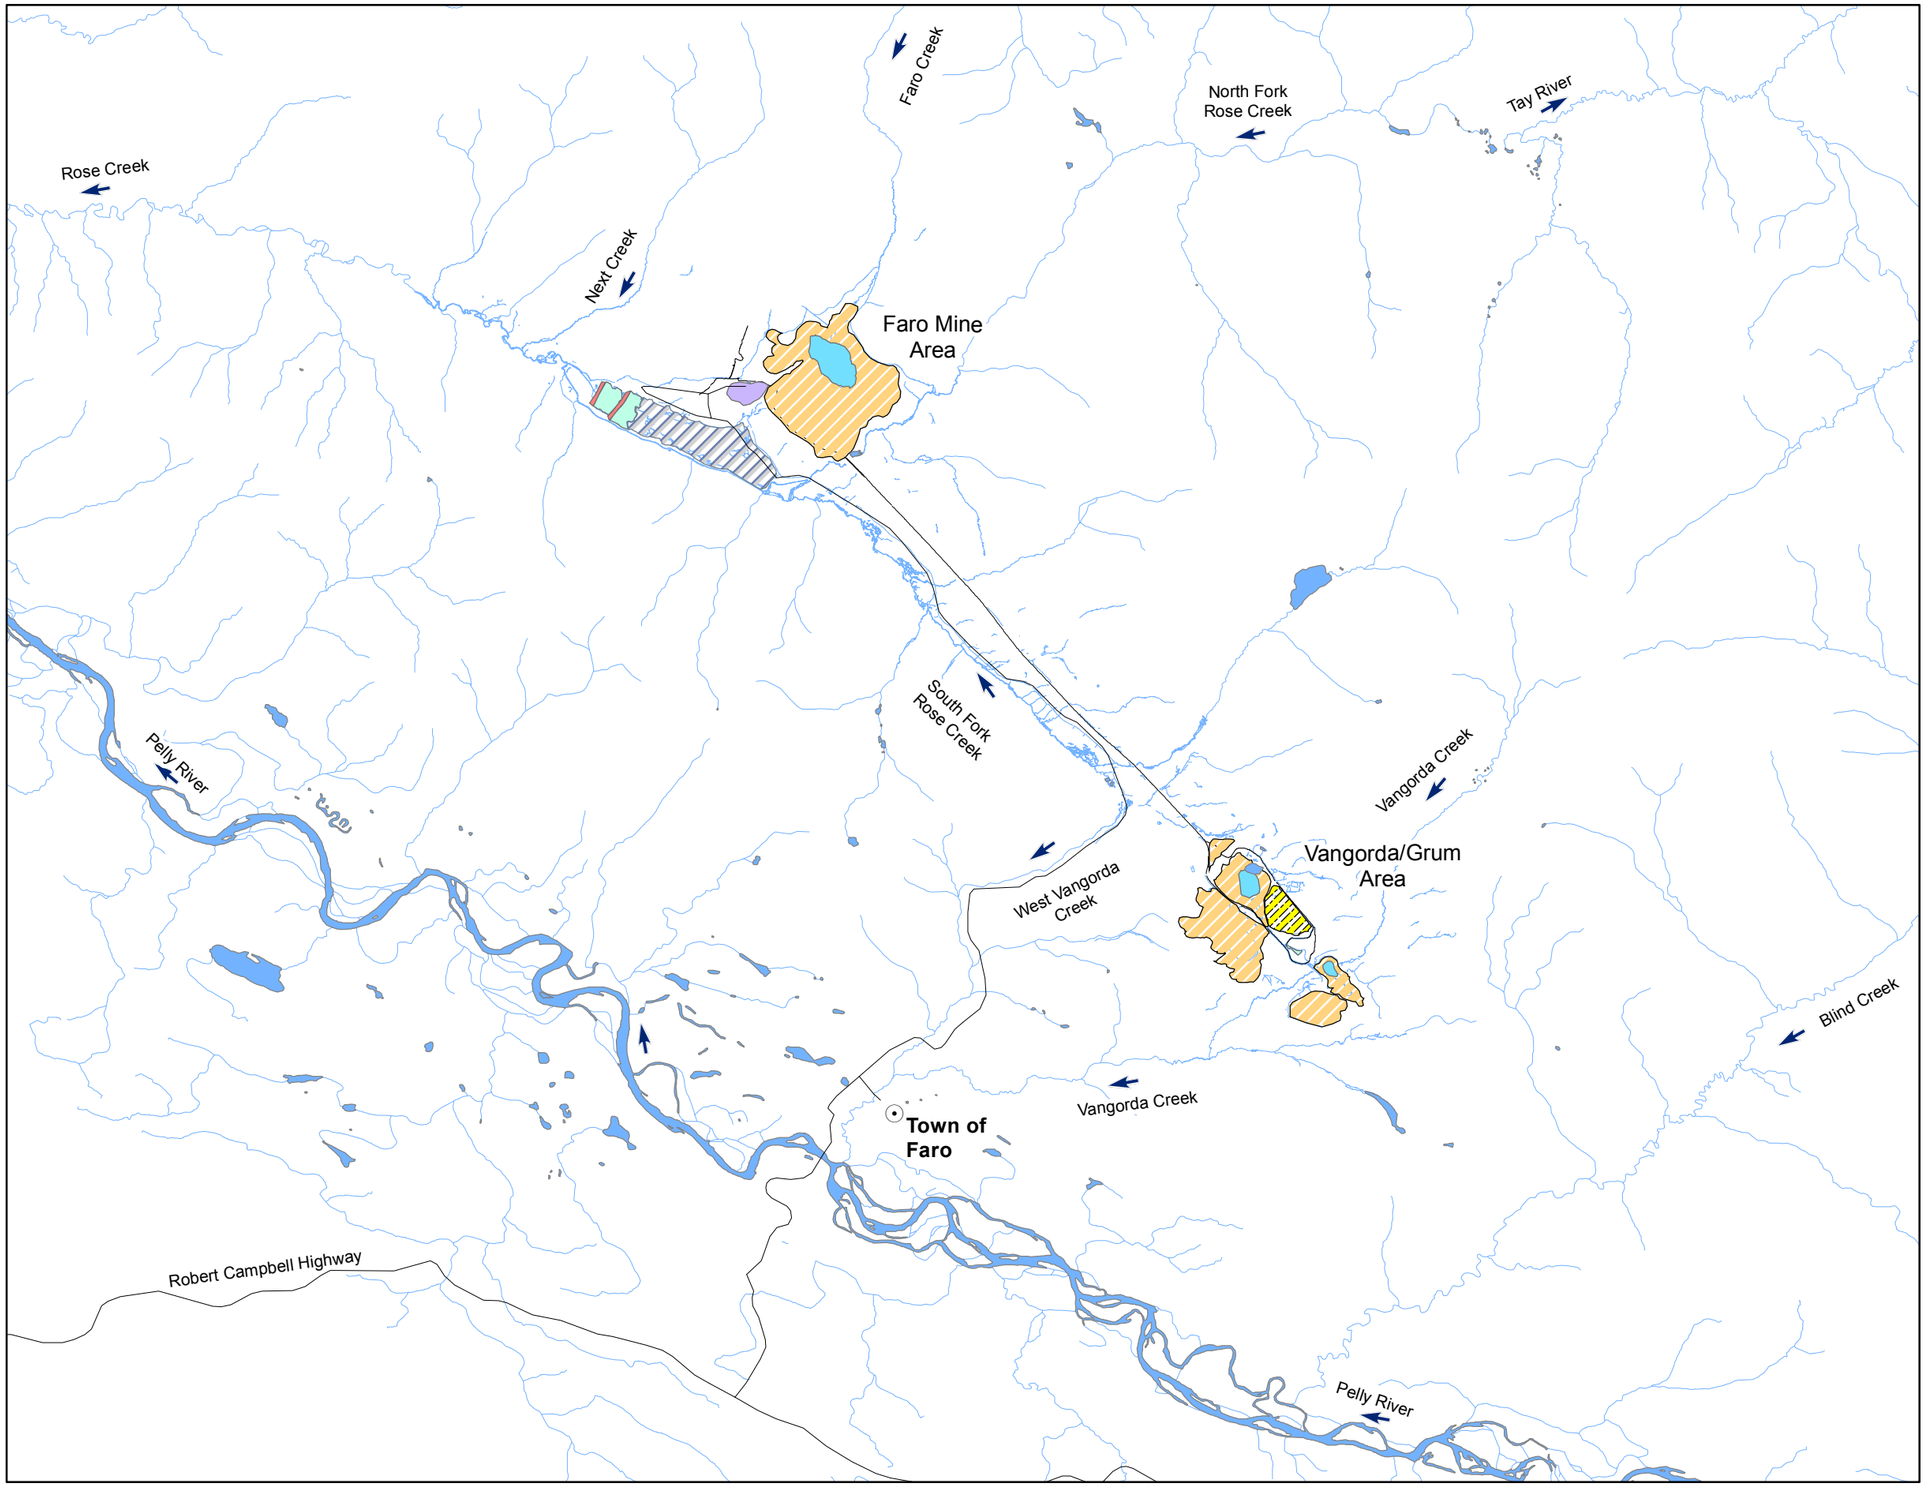
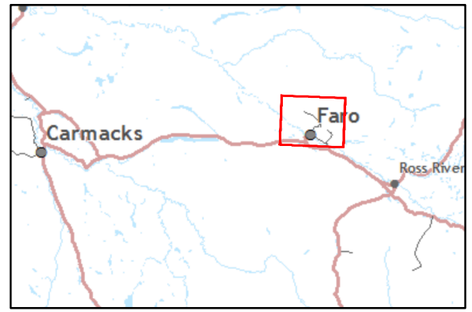
1.0 INTRODUCTION



1.1 Background

The Faro Mine Complex (FMC), near Faro, Yukon, includes two areas of former mining activity: the Faro Mine and Mill (Faro Mine Area) and the Vangorda and Grum mines (Vangorda/Grum Area), which are located approximately 12 kilometres (km) apart (Figure 6H-1). The FMC was formerly owned by the Anvil Range Mining Corporation, which produced lead and zinc concentrates that were extracted for lead, zinc, silver, and gold. The Faro Mine Area was mined between 1969 and 1992, while the Vangorda/Grum Area was developed and mined between 1986 and 1998. Milling continued at the Faro Mine Area until April 1998, when all operations at the FMC were terminated due to poor economic circumstances and projections, and the site went into receivership. Until early 2009, management of the mine property was under the direction of Deloitte and Touche Inc., acting as the court appointed Interim Receiver. Site Care and Maintenance responsibilities were transferred in 2009 to Government of Yukon (YG).



While efforts continue towards development of the final scope and implementation of the overall Faro Mine Remediation Plan (FMRP), YG seeks authorization for 10 years of site management and maintenance activities. These activities are being collectively referred to as the Faro Mine Interim Works (FMIW) and will include the following:

- Site Operations, including operation of water management and water treatment facilities, and site maintenance activities;
- Site Investigations, including closure planning, monitoring and investigations;
- Down Valley Interim Hydraulic Upgrades; and
- Accessory Activities

A Project Proposal for the FMIW will be submitted under the *Yukon Environmental and Socio-economic Assessment Act* (YESAA). The Project Proposal will include a description of current (baseline) conditions. Minnow Environmental Inc. (Minnow) was retained by CH2M HILL Canada Limited (CH2M HILL), the company preparing the FMIW Project Proposal on behalf of the proponents (YG and Aboriginal Affairs and Northern Development Canada), to complete the characterization of baseline surface water quality and the aquatic ecosystem conditions, which is more simply referred to, herein, as the "Aquatic Baseline Characterization".

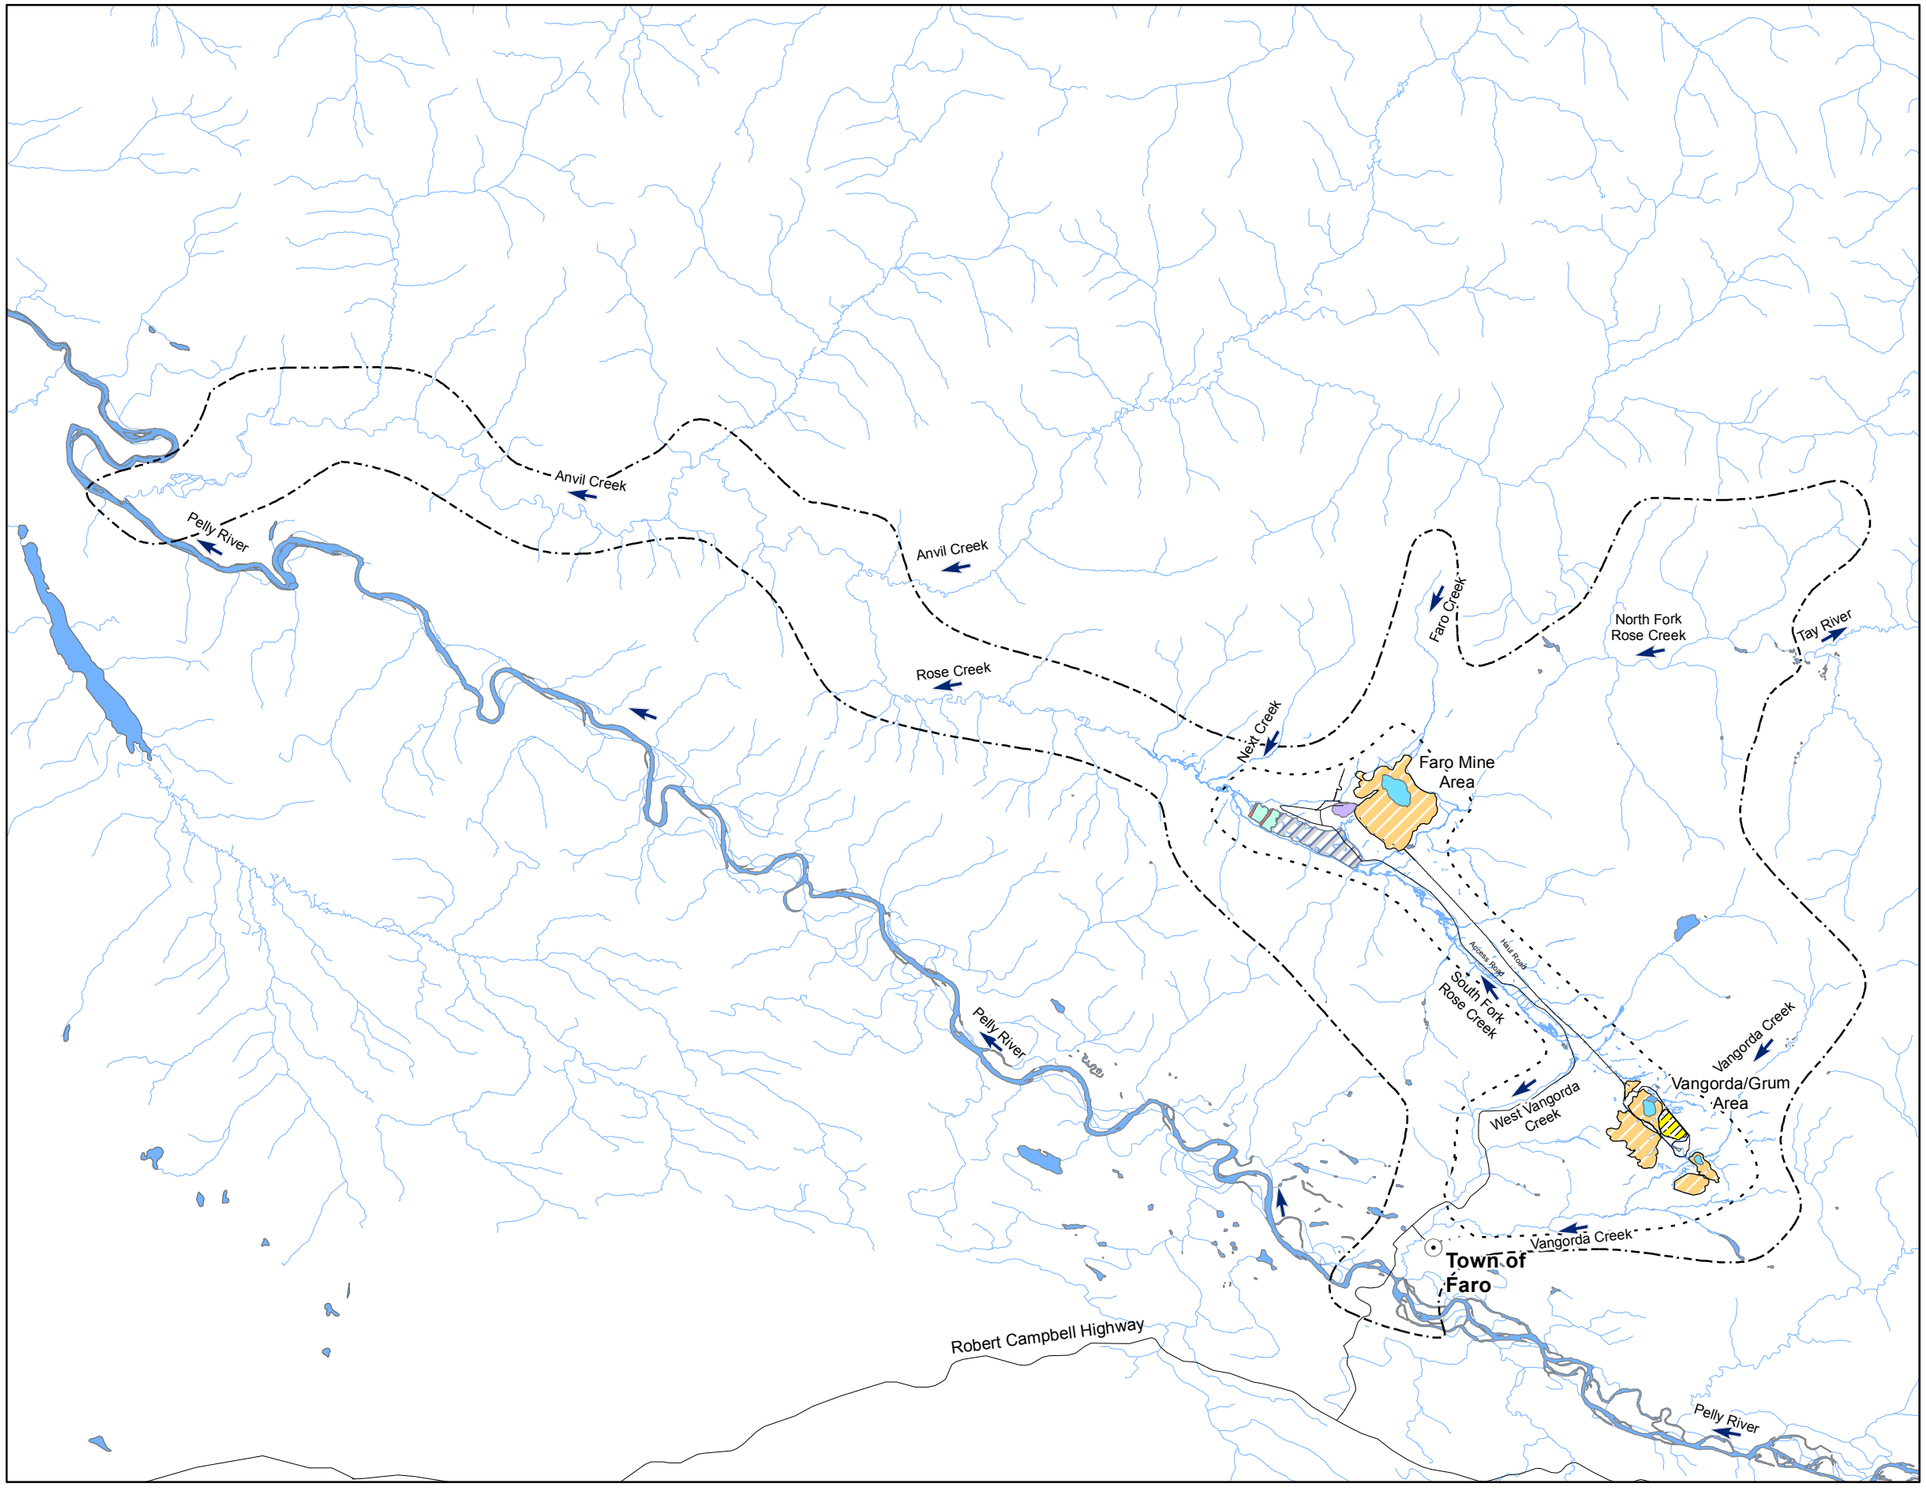
1.2 Report Organization

Methods associated with the gathering and evaluation of baseline information are described in Section 2.0. Sections 3.0 to 8.0 present the information for different aspects of the aquatic ecosystem near the FMC: habitat characteristics, water quality, sediment quality, periphyton, benthic invertebrates, and fish, respectively. A summary of the aquatic baseline conditions is presented in Section 9.0. References cited throughout the report are presented in Section 10.0

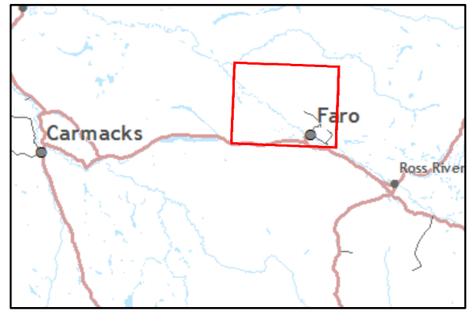
2.0 METHODS

2.1 Study Area



Both local and regional study areas are defined below for the FMIW aquatic baseline characterization, although, in the context of describing aquatic baseline conditions, these two areas are not functionally separate or distinct. Therefore, the aquatic baseline characterization refers to specific streams and locations within streams, where it is appropriate to do so, and otherwise considers local and regional study areas together as "the study area".

2.1.1 Local Study Area



The local study area (LSA) is the area within which the activities of the FMIW will take place and associated effects, if any, are most likely to be realized. For the surface water and aquatic ecology baseline characterization, the LSA encompasses the footprint of the former FMC operations and streams within approximately 500 metres (m) of the mine disturbance footprint (Figure 6H-2). The mine disturbance footprint includes the Faro Mine Area, to the west, and the Vangorda/Grum Area, to the east, as well as the area between the two in which the Access Road and the Haul Road are located. The western and middle portions of the LSA include portions of Faro Creek and the North and South Forks of Rose Creek, as well as the Rose Creek Diversion and Rose Creek immediately downstream from the tailings impoundment (Figure 6H-2). To the east, the LSA, associated with the Vangorda/Grum Area, includes portions of the west and main branches of Vangorda Creek.

2.1.2 Regional Study Area

The regional study area (RSA) for the surface water and aquatic ecology baseline characterization is defined as the maximum area over which there is potential for measureable project-related effects. For the purpose of the FMIW Project, the RSA has been defined as the drainages downstream from the LSA to the Pelly River, including the areas within the Pelly River immediately upstream and downstream of the mouths of Anvil and Vangorda creeks (Figure 6H-2).

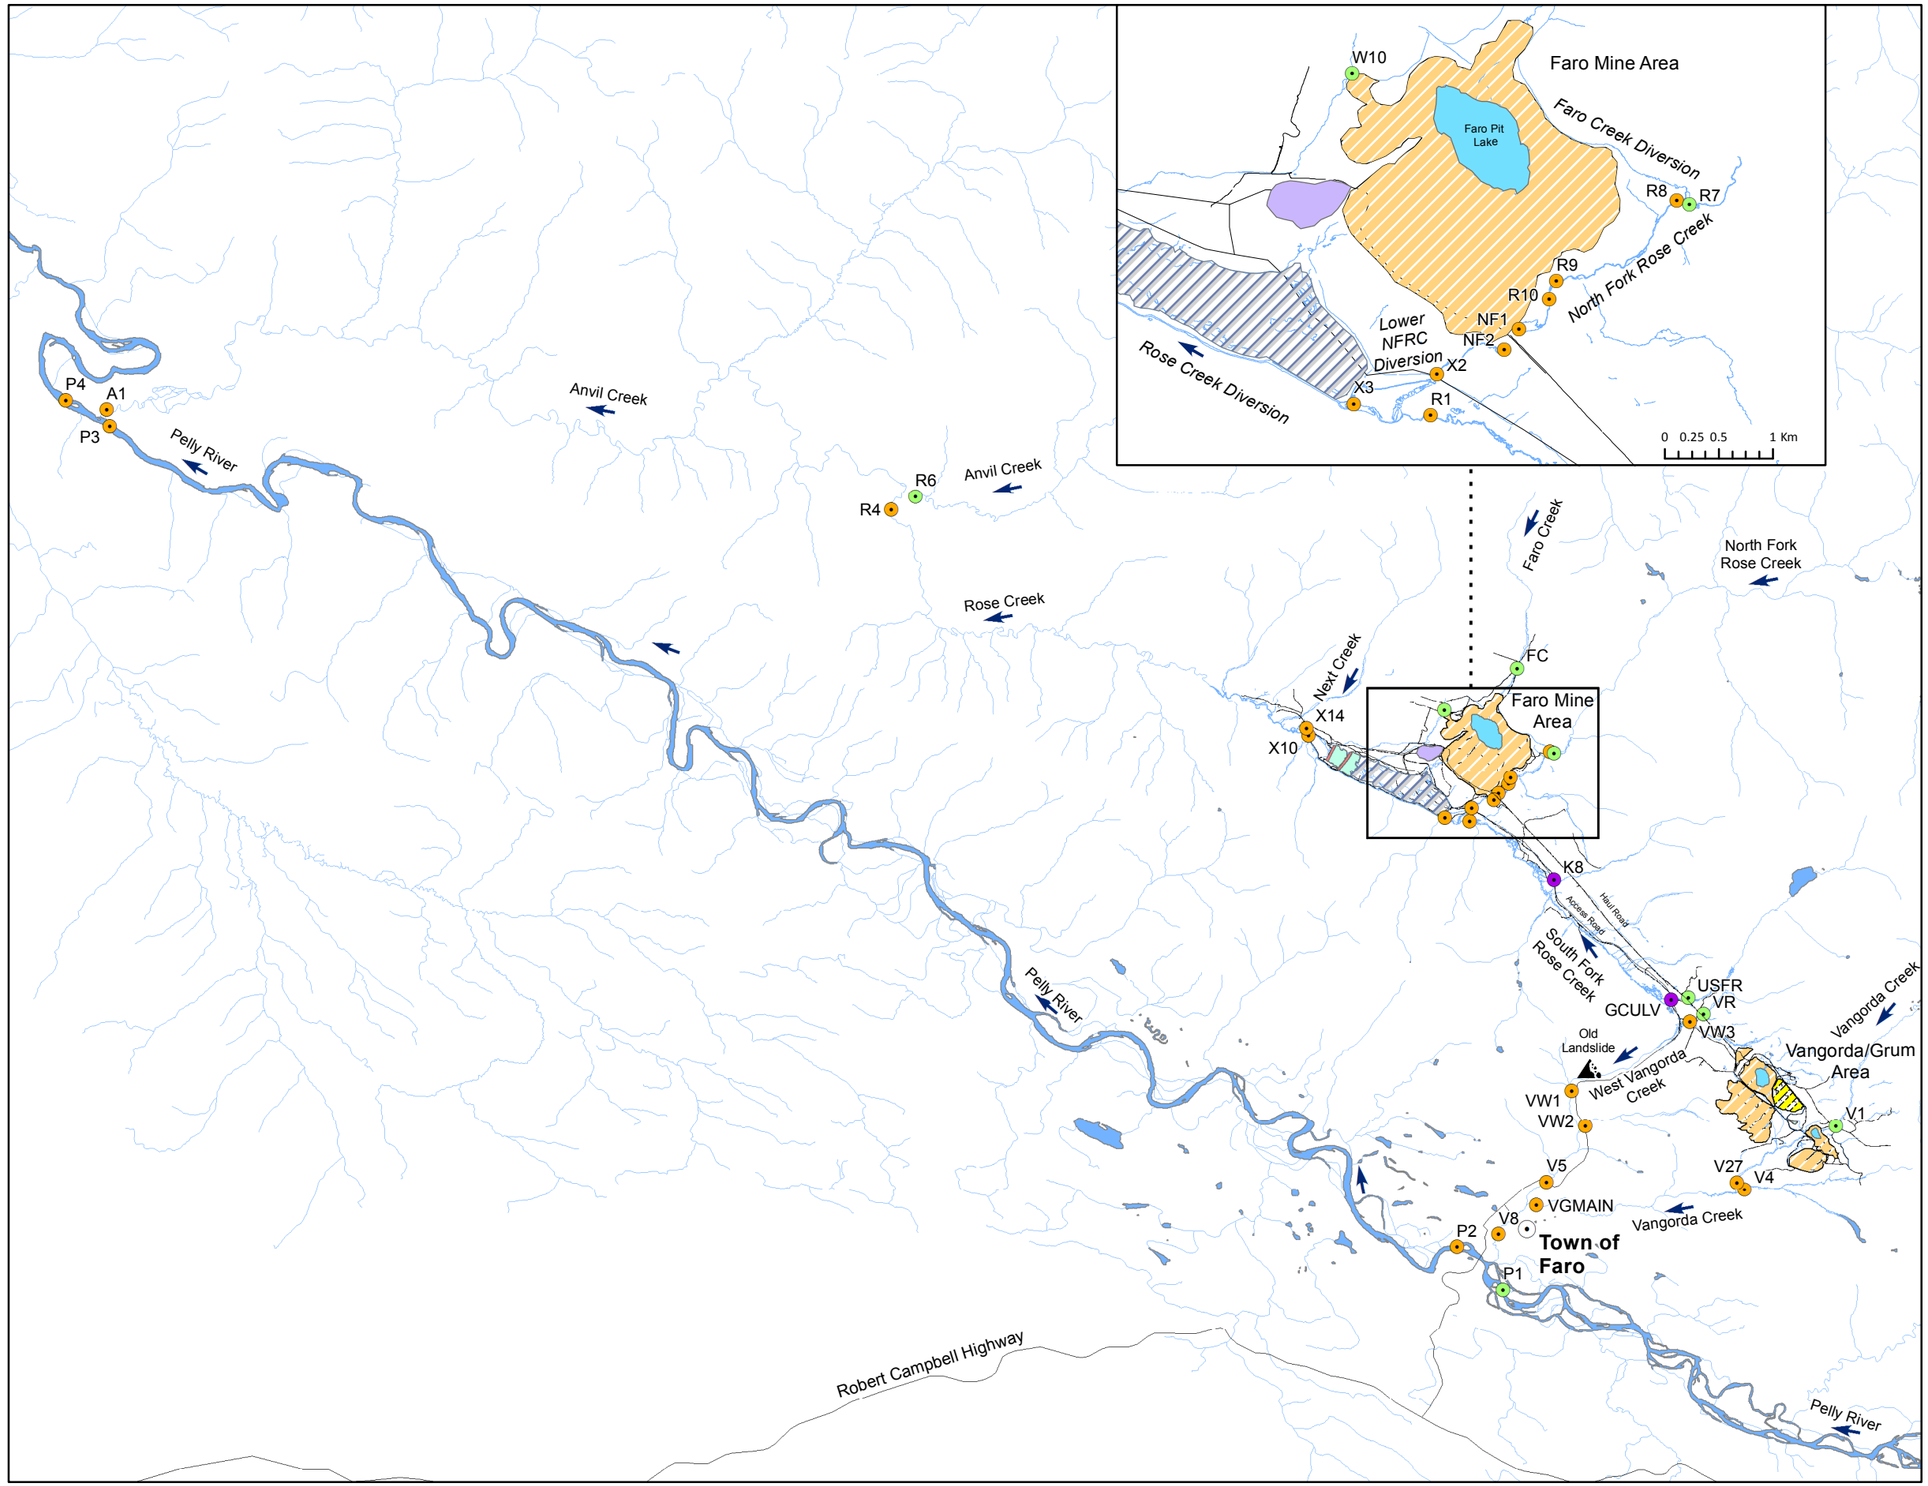
2.2 Sources of Data and Information

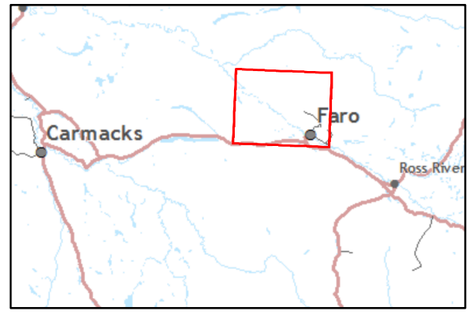
2.2.1 Water Quality

Data were provided by CH2M HILL for surface water stations and analytes requested by Minnow for the period 2008-2012, inclusive. This timeframe was selected to characterize baseline conditions using the most recent data available while also ensuring that the data represented a sufficient number of years to account for temporal variation.



The stations for which water data were acquired included (Figure 6H-3):

- Reference stations: W10, FC, R7, USFR, V1, VR, R6;
- Mine-exposed stations: R8, R9, R10, NF1, NF2, X2, R1, X3, X10, X14, R4, A1/R11 (same location), V27, V4, VGMAIN, VW1, VW2, VW3, V5, V8;
- Pelly River stations: P1, P2, P3, P4; and
- First Nations traditional drinking water stations: GCULV, K8.



Acquired data pertained to analytes identified in past evaluations of surface water at the FMC to be most strongly indicative of mine-related influence on water quality (Minnow 2007, 2010) plus supporting variables that may contribute to water quality interpretation:

- Metals: cadmium, calcium, cobalt, iron, lead, magnesium, manganese, nickel, potassium, silver, sodium, strontium, uranium, zinc;
- Non metals: alkalinity, ammonia, hardness, nitrate, sulphate, total organic carbon (TOC), dissolved organic carbon (DOC), total dissolved solids (TDS), total suspended solids (TSS), turbidity; and
- Field measurements: conductivity, pH.

The data were extracted from an Environmental Quality Information System (EQuIS) that is currently being managed by CH2M HILL and were emailed to Minnow by CH2M HILL on October 9th, 2013. The data were received by Minnow in a Microsoft Excel spreadsheet matrix format organized by sample location and date (rows) versus analytes (columns). Additional data for 2004 through 2007 were requested for representative analytes (zinc, cadmium, sulphate, TSS, and turbidity) to provide a longer-term temporal perspective of water quality related to the FMC. Data collected prior to 2004 were not requested based on data quality concerns described by Minnow (2007) for some analytes.

2.2.2 Historical Reports and Data

Baseline information related to aquatic habitat characteristics, sediment quality, periphyton communities, benthic invertebrate communities, and fish communities in the vicinity of the FMC were compiled from past environmental reports, which are referenced in the appropriate sections of this report. Periphyton (primary producers), benthic invertebrates (consumers), and fish represent the various trophic levels within the aquatic ecosystem that may be impacted by changes in water and sediment quality. Aquatic habitat data were taken from reports dating as far back as the mid-1970s, based on the assumption that current physical habitat characteristics are likely comparable to past descriptions in areas that have not been physically altered by mine development. Also, individual studies of fish communities provide only a snap-shot in time of species composition and distribution, whereas compilation of data over time provides a more robust perspective of seasonal habitat utilization and abundance. Interpretation of historical habitat and fish community data considered that mine operations were active until 1998, and emphasis has been placed on information acquired in the years since mine operations ceased, particularly with respect to chemical concentrations in environmental media. Sediment quality and benthic invertebrate community data were compiled from studies conducted during the post-operational period, with emphasis on data collected since 2007.

2.3 Data Analyses

2.3.1 Water Quality

The data set was inspected for potential outliers that might confound summary statistics and data interpretation, focusing on identification of impossible or improbable values (e.g., values one or more orders of magnitude above all other values) and concentrations reported as being below the analytical detection limit (<DL) when the detection limit was problematically high (e.g., <DL value that was above the majority of quantified results or a water quality guideline). Decisions to include or exclude values from summary statistics were made on a case-by-case basis using professional judgement, although values were generally excluded only if their retention was likely to bias results or interpretation. All values flagged as potential outliers are highlighted in raw data tables in Attachment B (reference stations; Tables B.9 – B.16) and Attachment C (mine-exposed stations; Tables C.22 – C.48) with footnotes indicating how each value was ultimately handled.

2.3.1.1 Comparisons to Background Concentrations

All available data for reference stations monitored between 2008 and 2012 were pooled and used to compute summary statistics for each water quality analyte, including minimum, maximum, median, mean, standard deviation, and 5th and 95th percentiles. Raw data for the pooled data set and individual reference stations are presented in Attachment Tables B.9 to B.16. The 5th and 95th percentiles of the pooled reference data set were used to approximate the lower and upper range of background concentrations, respectively, for each analyte, and are referred to in this report as upper and lower "background benchmarks" (BGBM). Data for mine-exposed areas were compared to the BGBM for each analyte to identify locations and analytes with concentrations outside of the background concentration range (i.e., indicative of mine-related influence on water quality). In most cases, the upper BGBM was used as the basis of comparison, because mine influence on water quality would usually be expected to increase concentrations relative to background levels. In the cases of pH and alkalinity, it was relevant to also consider potential decreases in concentration due to the acid-generating potential of waste rock dumps and stored tailings. In addition, potential reductions in organic carbon concentrations downstream of mining were evaluated because such occurrences could limit the mitigation capacity of the receiving environment with respect to metal effects on biota (i.e., resulting from complexation of metals with organic carbon). Therefore, for pH, alkalinity, TOC and DOC, concentrations at mine-exposed stations were compared to the lower BGBM (reference 5th percentile), as well as the upper BGBM (reference 95th percentile).

Approximately 5% of concentrations of a given analyte at any station could be expected to naturally occur above the upper BGBM (95th percentile) and 5% could naturally occur below the lower BGBM (5th percentile). However, on a station-by-station basis, some variability could be expected in the specific percentage of samples naturally falling outside of the background range. For greater certainty in identifying locations and analytes with concentrations outside of the background range, analytes having at least 10% of samples above (all analytes) or 10% below (alkalinity, pH, TOC, DOC) the background range were considered to be indicative of mine influence.

In addition to determining the percentage of samples at each station having concentrations outside of the background range, the magnitude of current mine-related influence on water quality was evaluated by computing the ratio of the median concentration of each analyte at each station to the background benchmark.

2.3.1.2 Comparisons to Water Quality Guidelines

For most surface water stations, observed concentrations were compared to guidelines for protection of aquatic life. Canadian water quality guidelines (CWQG) were used if available (Canadian Council of Ministers of the Environment [CCME] 2014); otherwise, an alternative federal water quality criterion was used (e.g., Environment Canada 2013a, for cobalt). In the absence of a federal guideline, a guideline from British Columbia was selected, if available (Table 6H-1). An exception was that the newer British Columbia Ministry of the Environment (BCMOE) guideline (2008) for iron was used instead of the Canadian Council of Resource and Environment Ministers (CCREM) guideline (1987) because the former accounts for differences in toxicity associated with total versus dissolved iron forms.

Some water quality criteria vary on the basis of water hardness (sulphate, cadmium, lead, manganese, nickel, zinc) (Table 6H-2), so median hardness at each station was used to derive station-specific guidelines. This allowed for evaluation of samples for which hardness was not reported. Also, analyses were subsequently performed to verify that this approach did not result in overlooking guideline exceedances for samples with hardness less than the station median (i.e., instances where an analyte would have been flagged as exceeding the guideline, had the guideline been adjusted to the actual sample hardness rather than the median). Such instances were so rare that they had no influence on the overall patterns and interpretation of data. Water quality criteria for total alkalinity, DOC, TOC, TSS, and turbidity are expressed as a change relative to background means or medians; however, this resulted in guidelines that were well within the range of background concentrations. Therefore, the guidelines were modified by applying the incremental change specified by each guideline to the upper BGBM (and lower BGBM, if applicable) instead of to the mean or median (Table 6H-2).

The CWQG for ammonia is expressed on the basis of un-ionized ammonia, which comprises an increasing fraction of the total ammonia present in water as either water pH or temperature increase (or both). However, temperature and/or water pH data were not consistently reported among samples to support sample-specific calculation of the proportion of total ammonia present in the un-ionized form. Because the temperature and pH of surface waters near the FMC rarely rise above 15 degrees Celsius (°C) or 8.5, respectively, it was conservative to compare observed total ammonia concentrations at each station to the total ammonia concentration corresponding to an un-ionized concentration of 0.019 mg/L (the CWQG) at 15°C and pH 8.5 (Table 6H-2). This was calculated using the equation of Emerson et al. (1975):

Table 6H-1: Water quality guidelines for protection of aquatic life that were used to evaluate surface water quality data (selected value is shaded). See Table 6H-2 for site-specific adaptation of guidelines dependent on other water characteristics.

Variable		Units	Canadian Water Quality Guidelines (for protection of aquatic life), CCME 2014[a], unless otherwise footnoted	British Columbia Water Quality Guidelines (for protection of aquatic life), BCMOE 2006[b], 2013[c]
Non-Metals	Unionized ammonia (as NH_3-N)	mg/L	0.0156 (0.019 as whole ion)	guideline expressed as total ammonia[c]
	Nitrate (as NO_3-N)	mg/L	3 (13.0 as whole ion)	3 (13.0 as whole ion)[c]
	Dissolved organic carbon	mg/L	-	30-day median ± 20% of the median background concentration (approved)[c]
	Total organic carbon	mg/L	-	30-day median ± 20% of the median background concentration[c]
	pH	pH units	6.5-9.0	6.5 - 9.0[c]
	Sulphate	mg/L	-	128 - 429 mg/L[c] (hardness dependent)
	Total dissolved solids	mg/L	-	-
	Total suspended solids	mg/L	maximum average increase of 5 from background levels	mean of background plus 5 over 30 days if background is less than or equal to 25[c]
	Turbidity	NTU	maximum average increase of 2 from background levels	mean of background plus 2 over 30 days if background is ≤8 NTU[c]
Metals and Metalloids	Cadmium	mg/L	0.00004 - 0.00037 (hardness dependent)	0.00001 - 0.00006 (hardness dependent)[b]
	Cobalt	mg/L	0.0025[d]	0.004[c]
	Iron	mg/L	0.3	1 (total), 0.35 (dissolved)[c]
	Lead	mg/L	0.001 - 0.007 (hardness dependent)	0.004 - 0.016 (hardness dependent)[c]
	Magnesium	mg/L	-	-
	Manganese	mg/L	-	0.7 - 1.9 (hardness-dependent)[c]
	Nickel	mg/L	0.025 - 0.15 (hardness dependent)	0.025 - 0.15 (hardness dependent)[b]
	Potassium	mg/L	-	373[b]
	Silver	mg/L	0.0001	0.00005 - 0.0015 (hardness-dependent)[b]
	Uranium	mg/L	0.015	0.3[b]
	Zinc	mg/L	0.03	0.075 - 0.24 (hardness dependent)[c]

[d] Environment Canada. 2013a. Federal Environmental Quality Guidelines: Cobalt. February 2013.

Table 6H-2: Explanation of guidelines that depend on other water characteristics.

Variable		Guideline			Comment
		Value	Units	Source	
Non-metals	Total Ammonia (as NH3-N)	0.20	mg/L	CCME (2014)[b]	Guideline is specified as un-ionized ammonia (whole ion), which equals 0.0156 mg/L as un-ionized NH3-N. The equation of Emerson et al. (1975) was used to convert the guideline to total ammonia (as N) based on conservative assumptions of water pH of 8.5 and temperature of 15ºC, as explained in text.
	Organic carbon, dissolved	0.6 - 19.3	mg/L	BCMOE (2013)[a]	Guideline specified as ± 20% of background median concentration but this would not even encompass the range of background values. Instead, the guideline range was calculated by subtracting 20% from the 5th (0.8 mg/L) percentile and adding 20% to the 95th percentile (16.1 mg/L) of the pooled reference station data.
	Organic carbon, total	0.6 - 19.3	mg/L	BCMOE (2013)[a]	Guideline specified as ± 20% of background median but this would not even encompass the range of background values. The 5th (0.7 mg/L) and 95th (13.1 mg/L) percentiles were similar to those for dissolved organic carbon. Total organic carbon cannot be lower than dissolved organic carbon, so the guideline range derived for dissolved organic carbon was adopted for total organic carbon.
	Sulphate		mg/L	BCMOE (2013)[a]	Guidelines depends on water hardness: 0-30 mg/L hardness = 128 mg/L, 31-75 mg/L hardness = 218 mg/L, 76-180 mg/L hardness = 309 mg/L, 181-250 mg/L hardness = 429 mg/L. Median station hardness was used for guideline selection.
	Total suspended solids	25	mg/L	CCME (2014)[b]	Guideline is specified as mean of background TSS (lab) plus 5 mg/L. The mean (7.4 mg/L) of the pooled reference data plus 5 mg/L would result in a guideline of only 12.4 mg/L, which is much lower than the 95th percentile (20 mg/L) and maximum (400 mg/L) of pooled reference station data. Therefore the guideline was calculated as the 95th percentile plus 5 mg/L.
	Turbidity	4.23	NTU	CCME(2014)[b]	Guideline is specified as the mean of background turbidity (lab) plus 2 NTU. The mean (0.8 NTU) of the pooled reference data plus 2 NTU would result in a guideline of only 2.8 NTU, which is only marginally higher than the 95th percentile of background values (2.23 NTU) and much less than the background maximum (6.2 NTU). To maintain consistency with TSS, from which the turbidity guideline was derived (CCME 2002), the turbidity guideline was calculated as the 95th percentile (2.23 NTU) plus 2 NTU.
Metals	Cadmium		mg/L	CCME (2014)[b]	Guideline is hardness-dependent and expressed as ($10^{0.83(\log\{\text{hardness}\})-2.46}$)/1000 to an upper limit of 0.00037 mg/L for waters with hardness above 280 mg/L. Median station hardness was used for guideline derivation.
	Lead		mg/L	CCME (2014)[b]	Guideline is hardness-dependent and expressed as ($3.31 + e^{(1.273\ln(\text{mean hardness})-4.704)}$)/1000. Median station hardness was used for guideline derivation.
	Manganese		mg/L	BCMOE (2013)[a]	Guideline is hardness-dependent and expressed as (0.0044 x hardness) + 0.605. Median station hardness was used for guideline derivation.
	Nickel		mg/L	CCME (2014)[b]	Guideline is hardness-dependent and expressed as ($e^{(0.76\ln(\text{mean hardness})+1.06)}$)/1000. Median station hardness was used for guideline derivation.

[a] BCMOE (British Columbia Ministry of the Environment). 2013. British Columbia Approved Water Quality Guidelines. Environmental Protection Division, Victoria, British Columbia. Accessed at http://www.env.gov.bc.ca/wat/wq/wq_guidelines.html, November 2013.

[b] CCME (Canadian Council for Ministers of the Environment). 2014. Canadian Water Quality Guidelines for the Protection of Aquatic Life. Accessed at http://st-ts.ccme.ca/, February 2014.

$$\text{Fraction UI-NH3} = 1/(1+10^{(pKa-pH)}), \text{ where } pKa = 0.09 + 2730/(273+T°C)$$

Exceptions to the above were stations GCULV and K8, which are locations of traditional drinking water used by local First Nations. For those stations, analyte concentrations were compared to Health Canada drinking water guidelines, if available, otherwise to provincial guidelines (Table 6H-3).

2.3.2 Sediment Quality

Historical sediment metal chemistry data were compiled for the Rose-Anvil and Vangorda creek systems. In cases where replicate samples were collected, mean values were calculated for each metal to facilitate comparisons of sediment quality among areas and over time. Concentrations in each area were evaluated relative to Canadian Sediment Quality Guidelines for the Protection of Aquatic Life (CSQG), which are numerical criteria that are designed to be protective of sediment-dwelling organisms based on long-term exposure (CCME 2013).

2.3.3 Periphyton, Benthic Invertebrates, and Fish

Characterization of periphyton, benthic invertebrates and fish relied primarily on critical review of, and compilation of information from, existing reports and data, as well as the overall conclusions presented in each report regarding existing mine-related influences on biota. Maps were prepared to depict sampling areas. Relevant data were summarized in tables and figures (presented in subsequent report sections).

For benthic invertebrate community evaluation, the results of studies conducted in 2008 (Minnow 2009) and 2010 (Laberge Environmental Services [Laberge] 2011) were re-evaluated by collating data for areas that were sampled using the same methods in both studies so results could be directly compared. Statistical methods were consistent with those reported by Minnow (2009) involving non-central t-tests (Kilgour et al. 1998) to determine if the community at each mine-exposed station was different from the reference condition defined by communities sampled in multiple reference areas.

Table 6H-3: Drinking water quality guidelines used to evaluate data for drinking water stations GCULV and K8 (selected value is shaded).

Variable		Units	Canadian Drinking Water Quality Guidelines, Health Canada (2010)[a]	British Columbia (Drinking Water), BCMOE 2006[b,c]	Ontario Drinking Water Quality Standards, Objectives and Guidelines, OMOE (2006)[d]

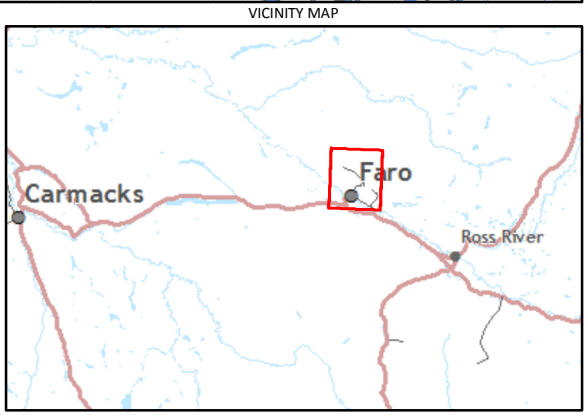
3.0 HABITAT DESCRIPTION

3.1 Watershed Areas

The Rose-Anvil Creek and Vangorda Creek watersheds affected by the Faro Mine Complex have areas of 980 square kilometres (km^2) and 90 km^2 respectively and are tributaries to the Pelly River. By comparison, the Pelly River watershed has a total drainage area of 49,000 km^2, so the Rose-Anvil Creek and Vangorda Creek drainages represent approximately 2% and 0.2%, respectively, of the total Pelly River drainage area. The Pelly River is a major headwater of the Yukon River. With a total basin area of approximately 49,000 km^2, the Pelly River represents about 6% of the basin area and flow to the Yukon River.

Additional information regarding the hydrology of these systems is provided by CH2M HILL (2013).

3.2 Rose and Anvil Creeks



The upper portions of Rose Creek are divided into the North Fork (NFRC) and South Fork (SFRC) which converge just upstream of the Rose Creek Tailings Area (RCTA) (Figure 6H-4). Several physical alterations to stream courses have occurred over time to accommodate mine features, including the Faro Creek Diversion, the North Fork Rock Drain, the lower NFRC diversion, the constructed ground water recharge ponds along the lower NFRC, the creation of the Pumphouse Pond on SFRC, the creation and removal of the freshwater reservoir on the SFRC, the Rose Creek Diversion (RCD), and numerous road crossings (Figure 6H-5); these features are described, as applicable below. Natural aquatic habitat within the Rose Creek and Anvil Creek watersheds has been described in various past projects for the FMC, and this information has been summarized for key reaches (Table 6H-4, Figure 6H-6), and is discussed below. Common features among most reaches of the Rose-Anvil Creek system include boulder and cobble substrate, with boulders and pools providing in-stream cover for fish (Table 6H-4).

3.2.1 North Fork Rose Creek

Aquatic habitat in the upper reaches of the NFRC is relatively undisturbed (de Graff 2013). The creek originates in a wetland that also drains towards the Tay River (Figure 6H-4). Limited fish migration has been speculated to occur between the wetland and the Tay River system during high water events (White Mountain Environmental Consulting [WMEC] 2005b). The upper reach of the NFRC includes ponded areas, deep channels (2

Stream Reaches for which Habitat Data have been Summarized

Faro Mine Interim Works

Minnow Project No.: 2499 Date: February 2014

to 3 m deep and less than 5 m wide) with large boulder substrate, and wider flat glades with braiding and summer depths from 0.2 to 0.8 m (WMEC 2005b). A small lake located near the middle of the section of NFRC upstream from the Haul Road discharges to the NFRC though a steep creek that is impassable to fish (Figure 6H-4, WMEC 2005b). Immediately upstream of the Faro Creek Diversion, the channel is deep (2 m) and u-shaped, with finer substrate.

North of the Faro Mine Area, Faro Creek has been diverted from its original flow path so that it now flows around the northeast side of the Faro Pit and into the NFRC (Figure 6H-5). Farther downstream, the NFRC is divided by the rock drain at the Haul Road, which is impassible to fish (Figure 6H-5). In the NFRC reach between the confluence with the Faro Creek Diversion and the Haul Road, stream gradient ranges from 0.2 to 2%, with channel widths between 8 and 12 m (Table 6H-4). de Graff (2013) reported that the stream morphology within in this reach is riffle-pool, and that the channel is frequently confined. A pond located just upstream from the Haul Road was approximately 250 m long and 115 m wide during spring sampling (WMEC 2005a), but the surface area lessens following freshet as flows decrease. Depths also fluctuate depending on time of year and precipitation; average depth in the spring was greater than 4 m, but depth had declined to approximately 1 m when surveyed in August (WMEC 2005b).

Downstream from the Haul Road, the NFRC channel width is approximately 8.5 m, with gradient ranging from 0.4 to 1.6%. The channel is predominantly confined and morphology is mostly riffle-pool, with an area of cascade-pool (de Graff 2013).

Downstream from the Access Road, the NFRC splits into two separate channels (Figure 6H-5). The main channel contains remnants of the original streambed, flowing south to the confluence with the SFRC through five, small (<0.2 hectares [ha]), constructed ponds (de Graff 2013). The constructed ponds were intended to allow surface water to recharge groundwater wells nearby, which were utilized during the winter mine operations (prior to 1997) to augment the supply of process water (Gartner Lee Limited [GLL] 2002). There are culverts at the upper end of these ponds which may seasonally restrict fish movement, but the habitat upstream is accessible through a second channel that forks to the west (lower NFRC diversion, de Graff 2013). The second channel was constructed to divert sediment-laden water away from the Pumphouse Pond (Figure 6H-5) during spring freshet and to provide fish passage into the NFRC (GLL 2002).

3.2.2 South Fork Rose Creek

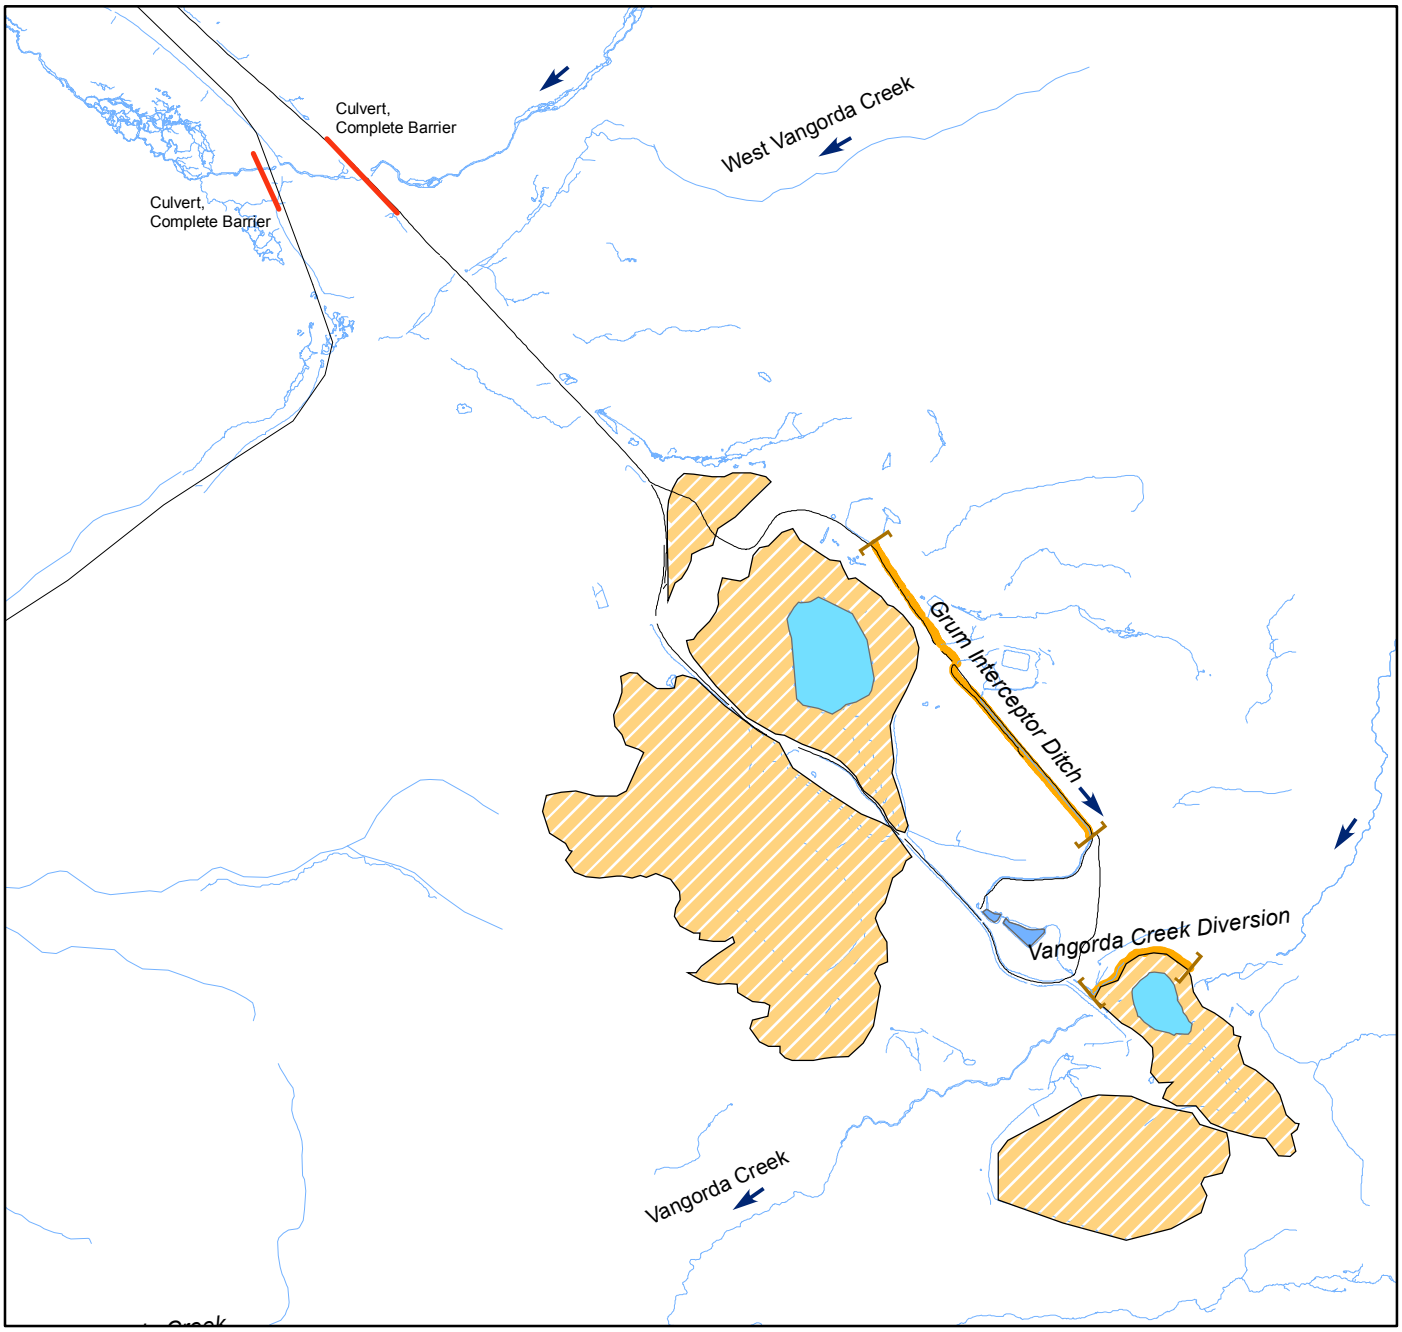
The SFRC originates just upstream from Dixon Lake (Figure 6H-4). Similar to the NFRC, fish habitat along the SFRC is divided with impassible culverts located at the Haul Road and the Access Road (Figure 6H-4). Aquatic habitat has not been well characterized for most of the reach upstream from the Haul Road. Immediately upstream from the Haul Road, the bankfull width is approximately 8.6 m, the gradient is 4.8%, and the morphology is predominantly riffle (Minnow 2009). A section with a gradient greater than 20% is also present upstream from the Haul Road (GLL 2003) and may present a natural barrier to upstream movement of fish. The reach downstream from the Haul Road to the confluence with the North Fork is approximately 10 km long, with bankfull widths ranging from about 5 to 10 m and gradient ranging from 0.2 to 2.5% (Table 6H-4). The upper portion of this reach (2.2 to 2.5%) is slightly steeper than the remainder, with boulder and cobble habitat (Harder 1991, AECOM 2009). Approximately 2.5 km upstream of the confluence with the NFRC is the location of the former Fresh Water Reservoir (Figure 6H-4), which was decommissioned in late 2003. The valley where the reservoir was located is relatively flat (0.2%) such that, after the reservoir dam was breached, the creek reverted to its original, meandering morphology, with substrate dominated by gravel and finer particles (AECOM 2009). Downstream from the former reservoir is another section of riffle habitat, followed by a wetland complex, and subsequently more riffle habitat downstream to the confluence with the NFRC (AECOM 2009). Boulders and pools provide instream cover for fish throughout most of the SFRC downstream from the Access Road. The SFRC receives some flow via the constructed ponds of the lower NFRC before flowing through the Pumphouse Pond, which is approximately 250 m by 40 m. The Pumphouse Pond was constructed as a water source for mill processing, with flows being augmented as required from the former reservoir. Thereafter, the creek receives flow from the lower NFRC diversion and the combined flow of the north and south forks is routed past the RCTA via the RCD.

3.2.3 Rose Creek Diversion

Downstream from the confluence of the NFRC and SFRC is the RCD, a channel that was constructed to divert water around the RCTA (Figure 6H-5). Generally, habitat and fish cover in the RCD is constrained by the lack of natural stream processes, homogenous substrates and sparse riparian vegetation (de Graff 2013). Wetted widths measured in late summer range from 13 to 15 m (de Graff 2013). In the upper two-thirds of the RCD, gradient is typically 0.5% or less, with predominantly boulder substrate, interspersed with

some cobble and gravel substrate. The lower third of the RCD has a gradient of equal to or greater than (≥) 5%, with predominantly boulder substrate (de Graff 2013). Despite the steep gradient, there are no significant drops along this section, and velocities, though fast, vary across the stream width, including slower-flowing refuges that allow fish with sufficient size and burst speed to migrate upstream during high flow (Environmental Dynamics Inc. [EDI] 2013b). The RCD rejoins the original Rose Creek channel several hundred metres downstream from the RCTA (Figure 6H-5).

3.2.4 Lower Rose Creek and Anvil Creek



Downstream from the Faro Mine Area, Rose Creek flows approximately 20 km (river, not straight line, distance) to its confluence with Anvil Creek. The substrate of this portion of Rose Creek is predominately cobble/gravel, with gradients from 0.5 to 1.5% (Table 6H-4). Channel widths range from 15 to 25 m. Instream cover is provided by pools, boulders and undercut banks (WMEC 2008).

Thereafter, Rose Creek converges with Anvil Creek, which flows another 40 km (river distance) to the Pelly River, with creek width ranging from 35 to 80 m, and gradients from 0.7 to 1.9% (Table 6H-4). Substrate is predominantly boulder and cobble.

3.3 Vangorda Creek

Vangorda Creek originates approximately 7 km upstream of the Vangorda/Grum Area near the top of Mount Mye. Portions of upper Vangorda Creek have been diverted around pits and rock piles, including a section that flows through a large, metal half-culvert (Figure 6H-7). The main stem of upper Vangorda Creek has a channel width of 4 to 7.4 m, gradients ranging from 3.5 to 6.8%, and substrate dominated by boulder, cobble and gravel (Table 6H-4). Below the Vangorda/Grum Area, the confined channel consists mostly of gravel/cobble/boulder substrate and has a slope of approximately 4% (Robertson GeoConsultants Inc. [RGC] 1996). An 8-m waterfall, which represents a barrier to upstream fish migration, is located on the main stem just upstream from the confluence with West Fork Vangorda Creek (Figure 6H-4).

The West Fork Vangorda Creek originates approximately 3 km upstream from the Haul Road. It has channel widths from 2 to 5.6 m, gradients from 1.5 to 4.8%, and boulder, cobble and gravel substrates. The culvert under the Access Road, near the Town of Faro, presents an impassible barrier to fish migration at its downstream end (Figure 6H-4, GLL 2002).

CH2MHILL

Downstream from the confluence of the main stem and west fork, Vangorda Creek has channel widths of 7.8 to 10 m and gradients of 1.5 to 3.9% (Table 6H-4). The section from the waterfall to Campbell Street, at the Town of Faro, has a steeper gradient and more boulder substrate, compared to the reach downstream from Campbell Street to the Pelly River, which has a shallower gradient and more cobble and gravel substrate (Harder 1987).

4.0 WATER QUALITY

Characterization of baseline water quality focused on substances identified in previous studies as being elevated in surface waters downstream from the FMC (Minnow 2007, 2010) or having the potential to be elevated in the future based on concentrations in sources such as pit water and waste rock seeps (Minnow 2010) (see methods in Section 2.0). Concentrations of other water quality analytes were shown to be within the range of background surface water concentrations and are therefore not discussed.

Data for reference areas were compiled for relevant analytes and compared to concentrations measured at stations downstream of mine disturbances to identify the locations, frequency, and magnitude of measurable mine-related effects on water quality (Section 4.1). Concentrations measured at stations downstream of mine disturbances were then compared to water quality guidelines for protection of aquatic life to determine the extent to which biota may currently be affected by historical mine operations (Section 4.2).

4.1 Background Water Quality

Background water quality was characterized using data from reference stations located upstream of the FMC on Guardhouse Creek (W10), Faro Creek (FC), North Fork Rose Creek (R7), South Fork Rose Creek (USFR), West Vangorda Creek (VR), and Vangorda Creek (V1), as well as at Anvil Creek upstream of the confluence with Rose Creek (R6) (Figure 6H-3). As described in Section 2.3.1, the data for all reference stations were pooled so the data set would reflect the range of water concentrations naturally occurring among streams in the area. The 5^{th} and 95^{th} percentiles of the pooled data set were used to define the lower and upper range of background concentrations, respectively (Table 6H-5).

Summary statistics for the pooled data set indicate that reference streams tend to be slightly basic, with median pH of 7.7 (range 5.2-9.15). Water hardness is relatively low (median 48 mg/L as $CaCO_3$), but can range up to 251 mg/L. Organic carbon content is also low (median TOC of 2.4 mg/L) and is mainly in dissolved form (i.e., dissolved and total carbon concentrations are approximately equal). Total suspended solids and turbidity also tend to be low (<1 mg/L and 0.5 Nephelometric Tubidity Units [NTU], respectively) but can range up to 400 mg/L and 6.2 NTU, respectively, with highest concentrations typically being associated with spring snow melt and/or large rain events. Metal concentrations are also variable (Table 6H-5).

Table 6H-5: Water quality summary statistics for pooled reference station data (V1, VR, USFR, R7, FC, R6, W10)[a], Faro Mine, Yukon.

[a] Data for individual reference stations are summarized in Attachment Tables B.2 - B.8.

[b] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

4.2 Downstream Water Quality Relative to Background Levels

Water concentrations measured in mine-exposed areas were compared to background levels. For substances having the potential to be reduced by mine-related disturbances, such as pH and organic carbon, monitoring data indicated that concentrations at mine-exposed stations are rarely below the lower (5^{th} percentile) background benchmark (Attachment Tables B.22 to B.46); therefore, the comparisons subsequently focused on identifying locations and analytes having concentrations above the 95^{th} percentile of background concentrations (i.e., above the upper BGBM). Stations where more than 10% of samples contained analyte concentrations above the corresponding BGBM are shown in Table 6H-6. All substances previously identified as having concentrations that were elevated relative to background levels (Minnow 2010) continued to be elevated in more than 10% of samples collected at one or more stations downstream of mine disturbances in 2008 to 2012, inclusive (Table 6H-6).

Table 6H-7 presents the median concentrations measured at mine-exposed stations compared to the median and upper range of background concentrations, with shading used to highlight locations and analytes having median concentrations above the BGBM. Median concentrations of most analytes are above background levels at most stations located on Vangorda Creek. Such occurrences are less common in the Rose-Anvil Creek system, upstream of X14; however, concentrations at X14 are often more than double those observed at upstream stations. Elevated median hardness, sulphate, manganese, and potassium concentrations persist to A1, at the mouth of Anvil Creek (Table 6H-7)[1].

Monitoring of additional stations on West Vangorda Creek (VW1-VW3) began in 2009 based on recommendations made by Minnow (2010). While there are limited data for the period evaluated (flagged as "ID" in Table 6H-6), the data help to characterize inputs originating from the west side of the Vangorda/Grum Area relative to the effects of a historical landslide that crossed the creek between VW1 and VW3 (Figure 6H-3). Few analytes are elevated at VW3 compared to background concentrations (Table 6H-6, Attachment Table C.25). Data for VW1, farther downstream, provide some evidence that water quality is affected at that location though not many samples were collected over the period assessed (Table 6H-7). Data for a small tributary south of the Vangorda waste rock pile (VW2) suggest that water quality of West Vangorda Creek is influenced by this source as well (Table 6H-7). The effect on water quality from mine sources relative to the

[1] Although median turbidity is also elevated above background levels at A1, relatively lower concentrations at stations closer to the FMC indicate that there is a source of suspended solids between R4 and A1 that is not mine-related.

Table 6H-6: Analytes with concentrations above the corresponding upper background benchmark (95th percentile of reference data) in more than 10% of samples[a] at mine-exposed stations, 2008 - 2012. Blank cells represent variables for which <10% of samples were elevated relative to the upper background benchmark.

[a] limited data (n<10)

landslide cannot be conclusively determined from the available data. Concentrations of many analytes remain elevated above background levels to the mouth of Vangorda Creek at V8 (Table 6H-7).

For most variables, the ratio of the station median to the upper BGBM is less than three (Table 6H-8), indicating a relatively modest magnitude of mine-related influence on water quality relative to background concentrations.

4.3 Comparisons to Water Quality Guidelines

Water quality data from mine-exposed stations in the Rose-Anvil and Vangorda drainages were also compared to water quality guidelines for protection of aquatic life. The percent of samples at each station having concentrations above the respective guidelines is shown in Table 6H-9, to indicate frequencies of guideline exceedances, while the ratio of the median concentration to the guideline is shown in Table 6H-10 to indicate relative magnitudes of guideline exceedances among stations and analytes.

4.3.1 Non-metals

Approximately 16% of samples at X14 over the 2008 - 2012 period had concentrations of ammonia that were above the guideline (Section 2.3.1.2, Table 6H-9), which resulted from using conservative assumptions of temperature and pH to convert the guideline for un-ionized ammonia to a total ammonia guideline (Table 6H-2). This was done because temperature and pH values, which are needed to estimate the proportion of total ammonia present in the un-ionized form, were not consistently reported for samples. However, pH was available for most samples and using these values with a conservatively high temperature of 15ºC results in estimates of un-ionized ammonia at X14 that are consistently below the water quality guideline for protection of aquatic life of 0.0156 mg/L un-ionized NH3-N. Therefore, ammonia concentrations do not appear to be of concern in surface waters downstream of the FMC.

Sulphate concentrations were above background concentrations at mine-exposed stations in Vangorda Creek and at X14 in Rose Creek (Table 6H-8), but were consistently below the guideline for protection of aquatic life (Table 6H-9).

Of other non-metal analytes that had elevated concentrations relative to guidelines downstream of mine sources (Table 6H-9), TOC, DOC, TSS and turbidity all have guidelines that are derived as a specified magnitude or proportional increment from background concentrations (Tables 6H-1, 6H-2). Such guidelines would typically be

Table 6H-8: Ratio of median analyte values at mine-exposed stations to the upper background benchmark (95th percentile of reference data) [a]. Highlighted values indicate median concentrations that were at least 3 times higher than the upper background benchmark, to accentuate stations and variables reflecting greatest mine-related influence.

[a] In cases where the guideline covers a range of values (alkalinity, total organic carbon, and pH), the upper value of the range was used to calculate the ratio
[b] Median values that were reported as less than the detection limit (DL) were used at the DL for calculation
[c] Limited data (n<10 samples)

derived on a location-specific basis and take into account seasonal variation in background concentrations; however, to facilitate evaluation of data across numerous stations, a single guideline was derived for each substance, using a modified approach that took into account natural background variability (Section 2.3.2.1, Table 6H-2). Water monitoring data for 2008 – 2012 show that concentrations of organic carbon are generally within the guidelines except at stations in mid to upper Vangorda Creek (VGMAIN, VW1-VW3), and at stations R1 and R4 where sample sizes were limited. Table 6H-7 shows that median organic carbon concentrations are within the range of background concentrations at all stations; suggesting that even the modified guideline derivation process used for these variables is too conservative. Overall, the data indicate limited mine-related effect on organic carbon concentrations.

Although concentrations of both TSS and turbidity were elevated in some samples collected in the Vangorda Creek and Rose-Anvil Creek drainages (Table 6H-9), median station concentrations are usually below the modified guideline[2], as indicated by ratios <1 in Table 6H-10. This means that most samples had concentrations within or only slightly above the range of background concentrations. Also, median and maximum concentrations at most mine-exposed stations were comparable to or less than those measured at background (reference) stations (Table 6H-11).

Furthermore, it appears that elevated concentrations of TSS and turbidity are contributed by sources other than the FMC. For example, elevated TSS and turbidity concentrations along West Vangorda Creek are likely at least partially attributable to the landslide that crossed the creek between VW3 and VW1 (Figure 6H-3). Also TSS and turbidity were more often elevated (Table 6H-9), and to a greater degree (Table 6H-10) at the most downstream Anvil Creek station (A1) than at stations closer to the FMC (e.g., X14). TSS and turbidity levels were also sometimes elevated at minimally-mine-affected station R1 (SFRC) (Table 6H-9). Stations R1 and A1 have larger catchment areas than the majority of reference stations monitored at the FMC, and thus could be expected to reflect higher TSS and turbidity levels (Moeller et al. 1979; Stein and Yoon 2007). TSS and turbidity levels of as low as 270 mg/L and 25 NTUs, respectively, have been associated with effects on aquatic biota (CCME 2002) but such concentrations were rarely exceeded in surface waters around the FMC that are accessible to fish (i.e., at V8 and stations in the Rose-Anvil drainage; Table 6H-11; Figure 6H-8; also see detailed data in Attachment Tables C.29 to C.42).

[2] The modified guideline being a small specified increase above the background concentration range as described in Table 6H-3.

Table 6H-11: Median and maximum concentrations of total suspended solids and turbidity for mine exposed stations compared to reference stations, 2008 - 2012.

Station	Total Suspended Solids (mg/L)		Turbidity (NTU)	
	Median	Maximum	Median	Maximum
Pooled Reference Stations	<1	400	0.53	6.2
V27	<1	61	0.3	1.3
V4	1.95	120	1.6	3.1
VGMAIN	<1	190	0.3	80.0
VW3	11.2	39	4.0	12.8

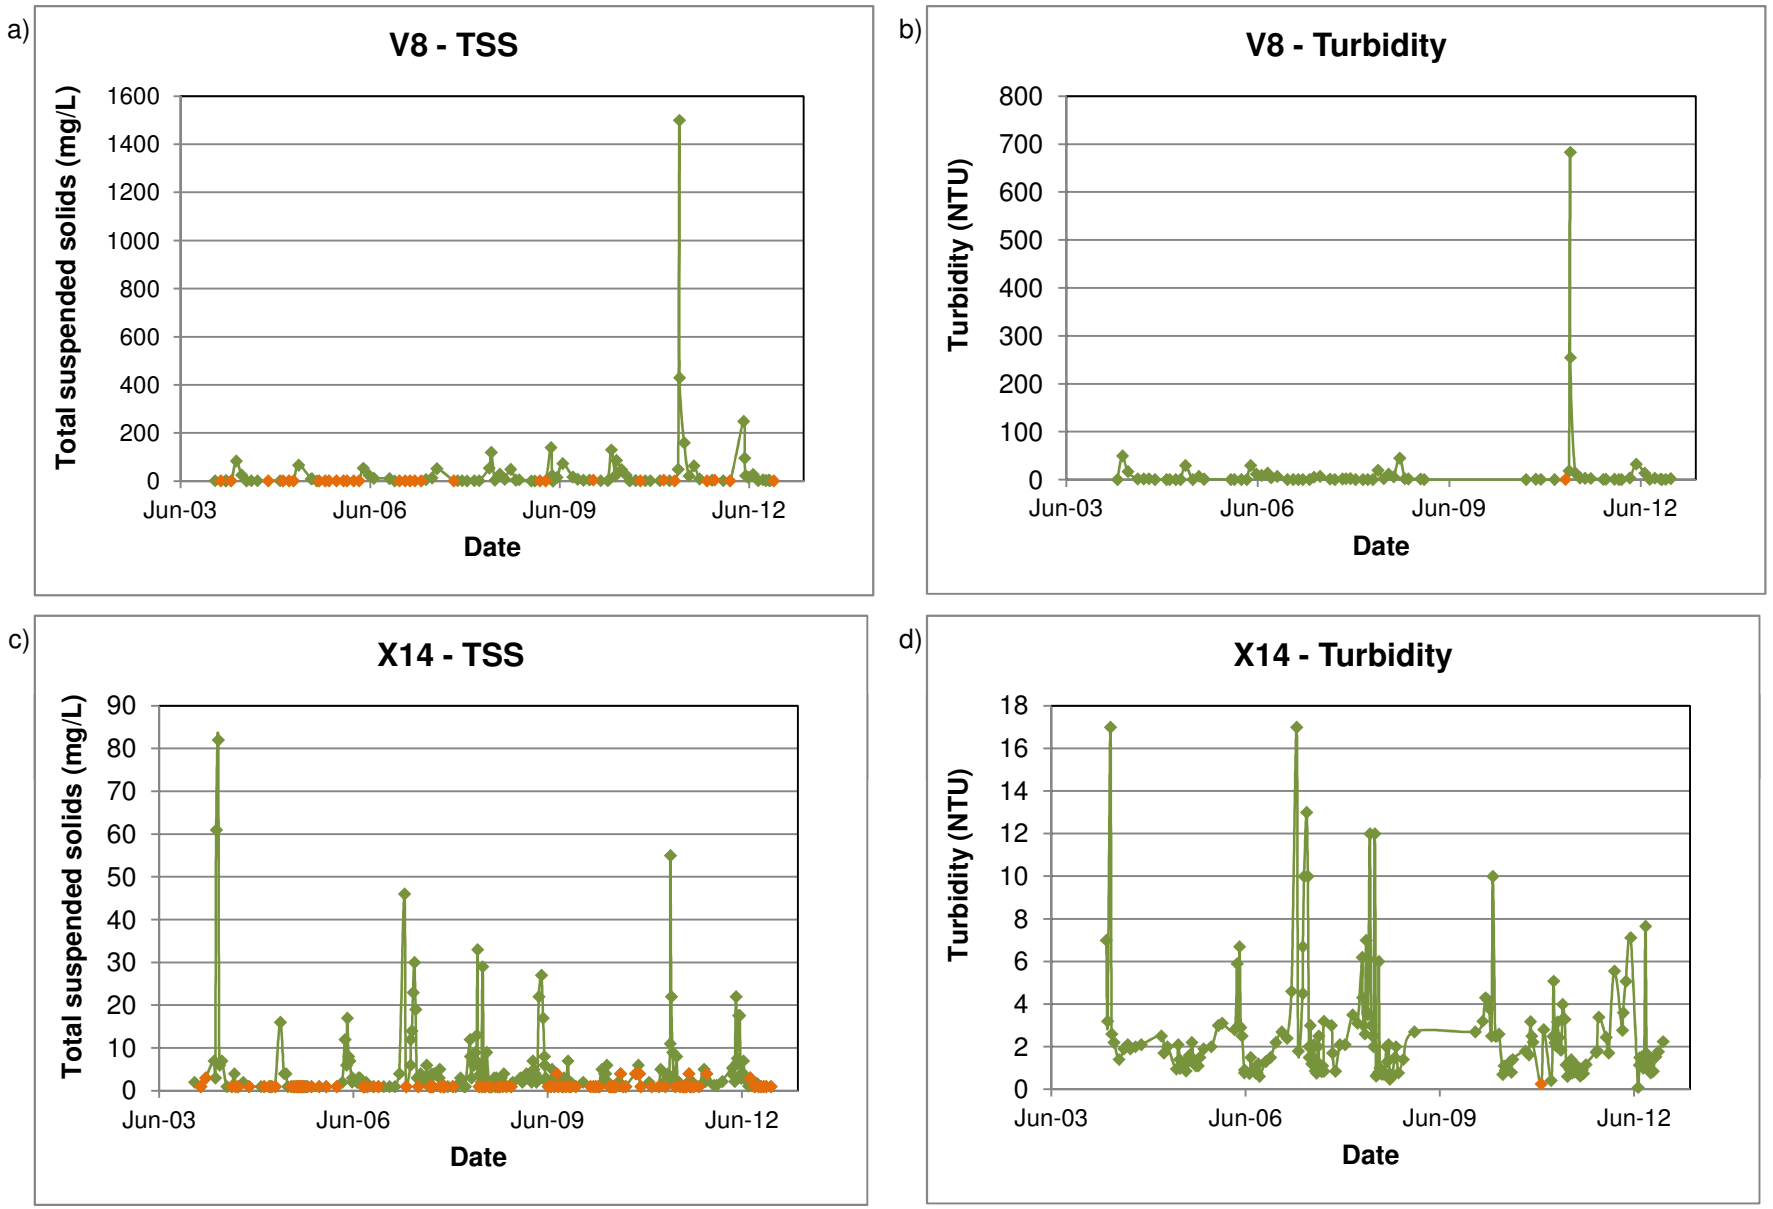

Figure 6H-8: Surface water concentrations of total suspended solids and turbidity at mine-exposed stations V8 and X14, 2004 to 2012. Orange points indicate values reported as less than the detection limit.

The above information indicates that non-metal variables discharged by the FMC currently pose little risk of effects to aquatic biota.

4.3.2 Metals

Concentrations of mine-related metals that were measured at stations downstream of the FMC were also compared to guidelines for protection of aquatic life. Cadmium, cobalt, iron, lead, manganese, uranium, and zinc concentrations were above guidelines in more than 10% of samples collected at one or more stations downstream of mine disturbances (Table 6H-9). Of these, the relatively more frequent elevations of iron at R1, which is relatively undisturbed, and at A1, well downstream of the Faro Mine Area, indicate sources other than the FMC; Figure 6H-9 shows that iron concentrations are positively related to TSS concentrations at these stations, with elevated levels of both likely being associated with mobilization of particulate matter during snowmelt and rain events. The pattern of data for West Fork Vangorda Creek also suggests that at least some of the iron measured at stations farther downstream (V5 and V8) originates from the landslide.

Furthermore, most of the total iron measured at V8 is in particulate, not dissolved; form (Attachment Figure C.1). Of the remaining mine-related metals, zinc was most often measured at concentrations above the guideline for protection of aquatic life at stations located downstream from FMC sources (Table 6H-9). Despite contributions from the Vangorda/Grum Area, and likely also the landslide across West Vangorda Creek, metal concentrations at V8 rarely (≤ 15% of samples) exceeded guidelines for protection of aquatic life (Table 6H-9) and median concentrations were ≤ half the guideline values (Table 6H-10).

Station NF1, located on NFRC immediately upstream of the Haul Road, had cadmium, cobalt, iron, lead, manganese, and zinc that were above guidelines in up to one-quarter of samples collected from 2008 - 2012, but the guidelines were less often exceeded at the next downstream station NF2 (Table 6H-9), suggesting a localized source near NF1. At station X14, concentrations of cobalt (31% of samples), manganese (40%), and zinc (73%) were sometimes also above guidelines (Table 6H-9; Figure 6H-10). However, guidelines were infrequently exceeded at stations farther downstream in Rose Creek (R4) and Anvil Creek (A1) (Table 6H-9).

Metal concentrations in Vangorda Creek and in Rose Creek downstream of the FMC (V8 and X14, respectively) have been relatively stable over the past decade (Figure 6H-11).

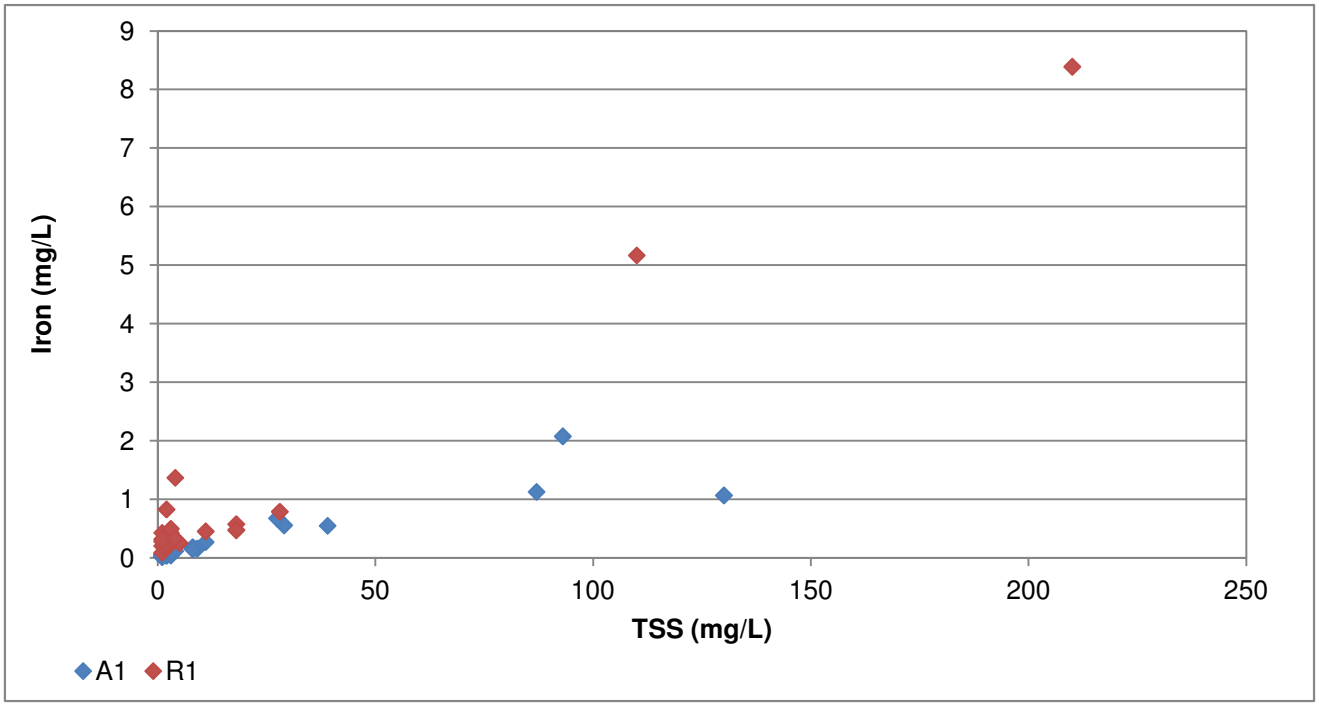

Figure 6H-9: Water concentrations of iron relative to TSS at relatively undisturbed station R1 (South Fork Rose Creek) and at station A1 (the mouth of Anvil Creek).

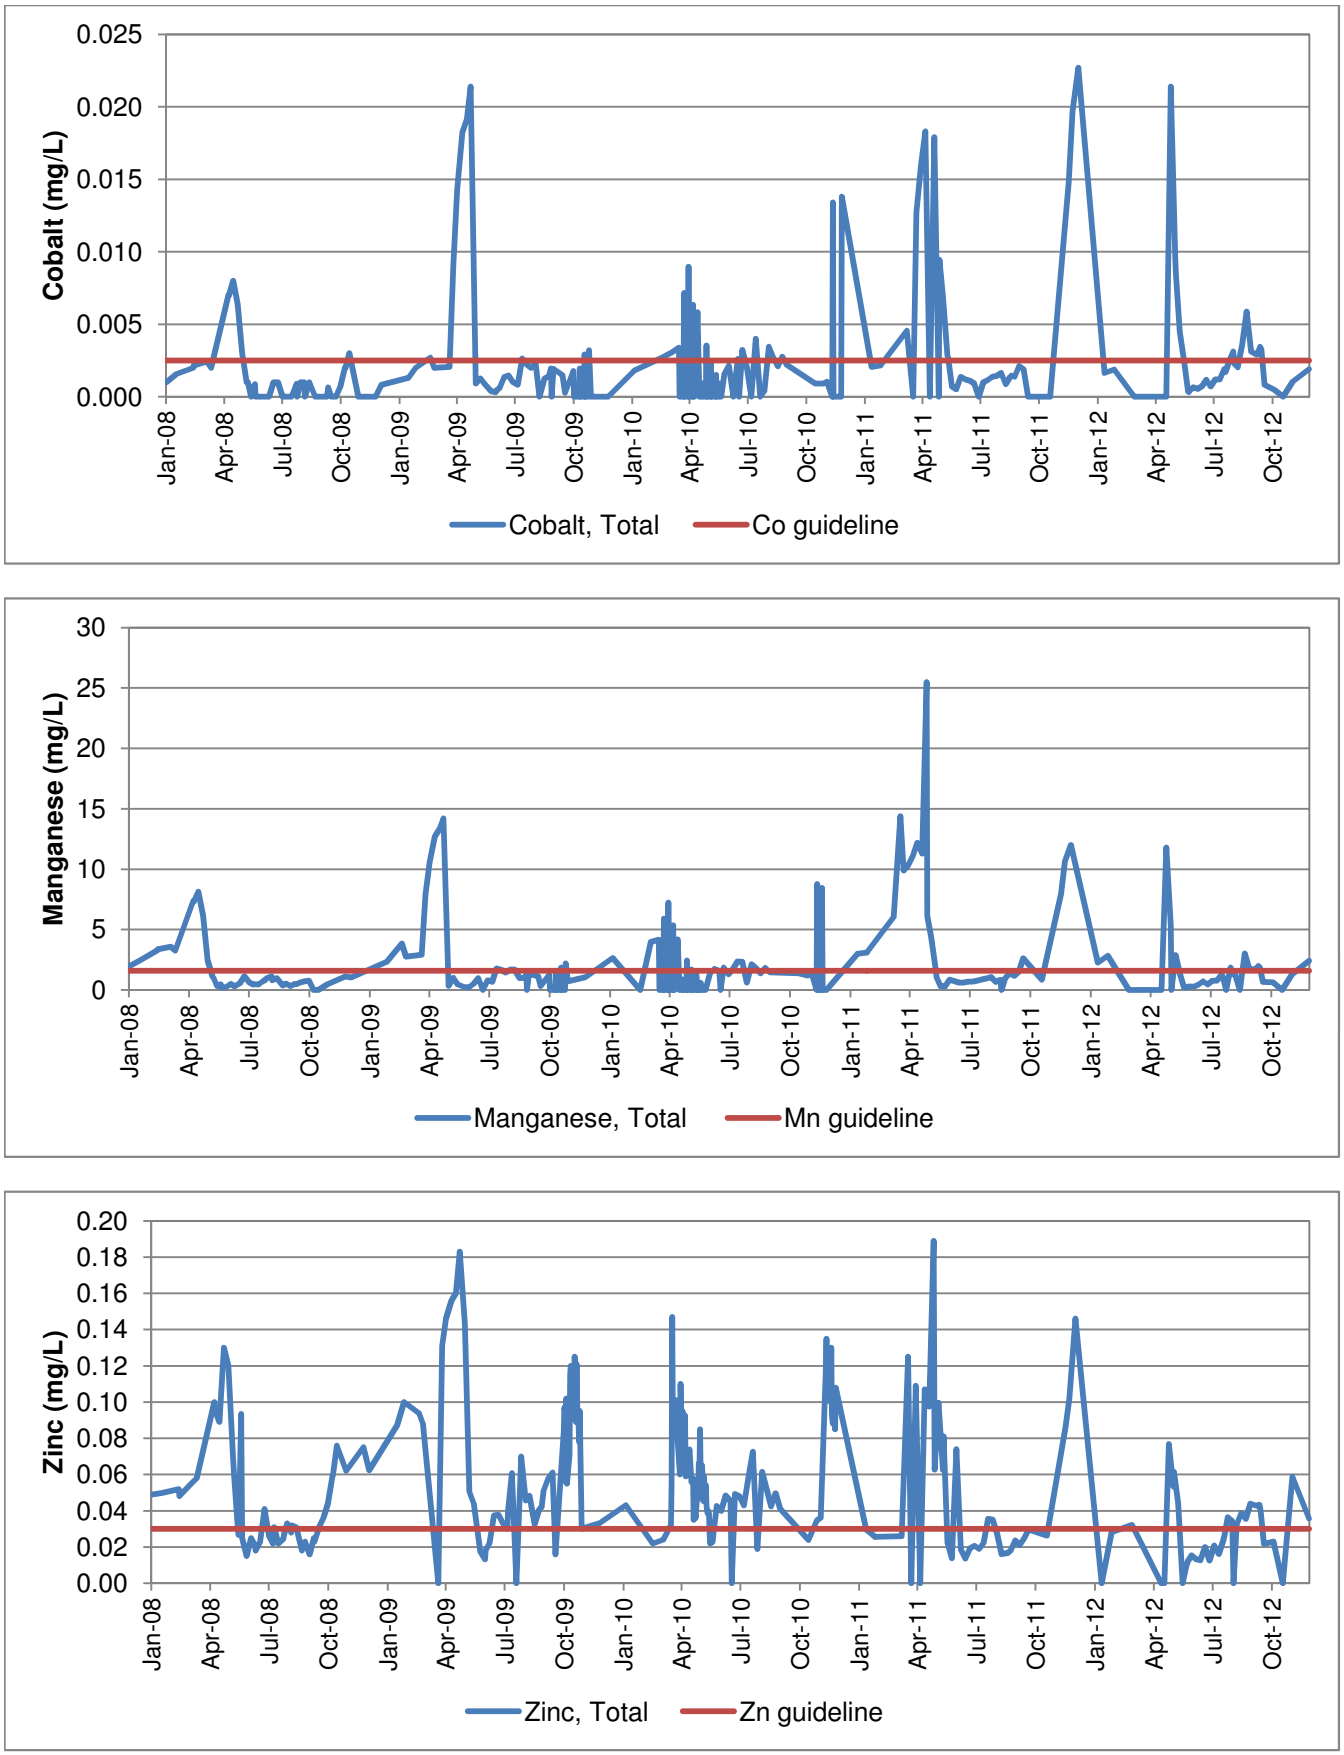

Figure 6H-10: Cobalt, manganese and zinc concentrations at X14 relative to water quality guidelines (2008 - 2012).

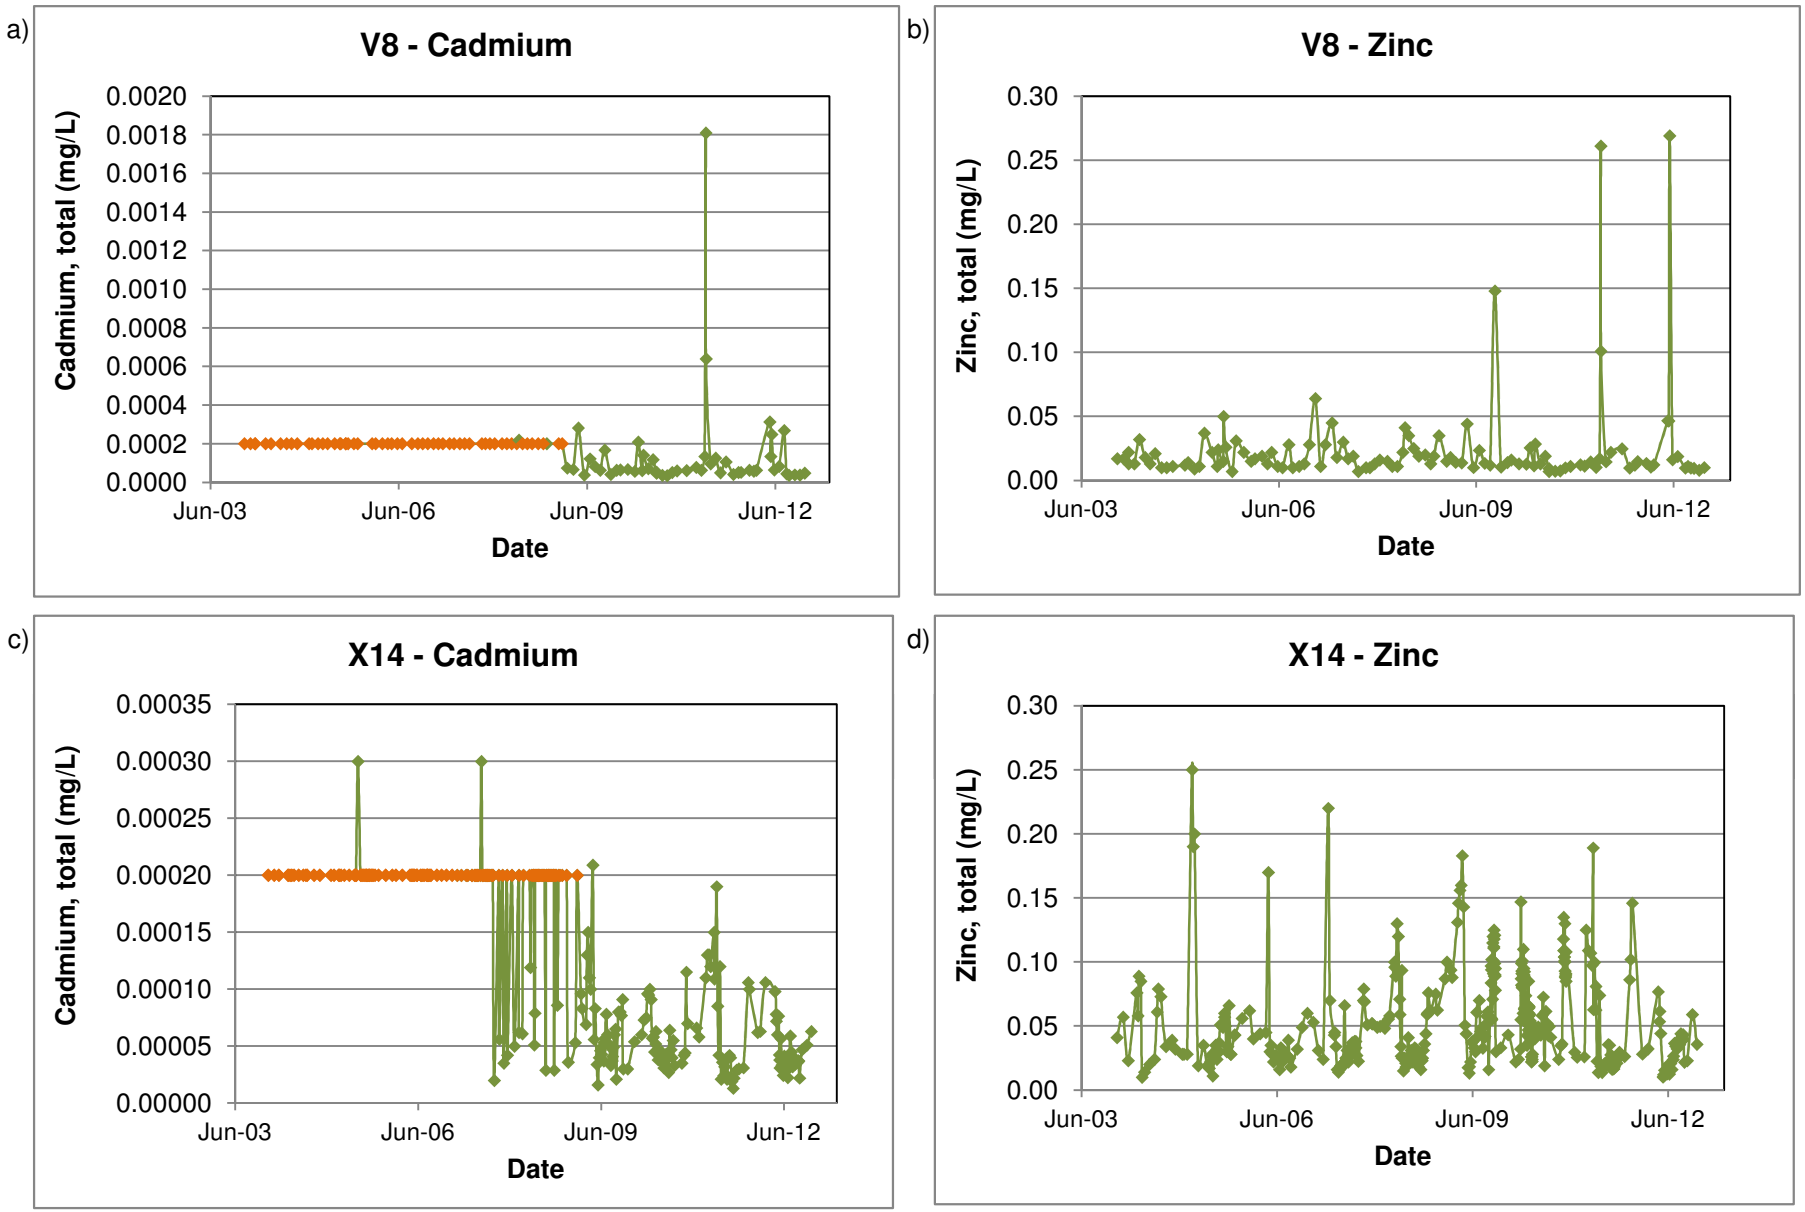

Figure 6H-11: Surface water concentrations of total cadmium and zinc at mine-exposed stations V8 and X14, 2004 to 2012. Orange points indicate values reported as less than the detection limit.

4.4 Pelly River

Water concentrations were compared among stations on the Pelly River upstream and downstream of Vangorda Creek (P1 and P2) and Anvil Creek (P3 and P4; Table 6H-12, Figure 6H-3). The comparison focused on selected analytes considered to be good indicators of mine-related disturbance on water quality (alkalinity, sulphate, manganese and zinc). There were no significant differences ($p<0.05$) in mean concentrations of alkalinity, sulphate, or zinc at P2-P4 compared to P1, based on ANOVA followed by post-hoc tests (Table 6H-12). Mean manganese concentrations at P2 and P3 were lower than those at P1. The data indicate that mine-related influences on surface water quality do not currently extend into the Pelly River.

4.5 Traditional Drinking Water Stations

Two water monitoring stations are traditional locations of drinking water taking by First Nations: GCULV (Grum culvert) and K8 (Figure 6H-3). Water quality at these stations was compared to drinking water quality guidelines. Organic carbon, turbidity, iron, and/or manganese concentrations were occasionally above the guidelines between 2008 and 2012 (Table 6H-13).

4.6 Summary

Water quality data for the FMC from 2008 through 2012 indicate that concentrations of a variety of non-metals and metals are elevated in surface waters relative to the typical range of background (reference station) concentrations. Alkalinity, conductivity, hardness, sulphate, total dissolved solids, calcium, cobalt, magnesium, nickel, sodium, strontium, and zinc occur at concentrations above the background range in approximately half or more of samples collected downstream of the Vangorda/Grum Area (V8) and the Faro Mine Area (X14). Concentrations of non-metal analytes are below those expected to have adverse effects on aquatic biota.

Metal concentrations in lower Vangorda Creek (V8) rarely (≤ 15% of samples) exceed guidelines for protection of aquatic life and median concentrations are usually less than half the guideline values. Water concentrations of several metals (cadmium, cobalt, iron, lead, manganese, zinc) are above guidelines in up to one-quarter of samples collected at NF1, on the North Fork Rose Creek (NFRC) upstream from the Haul Road, but zinc is the only mine-related metal that exceeds guidelines at stations between NF1 and Rose Creek station X14, just downstream of the Faro Mine Area. Cobalt and manganese are also found at concentrations above water quality guidelines for protection of aquatic life in up to

Table 6H-12: Statistical comparisons of water quality at Pelly River exposure stations (P2 - P4) compared to the upstream reference station (P1). Highlighted values indicate concentration at exposure stations that differed significantly from the P1 reference station based on ANOVA followed by post-hoc tests (p<0.05).

Analytes[a]	Units	Pelly River Reference (P1) Median	Pelly River Mine-Exposed Station Medians		
			P2	P3	P4

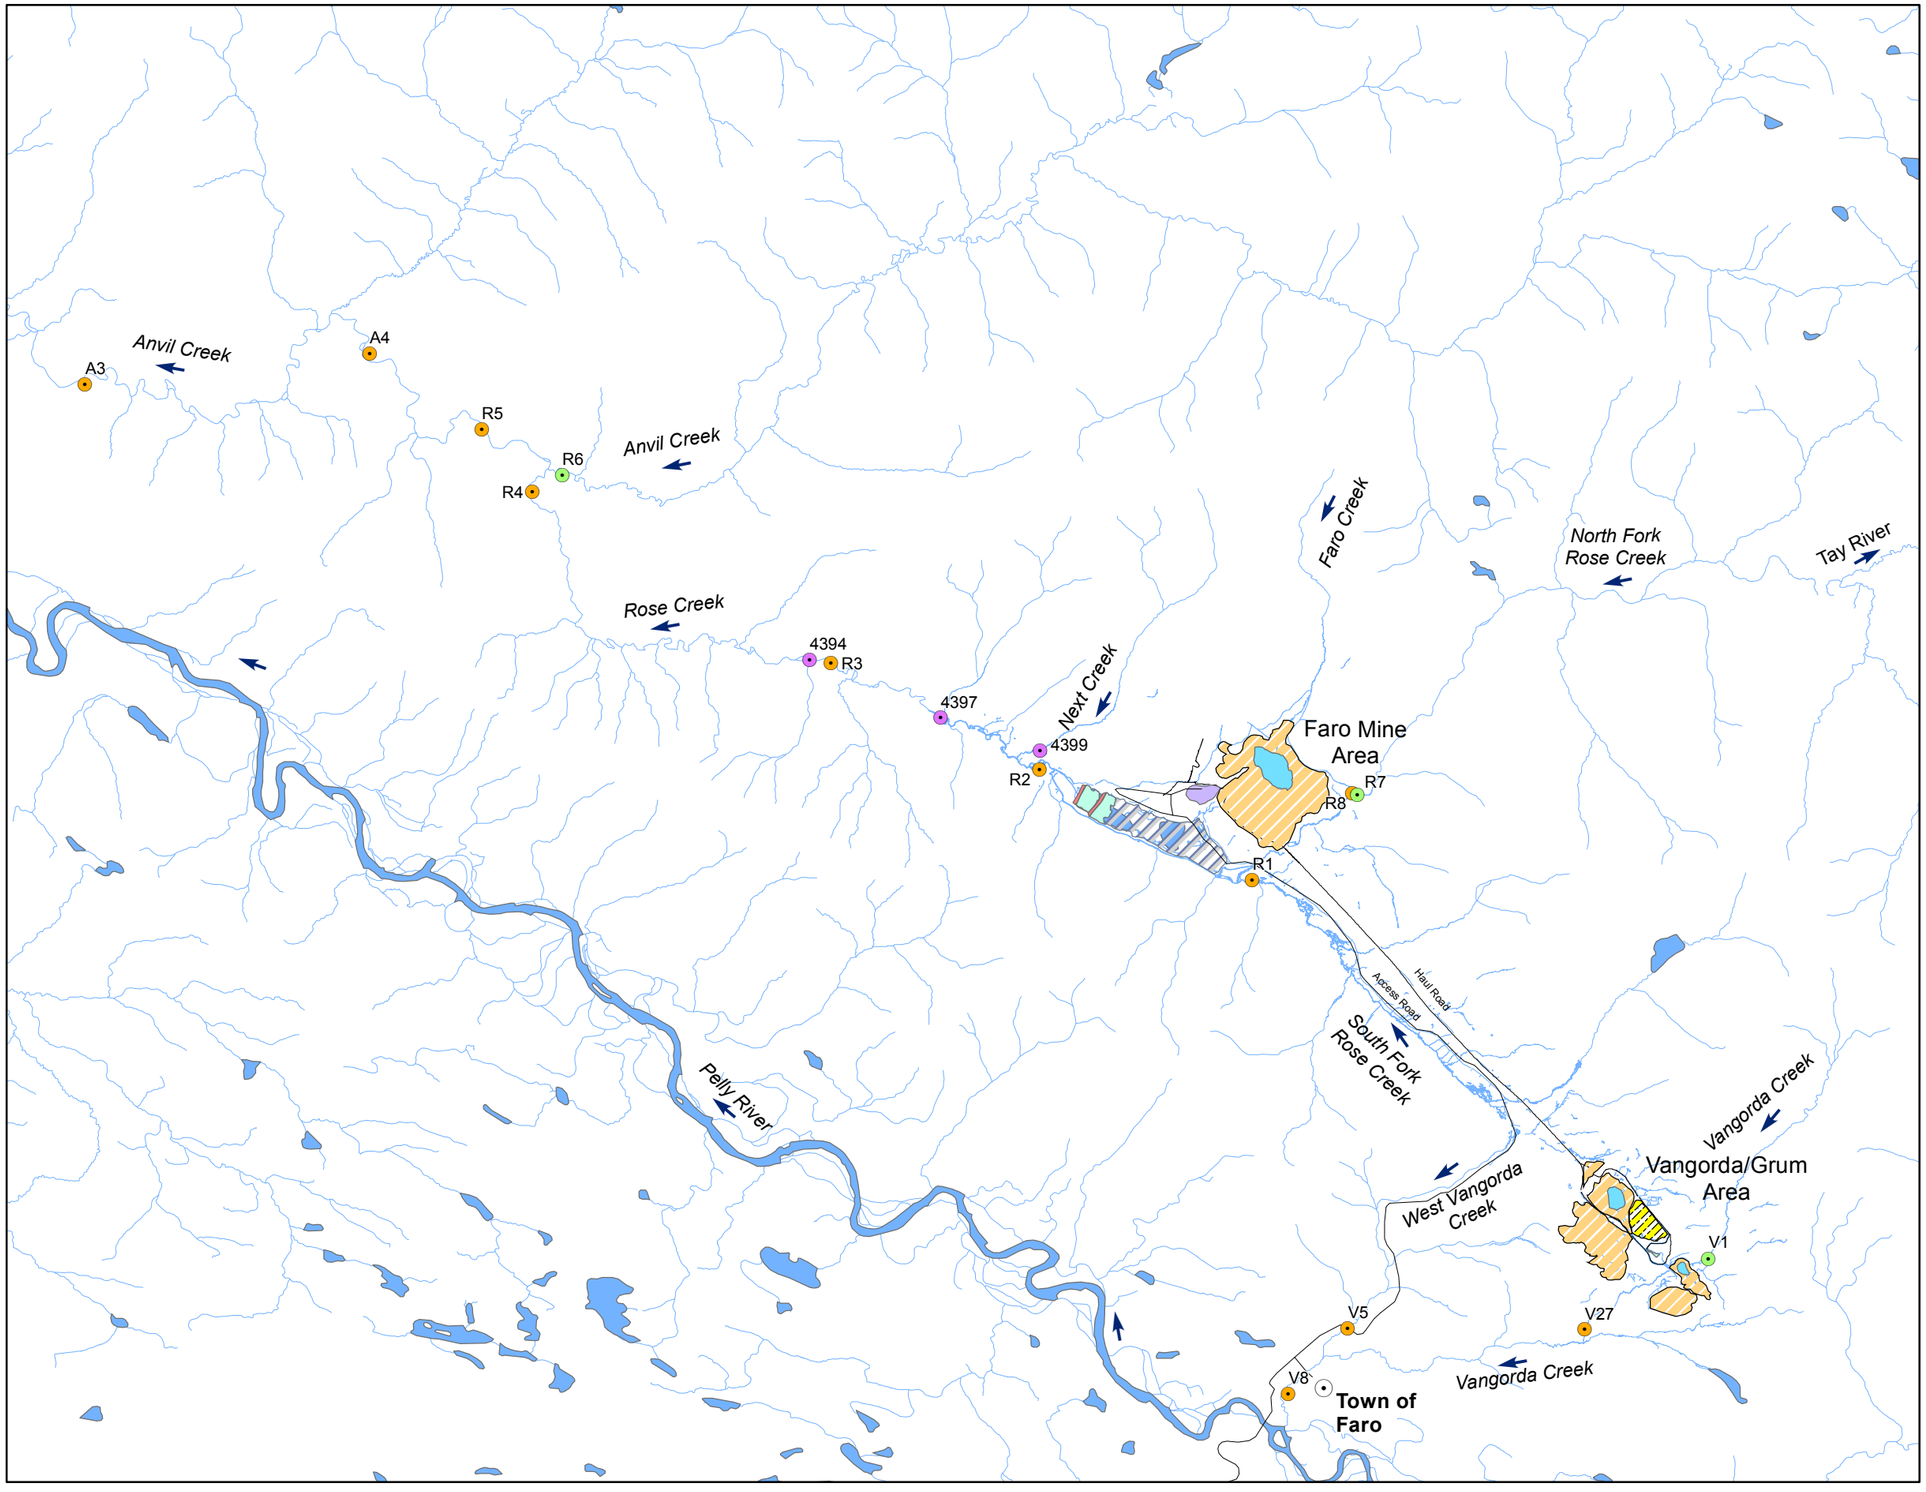
[a] Refer to Table 6H-3 for information regarding the source of drinking water quality guidelines

[b] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

40% of samples collected at X14, but median concentrations for all metals but zinc are below the guidelines. Water quality guidelines are infrequently exceeded at stations farther downstream in Rose Creek (R4) and Anvil Creek (A1) indicating that mine related effects on biota, if any, are likely localized around the Faro Mine Area. Mine-related effects on water quality do not extend into the Pelly River.

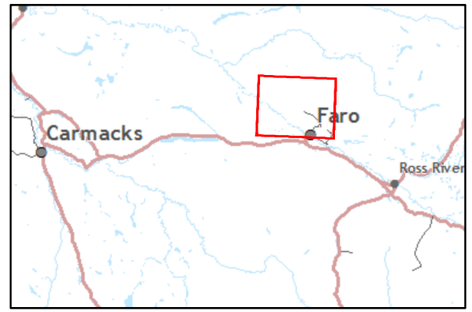
5.0 SEDIMENT QUALITY

5.1 Historical Studies



Sediment quality has been monitored in the Rose-Anvil Creek and Vangorda Creek systems since as early as 1973 and 1991, respectively (Figure 6H-12, Attachment Tables D.1 and D.2), and the results available to 2006 were summarized by Minnow (2007). There was some study-to-study variability in terms of precise sampling station locations, laboratory equipment/techniques, and the metal concentrations reported. However, sampling methods were similar among most studies; typically fine-grained sediment samples were collected in triplicate from streambed deposits using a trowel or shovel, then placed into glass jars, refrigerated, and shipped to a laboratory for analysis of metal content. Because fine sediment deposits were sparse in some areas, samples were sometimes collected from areas that were, or are sometimes, dry (i.e., soils above the water surface, not necessarily accessible to aquatic biota). Metals analyses were usually performed on the fraction of sediment samples that passed through a 100-mesh sieve (0.15 millimetres [mm]).

Metal concentrations were elevated in the fine fraction of sediment samples collected downstream of the FMC compared to reference areas (Figures 6H-13 and 6H-14). In particular, arsenic, lead, and zinc concentrations were above CSQG Probable Effect Levels (PEL) (CCME 2013). However, whole sediment concentrations, on which CSQG are based, were not measured except by Hoos and Holman (1973) and Minnow (2009). Samples collected in 2007 and 2008 (Minnow 2009) represent the most recent characterization of sediment quality and are discussed in more detail below.



5.2 Recent Surveys (2007-2008)

Sediment data collected in 2007 and 2008 (at stations V1, V27, R7, R2 and X2, Figure 6H-12) are considered representative of current conditions because water quality has been relatively stable in the interim (Figures 6H-8 and 6H-11). The grain size analysis results presented in Table 6H-14 demonstrate that sediments are composed mainly of sand and gravel, typical of fast-flowing, upper perennial creek habitats (Cowardin, et. al. 1979). Of the samples collected, combined silt and clay fractions represented <5% of the whole sediment samples, except in the case of X2, where silt and clay represented 25% and 6.5%, respectively. TOC content was also low (<4%) in all samples (Table 6H-14).

Sediment metal concentrations at reference areas V1 and R7 did not exceed sediment quality guidelines in either whole sediment samples (<1 mm) or the fine fraction (<0.15

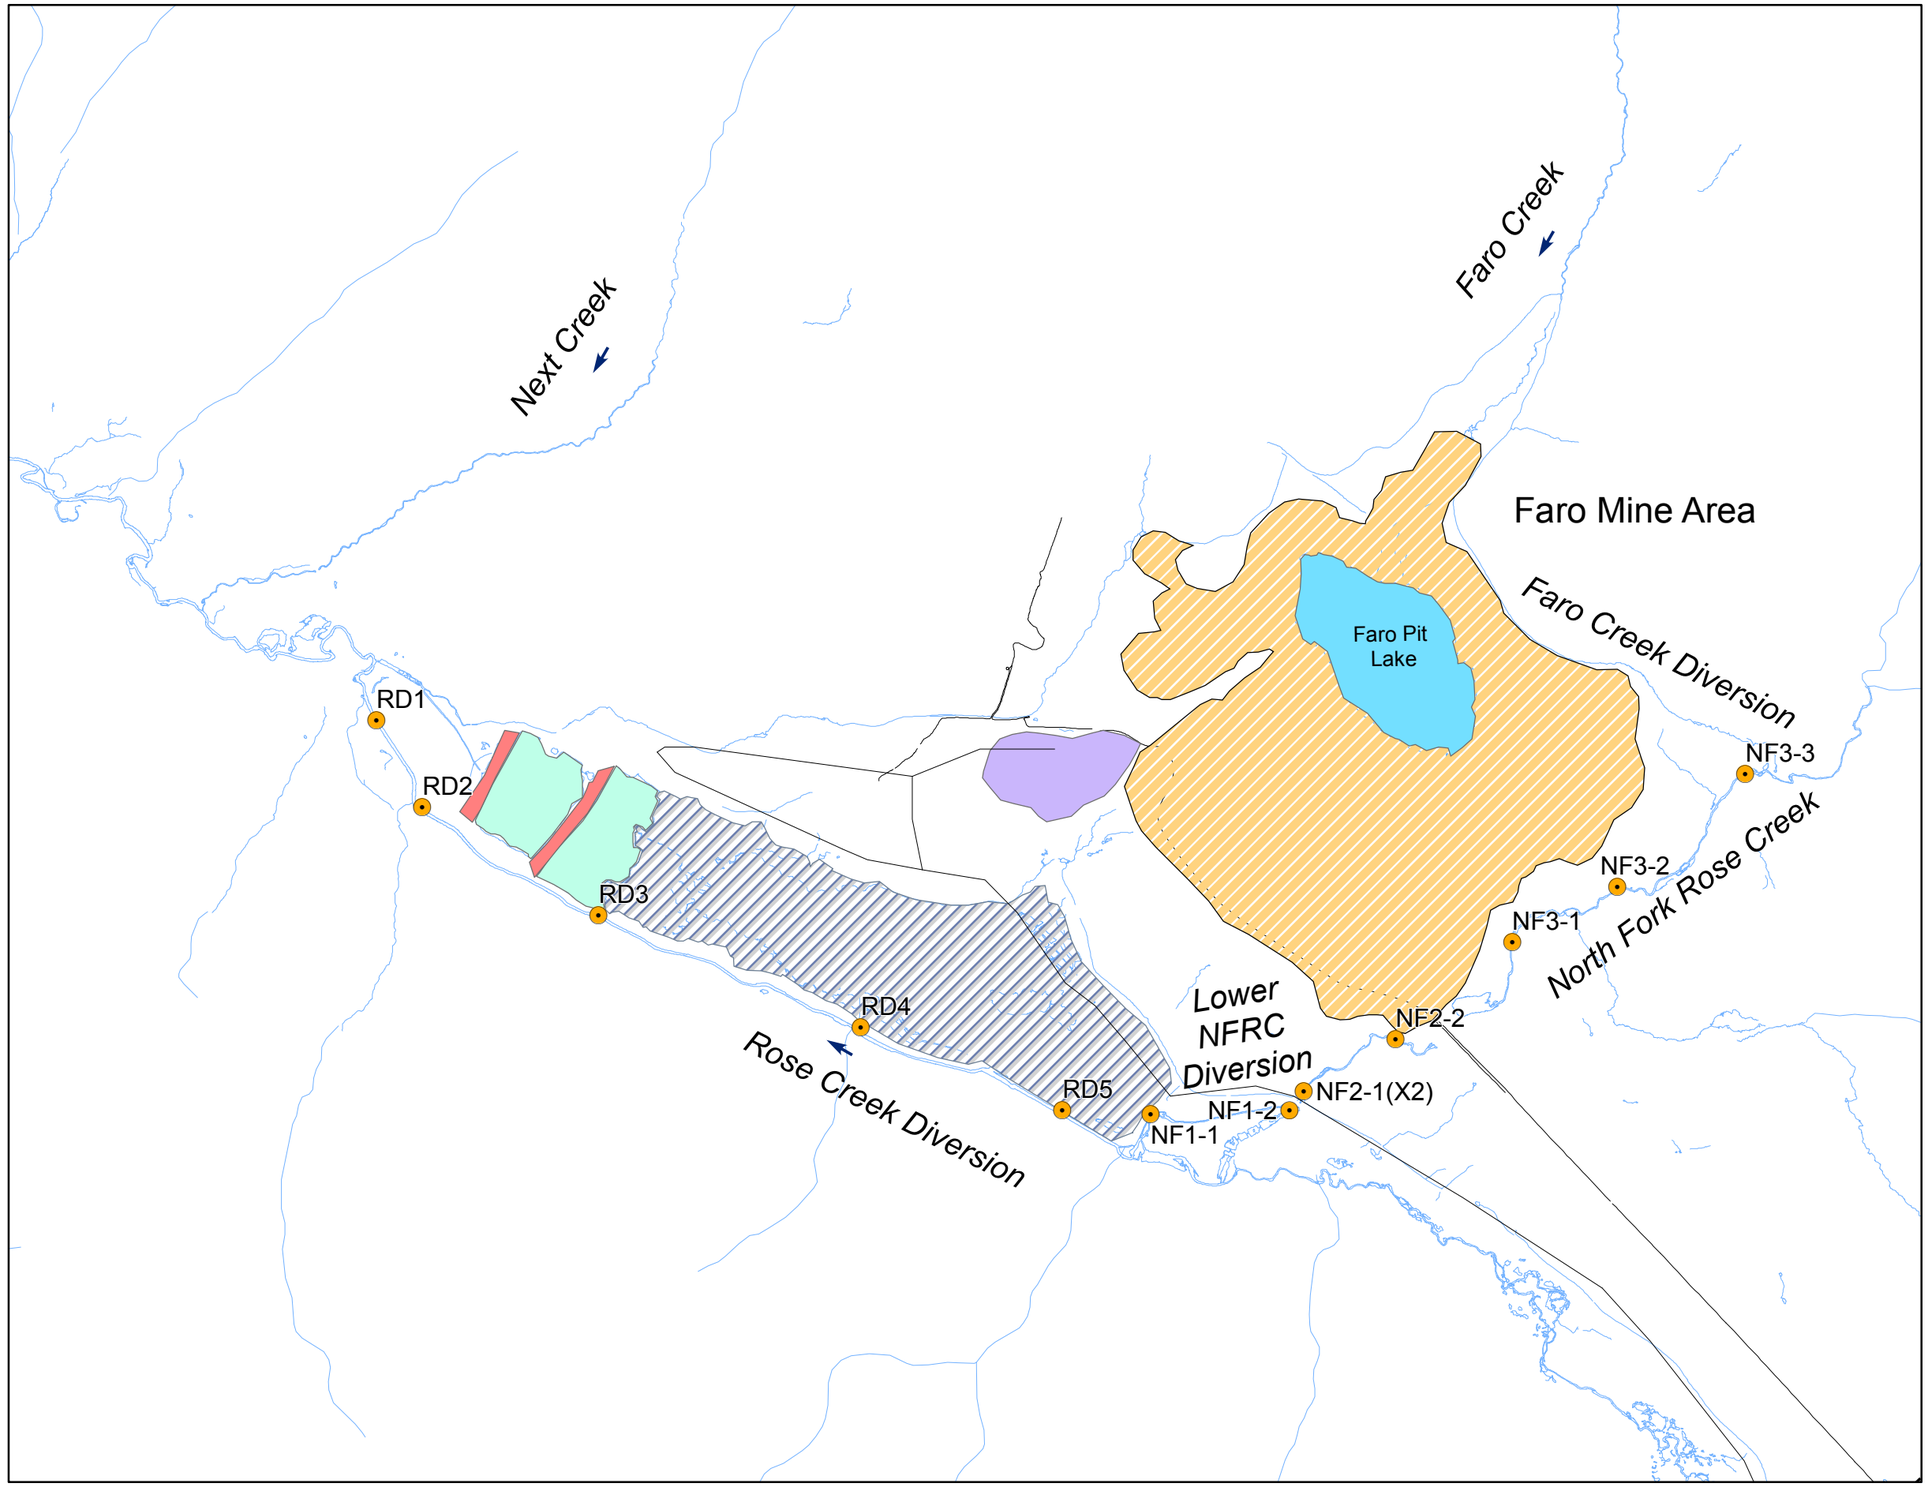
[g] Lowest effect level.
[h] Severe effect level.
[i] Samples for metal analysis were pre-screened to 2 mm to remove large particles that could bias sample results.

mm; Table 6H-14). Arsenic, lead, manganese, and zinc were elevated relative to sediment quality guidelines in samples collected at mine-exposed areas. Metal concentrations were typically about three times higher in the fine fraction than whole sediment (Table 6H-14), as would be expected in coarse sediments (Horowitz 1991). The exception was at X2, where the sediment sample contained more fines and concentrations were similar between the whole and fractioned sample (Table 6H-14). Thus, a large proportion of sediment metals is associated with fine sediment particles, which usually represents a small proportion of the total sediment composition.

Tests were conducted to determine if elevated sediment metal concentrations were associated with toxicity to aquatic biota. Samples from Rose Creek (X2 and R2) and Vangorda Creek (V1 and V27) were tested for potential effects on survival and growth of *Hyalella azteca* over a 14-day exposure period (Environment Canada 1997), with results expressed as percent survival and organism dry weight (Table 6H-15). No effects were observed among the organisms exposed to sediments collected from mine-exposed areas (V27, X2, R2) compared to those exposed to reference area (V1) or lab control sediment (Table 6H-15).

Table 6H-15: Results of 14-d survival and growth tests using *Hyallela azteca* for sediment samples collected near the Faro Mine Complex. Organisms were not significantly affected in mine-exposed sediment samples compared to lab controls (p>0.05 Tukey multiple comparison test) .

Sample	Sample Date	Mean Survival (%)	Mean Dry Weight (mg)
Lab Control	Aug-07	100	0.297
V1 (Reference)	Aug-07	100	0.410
V27-A	Aug-07	100	0.357
V27-B	Aug-07	100	0.307
V27-C	Aug-07	100	0.275
Lab Control	Aug-08	88	0.203
X2	Aug-08	90	0.186
R2	Aug-08	86	0.236



6.0 PERIPHYTON

Periphyton communities were characterized in 2009 along the NFRC and the RCD (de Graff 2013). The locations of investigations are illustrated on Figure 6H-15. The group of photosynthetic bacteria known as Cyanophyta dominated the communities in the NFRC just downstream from the confluence with the Faro Creek Diversion, but a shift to diatom (Bacillariophyceae)-dominated communities occurred closer to the Haul Road and continued downstream throughout the RCD (Figure 6H-16). Richness and Simpson's Evenness values were highly variable among sampling areas; however, diatom richness was elevated at downstream stations compared to the most upstream station (Attachment Table E.4).

The cyanophytes, *Chamaesiphon spp*., *Homoeothrix varians*, and *Clastidium setigerum,* were most abundant at station NF3-3 just downstream of the confluence of the NFRC with the Faro Creek Diversion, where mine influence is minimal, and were less abundant among stations farther downstream (Figure 6H-17). *Chamaesiphon spp*. have been shown to be both tolerant (Genter and Lehman 2000) and intolerant (Bray et al. 2008) to acid mine drainage, depending on the species. The 2009 data suggest that these three species are all intolerant of mine-related disturbances and may serve as future indicators of changes to aquatic health around the FMC.

The highest periphyton densities were observed in the NFRC just downstream of the Access Road (NF1-2) (Figure 6H-16a), where the diatom *Achnanthes minutissima* was most abundant (Figure 6H-17). In fact, *A. minutissima* made up roughly 44% (4 – 72%) of the diatom assemblage at all stations and was more abundant downstream than upstream of mine-related influences (Figure 6H-18). *Achnanthes*, especially *A. minutissima*, has previously been reported as the dominant diatom in streams affected by mining (Deniseger et al. 1986; Hill et al. 2000; Luis et al. 2009; Verb and Vis 2000). *A. minutissima* is generally considered tolerant of a wide variety of environmental conditions and is typically the only reported *Achnanthes* species in streams affected by acid mine drainage (Ponader and Potapova 2007). It also has been observed in higher relative abundance in areas with elevated levels of copper, lead, and zinc (Yoshiaki et al. 2004). As a result, its presence is frequently considered indicative of disturbed conditions (Sabater et al. 1998; Sabater 2000). Therefore, *A. minutissima* is likely indicative of the mine-related disturbances around the FMC.

The diatoms *Cymbella minuta*, *Fragilaria vaucheria*, and *Synedra ulna* showed a pattern similar to *A. minutissima* with respect to relative abundance among stations, while

FIGURE 6H-15

Location of Stations Sampled by de Graff (2013)

Faro Mine Interim Works

Minnow Project No.: 2499 Date: February 2014

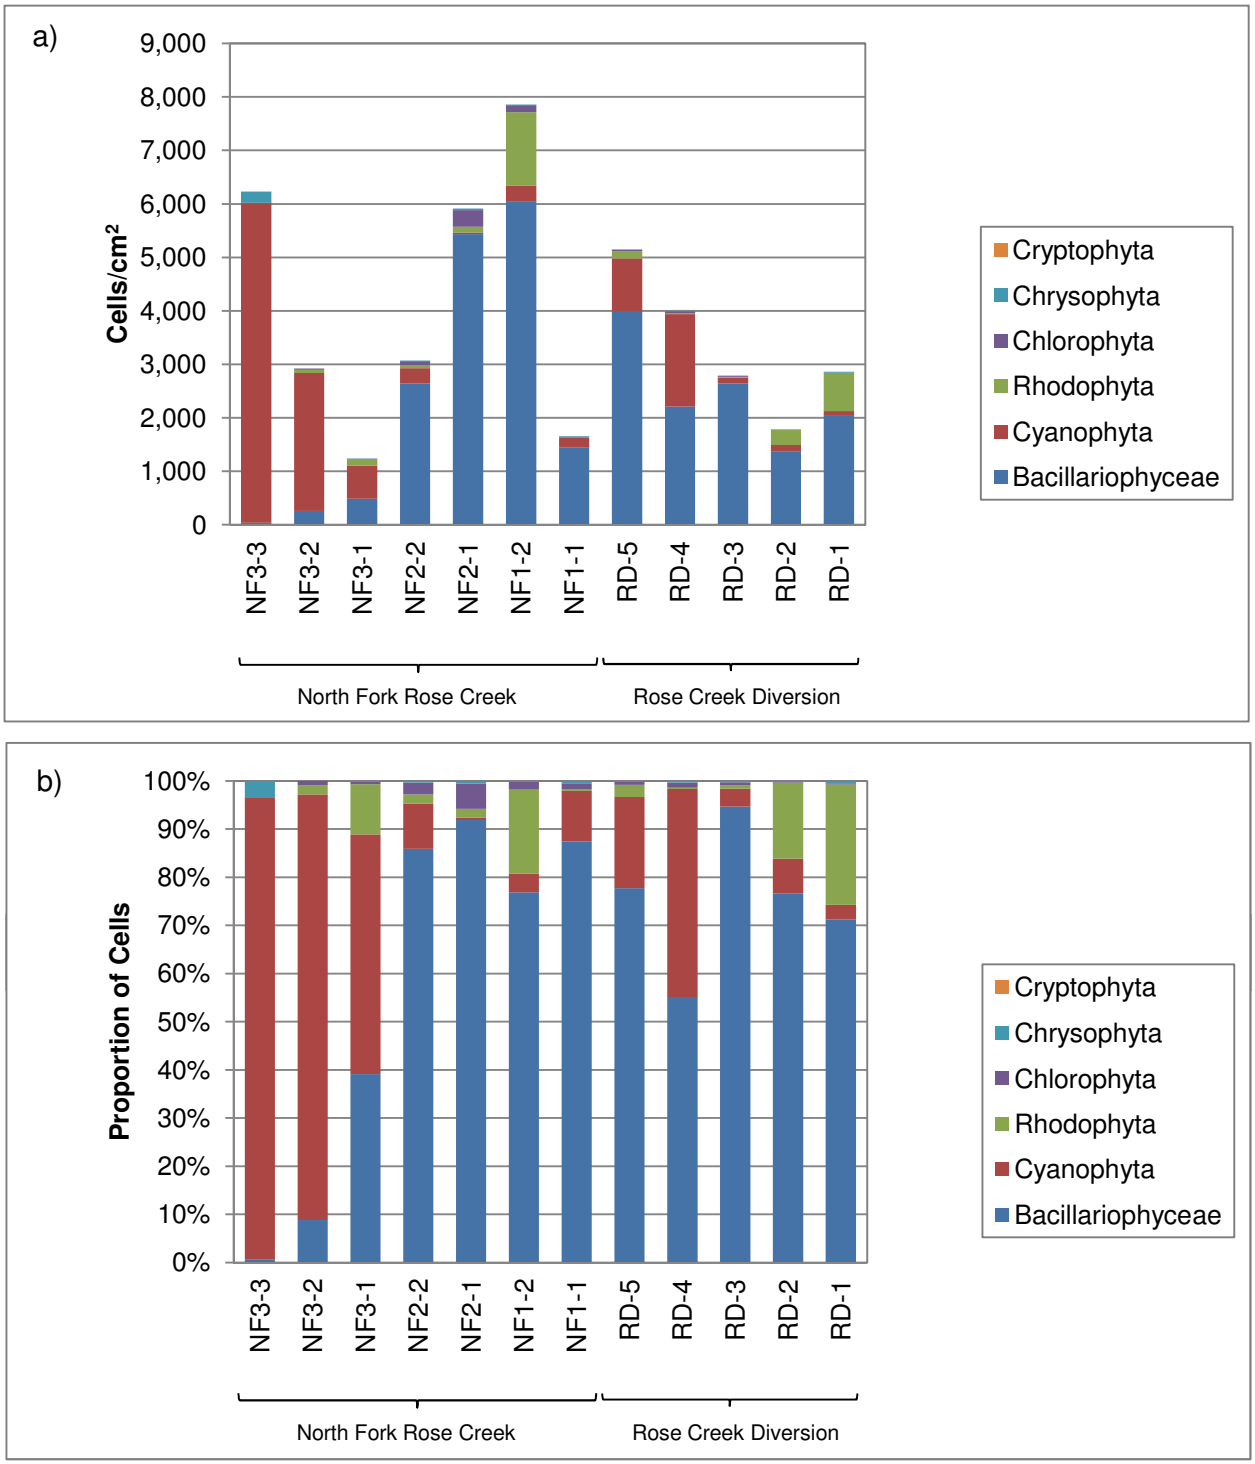

Figure 6H-16: Periphyton phylum a) abundance and b) proportion in the North Fork Rose Creek and Rose Creek Diversion, 2009. Data obtained from de Graff (2013).

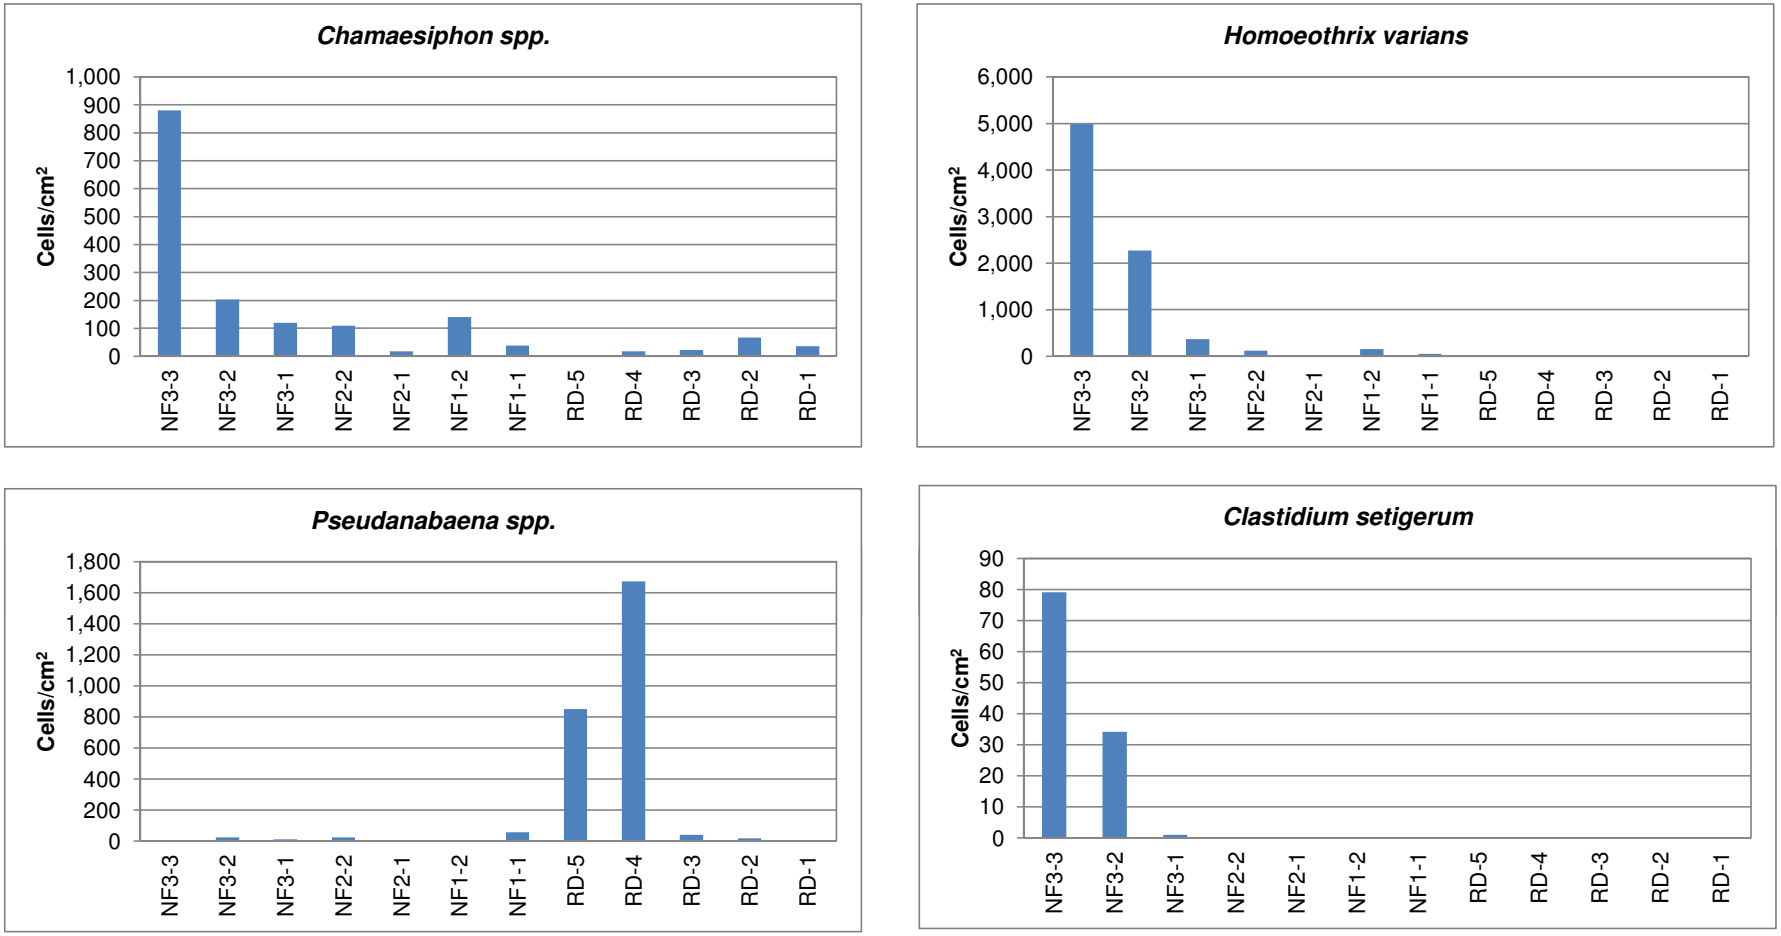

Figure 6H-17: Abundance of the four most common cyanophyta species (mean > 9 cell/cm^2) in the North Fork Rose Creek and Rose Creek Diversion, 2009. Data obtained from de Graff (2013).

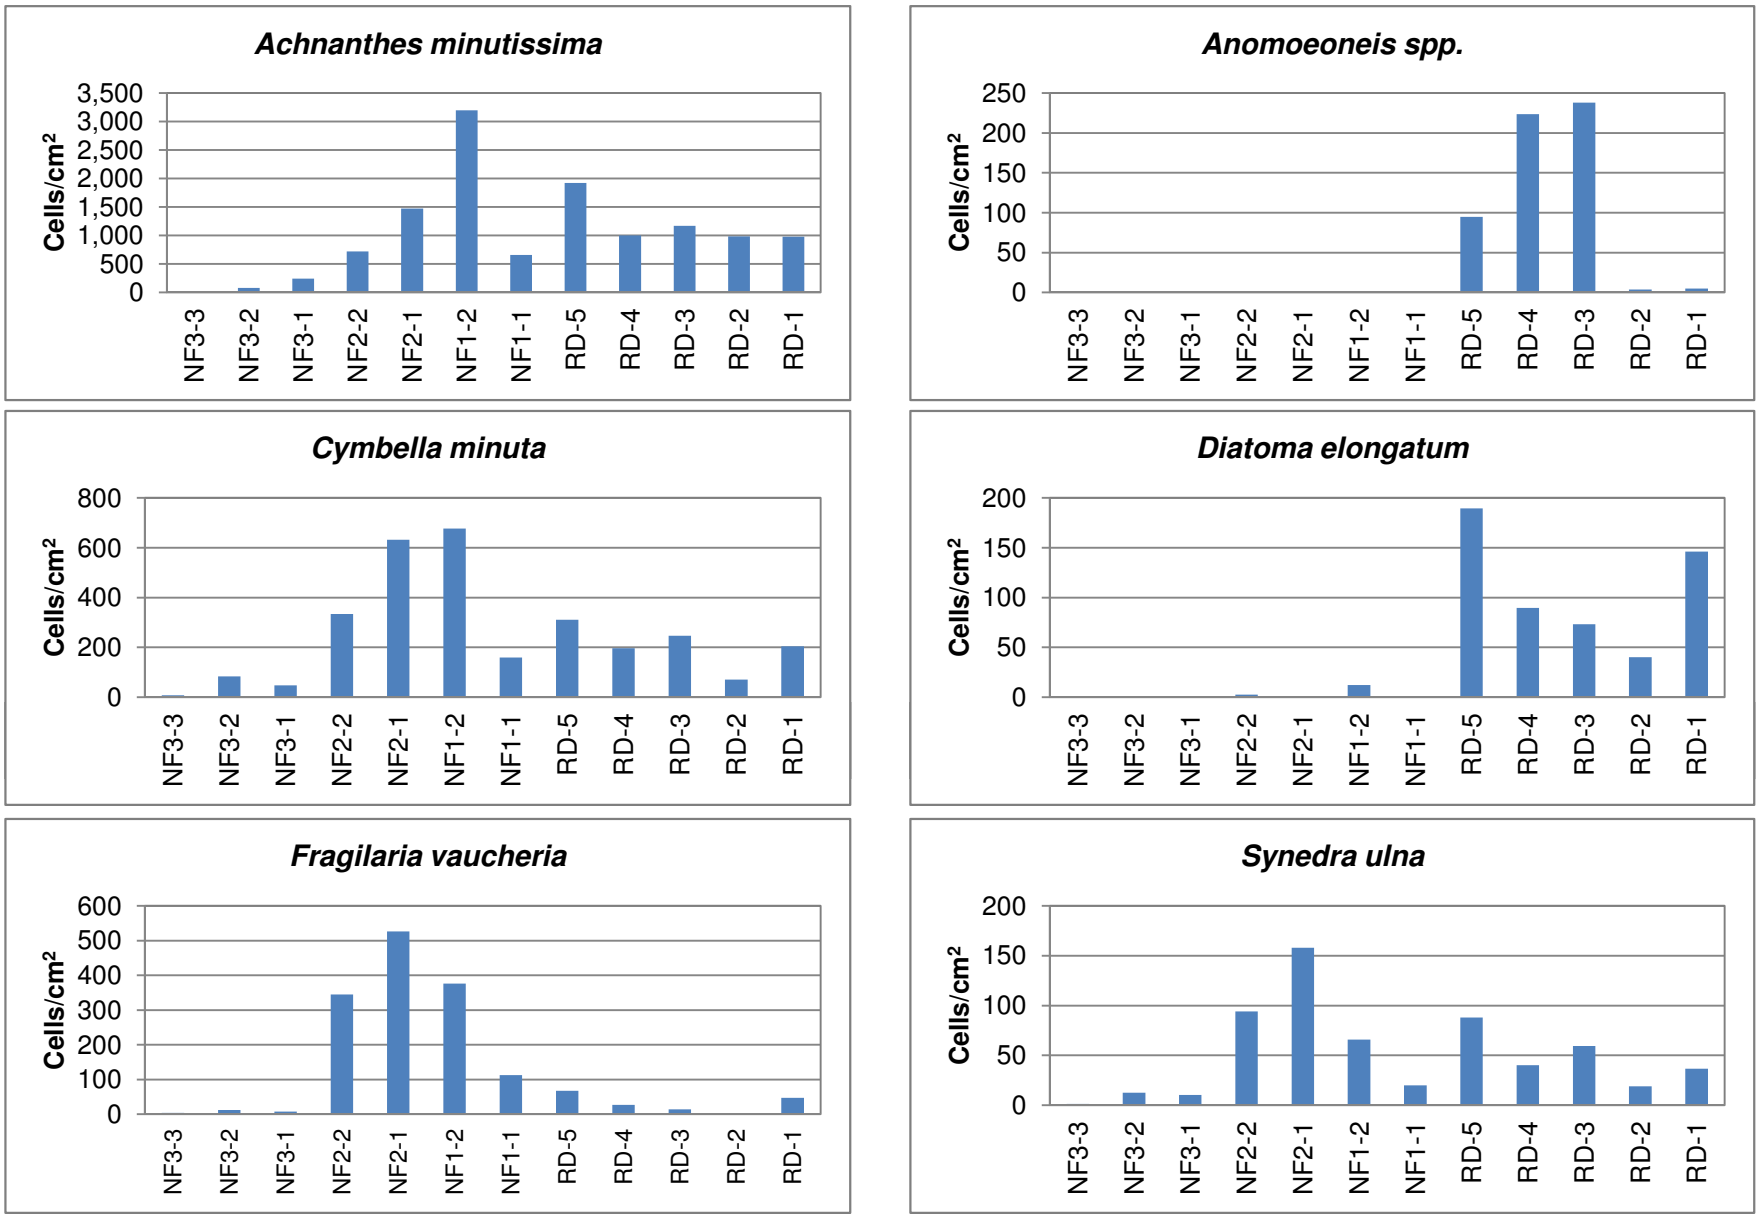

Figure 6H-18: Abundance of the six most common bacillariophyceae (diatom) species (mean > 40 cell/cm^2) in the North Fork Rose Creek and Rose Creek Diversion, 2009. Data obtained from de Graff (2013).

Anomoeoneis spp. and *Diatoma elongatum* were most abundant at stations in the RCD (Figure 6H-18). Data regarding the tolerance to mine-related disturbance of diatom species other than *A. minutissima* are generally sparse or lacking in the published literature.

7.0 BENTHIC INVERTEBRATE COMMUNITIES

7.1 Historical Data (to 2006)

Benthic invertebrate sampling was initiated in 1973 within the Rose-Anvil Creek basin and in 1975 within the Vangorda Creek basin. Table 6H-16 lists and describes the investigations completed. Figures 6H-19 and 6H-20 illustrate the sampling locations.

From 1991 until 2008, benthic invertebrate communities were monitored at standardized locations every second year (alternating between Rose and Vangorda Creeks), as per the requirements of FMC Water Licences. Artificial substrates (rock baskets) were used for the majority of studies, providing some consistency across much of the data set, although studies varied in terms of factors such as numbers of replicate samples and levels of taxonomic identification. Statistical analyses of data from studies conducted in Rose Creek downstream of the Faro Mine Area (e.g., R2-R4; Figures 6H-19 and 6H-20) in 2000, 2002, 2004 and 2006 indicated some differences in community characteristics compared to reference communities (e.g., R6, R7 and minimally impacted R1) (Minnow 2007). Similarly, data from 2001, 2003, and 2005 surveys of Vangorda Creek also revealed significant differences in benthic community composition between the reference station V1 and exposed station V27. However, the community differences between mine-exposed and reference communities in both the Rose Creek and Vangorda Creek basins did not appear to be mine-related, based on higher proportions of Ephemeroptera-Plecoptera-Tricoptera (EPT) and lower proportions of chironomids at some mine-exposed areas, which are patterns generally indicative of a different or improved habitat rather than a deleterious effect. Overall, the data indicated that temporal variability played as large a role as relative station location in structuring benthic communities sampled by artificial substrates in Rose Creek and Vangorda Creek (Minnow 2007). This may be because invertebrate communities have a relatively short window of time for colonization on artificial substrates (e.g., 6-8 weeks), and may be particularly affected (compared to organisms on natural substrate) by inter-annual variations in environmental factors such as water flow and temperature during the substrate deployment period.

7.2 Recent Surveys (2007-2010)

Benthic invertebrate surveys were conducted at the FMC in 2007 (Vangorda Creek) (Laberge 2007; Minnow 2009), 2008 (Rose Creek) (Laberge 2009; Minnow 2009), 2009 (Rose Creek) (de Graff 2013), and 2010 (Rose Creek and Vangorda Creek) (Laberge 2011). The results of each study are briefly summarized below.

Table 6H-16: Summary of sampling locations and methods associated with historical benthic invertebrate community assessments, 1973-2010.

Reference	Year Sampled	Stations	Sampler	Replicates/ station	Replicate Samples or Data Composited?	Incubation or Collection Dates	Mesh Size	Lowest Level of Taxonomy

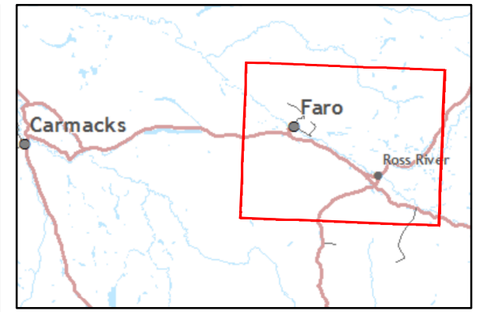
Faro Mine Interim Works



Minnow Project No.: 2499 Date: February 2014

CH2MHILL

C:\WORKSPACE\PROJECTS\FARO\FAROMAPSERVICES\FAROFIGURESTANDARD\CH2M_FARO_MAPSERVICE_11X17_LANDSCAPE.MXD MWHITE5 11/29/2012 12:05:14 PM

Using 2007 and 2008 survey data, Minnow (2009) compared results for three different benthic invertebrate community sampling methods (artificial substrates, Hess sampling, and kick net sampling) and two different sampling designs (discussed below) to determine the approach that would be most sensitive for detecting mine-related effects on benthic invertebrate communities in long-term monitoring at the FMC (Minnow 2009). Samples were collected from Vangorda Creek stations V27 (upper main stem), V5 (West Vangorda Creek), and V8 (lower Vangorda Creek), as well as Rose Creek stations X2 (NFRC upstream from Access Road) and R2 (downstream from Faro Mine Area). An additional 12 reference areas within and outside of the Rose Creek and Vangorda Creek watersheds were sampled. Community endpoints included abundance, number of taxa (identified to lowest practical level), percent dominant taxa, Simpson's diversity and evenness, and community structure as defined by correspondence analysis. Benthic community studies based on artificial substrates were concluded to be less sensitive for statistically detecting differences between mine-exposed and reference communities than sampling of resident communities from natural substrates using Hess or kick net methods. Using a traditional control-impact (CI) sampling design (Analysis of Variance [ANOVA] and pre-planned reference-exposure contrasts), Hess and kick samples produced the same number of significant reference-exposure differences among community endpoints, but the significantly different community endpoints differed between sampling methods. Using a reference condition approach sampling design (Bailey et al. 2004), the kick sampling method was slightly more sensitive at detecting benthic invertebrate community differences between mine-exposed and reference areas than the Hess sampling method and was recommended as the most cost-effective approach for long-term monitoring at the FMC. Taken together, the 2007 and 2008 data suggested that there were subtle, mine-related effects on benthic invertebrate community characteristics at X2 and V27, but neither these nor any of the other mine-exposed areas that were evaluated had community characteristics that were statistically conclusive with respect to being outside the range of reference area variability.

In 2009, de Graff (2013) sampled benthic invertebrate communities at stations along the NFRC and RCD using a kick net. Community metrics that were reported included taxonomic richness, Shannon-Weiner diversity index, number of EPT taxa and percent dominant taxa (Attachment Table F.1). However, the data were not evaluated based on these endpoints; instead community health was assessed using Environment Canada's web-portal known as the Canadian Aquatic Biomonitoring Network (CABIN) (Environment Canada 2013b). CABIN allows users to input benthic invertebrate data from areas of concern and, where available, to use regional models to compare community structure

against a suite of reference areas. Such models evaluate the invertebrate community at a test area by comparing it to communities at a group of reference areas using 3-dimensional nonmetric multidimensional scaling ordination The test area is considered divergent from the reference condition if its invertebrate community ordination scores cause it to fall outside of the 99% confidence ellipse in any one of three possible axis pairings.

All of the FMC communities sampled by de Graff (2013) were compared against the Yukon Reference Model January 2010 (Bailey and Reynoldson 2010). All mine-exposed stations were predicted to belong to Reference Group 4 of the territory-wide model. Reference Group 4 includes invertebrate communities sampled from 83 Yukon reference streams between 2004 and 2009; therefore, the reference group incorporates a potentially large amount of temporal and spatial variability that may have confounded the evaluation of communities at the FMC. All of the FMC stations were identified by the model as being within the reference condition, except for three located along the lower NFRC, of which only one (NF1-2; NFRC just downstream from the Access Road) was conclusively different from the reference group (two others were considered "somewhat" divergent from reference meaning results were inconclusive). The community at NF1-2 has not been sampled in other recent studies, but the de Graff (2013) location NF2-1, NFRC just upstream from the Access Road, generally corresponds with location X2 that was also sampled in 2008 (Laberge 2009; Minnow 2009). Results from the different studies were in agreement for the latter location, with de Graff (2013) concluding that the community at NF2-1 was within reference condition, and Minnow (2009) concluding that the community was only subtly different from the reference condition.

The most recent study, conducted in 2010 (Laberge 2011), also used kick nets to sample benthic invertebrate communities and considered community endpoints such as species and taxon richnesses, sample abundance, percent EPT, and percent chironomids (midges). Although results for reference and mine-exposed communities were not statistically compared, the study concluded that there was evidence of some impairment at the mine-exposed areas on Rose Creek (X2 and R2), with full community recovery evident downstream on Rose Creek at R4 (just upstream of the Anvil Creek confluence).

For this baseline characterization, data from the 2008 survey (Minnow 2009) were re-analyzed, along with the 2010 data (Laberge 2011), by comparing communities in each mine-exposed area to the range of community characteristics associated with the seven reference areas that were common to both studies, using the same statistical methods as those of Minnow (2009). Key community characteristics for reference and exposure

stations sampled in 2008 and 2010 are presented in Table 6H-17 and Figure 6H-21. EPT and chironomidae (midges) comprised the majority of taxa in all communities but relative proportions varied among areas and between years (Table 6H-17; Figure 6H-21; Attachment Tables F.2 and F.3). Data from both years indicated that communities at X2 (NFRC upstream of the Access Road), R2 (Rose Creek downstream from the Faro Mine Area), and V8 (lower Vangorda Creek; Figure 6H-19) were within or only slightly different from the reference condition based on all community characteristics examined (Attachment Tables F.4 and F.5).

In summary, benthic invertebrate surveys conducted in 2007, 2008, 2009, and 2010 indicated that most benthic invertebrate communities in streams adjacent to and downstream from mine-related disturbances at the FMC were similar to communities in reference areas uninfluenced by mining. Exceptions were communities along lower NFRC and in Rose Creek immediately downstream from the Faro Mine Area where modest differences from reference communities were evident in some studies.

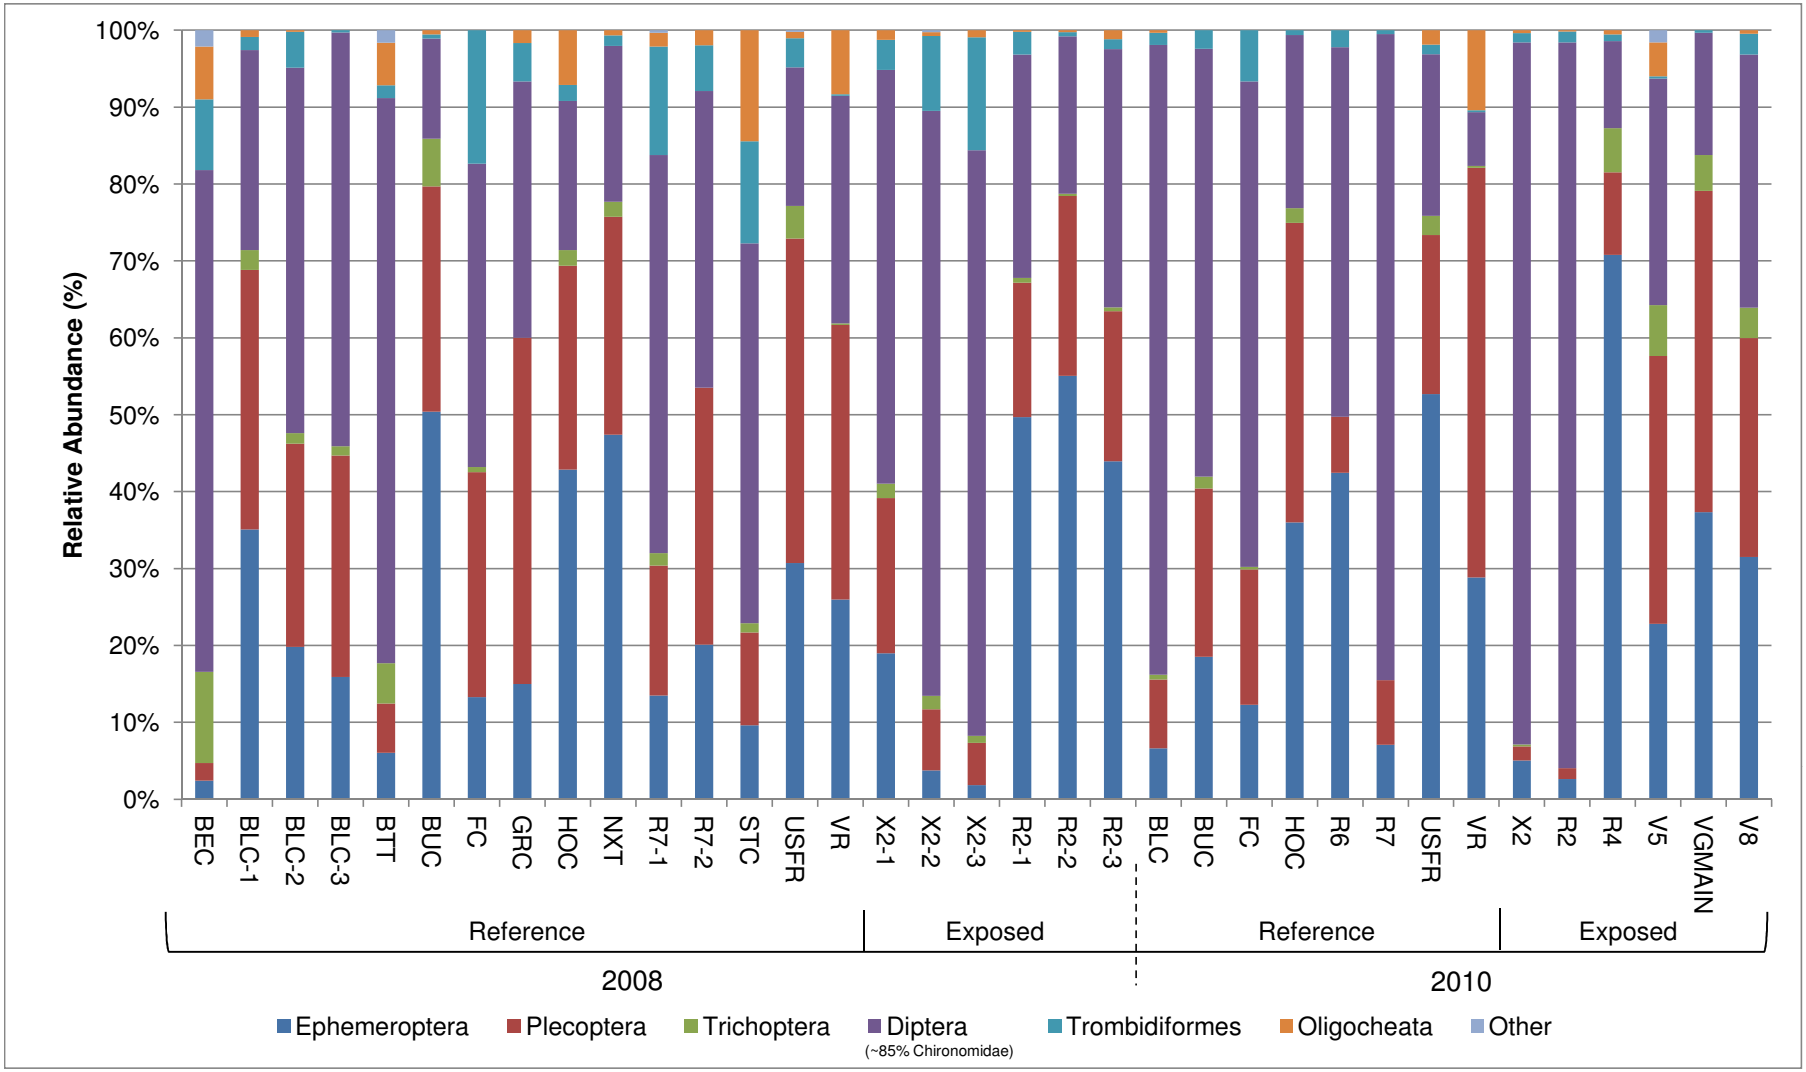

Figure 6H-21: Community composition of all stations sampled in 2008 and 2010 using the CABIN kick sampling method.

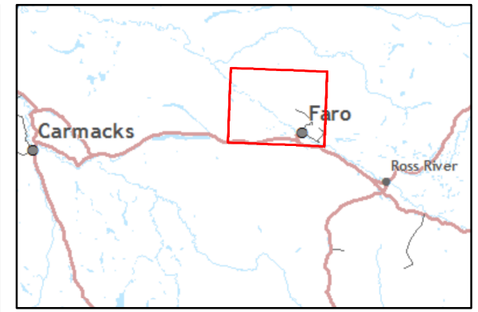
8.0 FISH

8.1 Community



Fish community characteristics were characterized from data presented in historical reports, with detailed records from individual reports presented in Attachment G. The data are summarized in Table 6H-18 and below for the stream reaches identified in Figure 6H-22, for which habitat was previously described (Section 3.0).

8.1.1 Rose Creek and Anvil Creek

Construction of the rock drain supporting the Haul Road has isolated fish in the upper reach of NFRC from the rest of the Rose Creek and Anvil Creek systems. Arctic grayling (*Thymallus arcticus*), slimy sculpin (*Cottus cognatus*), burbot (*Lota lota*), round whitefish (*Prosopium cylindraceum*) and longnose sucker (*Catostomus catostomus*) have been reported within this reach (Table 6H-18). Slimy sculpin were the most abundant species collected upstream of the Haul Road in both 2005 (upstream from Faro Creek Diversion, WMEC 2005b) and in 2009 (downstream from Faro Creek Diversion, de Graff 2013). Very few burbot and round whitefish have been observed and, were only found in the upper reaches of the NFRC (WMEC 2005b). Few arctic grayling were captured upstream from the Haul Road in August and October 2009 (de Graff 2013) and September 2012 (EDI 2013a), though numerous individuals were captured or observed in the pond immediately upstream from the Haul Road in August 2005 (WMEC 2005b). The pond appears to provide important over-wintering habitat for grayling because the water does not freeze to the bottom in the winter (EDI 2013b, WMEC 2005a). Potential grayling spawning habitats in the upper reaches of the NFRC include the mouth of the same pond, and near the ponded areas in the headwaters (WMEC 2005b).

Arctic grayling, slimy sculpin, burbot and round whitefish have been reported in the NFRC downstream from the Haul Road (Table 6H-18). Slimy sculpin were the most abundant species within this reach, though numerous arctic grayling were also present, mostly in close proximity to the Haul Road rock drain, near water monitoring station X3 and within the RCD (WMEC 2005, de Graff 2013, EDI 2013b). Arctic grayling spawning and spawning habitat have been reported in the NFRC downstream from the Haul Road and in the constructed ponds just upstream of the confluence with SFRC (EDI 2013a, WMEC 2005b).

[a] AECOM 2009. No data records provided.

Similar to the NFRC, the fish populations of the upper reach of SFRC have been separated from those in the rest of the system, due to culverts at both the Access Road and the Haul Road, and a steep gradient upstream from the Haul Road, that prevent the upstream migration of fish (GLL 2003, de Graff 2013). Arctic grayling and slimy sculpin were the only species captured upstream from the Haul Road in past studies (Table 6H-18). Although slimy sculpin have not been captured since 1989 (Attachment Table G.1), the section immediately upstream of the Haul Road has only been fished once since then (Minnow and WMEC 2009), and only arctic grayling were targeted in 2012 in and near Dixon Lake (EDI 2013a). Limited numbers of arctic grayling were captured in Dixon Lake and immediately downstream in 2012 (EDI 2013a) and also upstream from the Haul Road in 2008 (Minnow and WMEC 2009). Within the section of SFRC between the Access Road and the confluence with the NFRC, arctic grayling, juvenile Chinook salmon (*Oncorhynchus tshawytscha*), slimy sculpin, burbot and round whitefish have been captured or observed (Table 6H-18). Slimy sculpin was the most abundant species captured, followed by arctic grayling (AECOM 2009). Arctic grayling spawning has been observed in the Pumphouse Pond located at the confluence of the NFRC and SFRC (WMEC 2005b). The observation of juvenile Chinook salmon by WMEC in 2004 (WMEC 2005c) is the only reported occurrence of Chinook salmon upstream from the RCD. A pair of Chinook salmon were observed spawning within the RCD in 2009 by WMEC (Minnow 2010).

Arctic grayling movements within the Anvil and Rose Creek systems were recently characterized using radio telemetry (EDI 2013b). The study determined that some arctic grayling migrate downstream to the Pelly River to overwinter, while others overwinter in the RCD and NFRC. In the latter case, overwintering fish were observed both immediately upstream and downstream from the Haul Road. Upstream migration through the RCD in the spring was also confirmed by tracking a fish from Rose Creek downstream from the Faro Mine Area to the Pumphouse Pond, confirming fish passage can occur through the high-gradient portion of the lower RCD.

Downstream from the FMC, arctic grayling, juvenile Chinook salmon, slimy sculpin, burbot, round whitefish and longnose sucker have been observed or captured (Table 6H-18). The most abundant species below the Faro Mine Area was slimy sculpin, though numerous juvenile Chinook salmon were captured at R2 in 2004 using minnow traps (WMEC 2005c). The same species have been observed or captured in the lower reaches of Anvil Creek downstream from Rose Creek, as well as lake chub (*Couesius plumbeus*), which were captured near the mouth (Access et al. 2006). A study of Chinook spawning

by WMEC in Anvil Creek and the Pelly River suggested Anvil Creek typically has low numbers of spawners (WMEC 2010a). The Rose-Anvil Creek system has been identified as having moderate to low suitability for Chinook salmon spawning, with some habitat suitable for rearing juvenile Chinook salmon, although utilization may be limited at times due to environmental factors or conditions (Yukon Placer Secretariat 2010). Blind Creek, an adjacent watershed located further up the Pelly River, has high suitability for Chinook salmon spawning, providing spawning habitat, and critical migratory corridors required to access spawning habitat (Yukon Placer Secretariat 2010).

8.1.2 Vangorda Creek

An 8-m waterfall located approximately 3 km upstream from the mouth of Vangorda Creek, and a culvert under the Access Road on the west fork, represent barriers to upstream fish migration (Figure 6H-22). Consequently, no fish have been reported in upstream reaches of Vangorda Creek (RGC 1996, Minnow 2009). Within the lower portion of Vangorda Creek, arctic grayling, juvenile Chinook salmon, slimy sculpin, burbot, round whitefish, longnose sucker and lake chub have all been identified (Table 6H-18). The most abundant species in this reach has been juvenile Chinook salmon, though the number captured varies greatly between years (WMEC 2005c, WMEC 2008). The lower portion of Vangorda Creek has been identified as having moderate suitability for Chinook salmon, defined as habitats that are suitable for rearing juvenile Chinook salmon (Yukon Placer Secretariat 2010). High numbers of juvenile Chinook salmon have been reported during spring and summer months in lower Vangorda Creek, likely moving in from both Blind Creek and the Pelly River for the summer months before moving to overwintering or migratory habitats in the fall.

8.2 Tissue Metals

Fish tissues were periodically sampled from Rose, Anvil, Vangorda, and Blind creek areas between 1975 and 2005. Data include metals in muscle and liver collected from arctic grayling and in whole bodies of slimy sculpin (results are provided in Attachment Tables G.2 to G.4). Concentrations have occasionally been slightly elevated in fish collected near the FMC compared to fish collected in reference areas or farther downstream.

9.0 SUMMARY

Habitat

The FMC occupies portions of both the Rose Creek and Vangorda Creek watersheds. Both creeks are tributaries to the Pelly River, which is a major tributary to the Yukon River. Several physical alterations to stream courses have occurred over time around the FMC to accommodate mine features; these include several stream diversions and numerous road crossings, with some of the latter resulting in barriers to fish passage. Common features among most reaches of the Rose-Anvil Creek and lower Vangorda Creek system include boulder and cobble substrate, with boulders and pools providing in-stream cover for fish.

Water Quality

Water quality data for the FMC between 2008 and 2012 indicate that concentrations of a variety of non-metals and metals are elevated in surface waters relative to the typical range of background (reference station) concentrations. Alkalinity, conductivity, hardness, sulphate, total dissolved solids, calcium, cobalt, magnesium, nickel, sodium, strontium, and zinc occur at concentrations above the background range in approximately half or more of samples collected downstream of the Vangorda/Grum Area (V8) and the Faro Mine Area (X14). Concentrations of non-metal analytes are below those expected to have adverse effects on aquatic biota.

Metal concentrations in lower Vangorda Creek (V8) rarely (≤ 15% of samples) exceed guidelines for protection of aquatic life and median concentrations are usually less than half the guideline values. Water concentrations of several metals (cadmium, cobalt, iron, lead, manganese, zinc) are above guidelines in up to one-quarter of samples collected at NF1, on the North Fork Rose Creek (NFRC) upstream from the Haul Road, but zinc is the only mine-related metal that exceeds guidelines at stations between NF1 and Rose Creek station X14, just downstream of the Faro Mine Area. Cobalt and manganese are also found at concentrations above water quality guidelines for protection of aquatic life in up to 40% of samples collected at X14, but median concentrations for all metals but zinc are below the guidelines. Water quality guidelines are infrequently exceeded at stations farther downstream in Rose Creek (R4) and Anvil Creek (A1) indicating that mine related effects on biota, if any, are likely localized around the Faro Mine Area. Mine-related effects on water quality do not extend into the Pelly River.

Sediment Quality

Arsenic, lead, manganese, and zinc concentrations tend to be elevated in sediment samples collected at mine-exposed areas relative to sediment quality guidelines. However, the survival and growth of the invertebrate *Hyalella azteca* were not affected in 14-day laboratory tests of sediments collected from mine-exposed areas. Mine-related contaminants tend to be associated with fine sediment particles; however the aquatic environments around and downstream from the FMC are typically moderately to swiftly flowing, with sediments composed of particles that are mainly sand-sized or larger. Therefore, sediment exposure to mine-related contaminants represents a relatively minor pathway for potential effects to aquatic biota to mine-related contaminants.

Periphyton

Periphyton communities were characterized in 2009 along the NFRC and the RCD. The group of photosynthetic bacteria known as Cyanophyta dominated the communities in the NFRC just downstream from the confluence with the Faro Creek Diversion, but a shift to diatom (Bacillariophyceae)-dominated communities occurred closer to the Haul Road and continued downstream throughout the RCD. *Achnanthes minutissima* made up roughly 44% (4 – 72%) of the diatom assemblage at all stations and was more abundant downstream than upstream of mine-related influences. *Achnanthes*, especially *A. minutissima*, is generally considered tolerant of a wide variety of environmental conditions and, in other studies, has been observed in streams affected by mining or metals. Data regarding the tolerance to mine-related disturbance of diatom species other than *A. minutissima* are generally sparse or lacking in the published literature.

Benthic Invertebrate Communities

Benthic invertebrate surveys conducted annually between 2007 and 2010 indicated that communities are dominated by organisms in the mayfly (Ephemeroptera), stonefly (Plecoptera), and caddisfly (Trichoptera) groups, as well as midges (chironomids). Most communities in streams adjacent to and downstream from mine-related disturbances at the FMC are similar to communities in local reference areas uninfluenced by mining. Exceptions are communities along lower NFRC and in Rose Creek immediately downstream from the Faro Mine Area where modest differences from reference communities have been evident in some studies.

Fish

Slimy sculpin (*Cottus cognatus*), Arctic grayling (*Thymallus arcticus*), Chinook salmon (*Oncorhynchus tshawytscha*), burbot (*Lota lota*), round whitefish (*Prosopium cylindraceum*) and longnose sucker (*Catostomus catostomus*) have been reported in surface waters around and downstream from the FMC. Within the Rose-Anvil Creek system, slimy sculpin tend to be most abundant, followed by Arctic grayling. Both species appear to utilize surface waters around the Faro Mine Area year-round, although some Arctic grayling migrate to the Pelly River for overwintering. Although juvenile Chinook salmon have occasionally been observed in the Rose Creek system near the FMC, the Rose-Anvil Creek system has been classified as having low to moderate suitability for Chinook salmon spawning and adults have rarely been observed in surface waters around the FMC. Blind Creek, to the east of Vangorda Creek, is a local stream that provides more important habitat for salmon. Downstream of the Vangorda/Grum Area, in lower Vangorda Creek, juvenile Chinook salmon are typically the most abundant fish because this area provides valuable rearing habitat for juveniles that move in from the Pelly River and other tributaries.

Culverts and rock drains associated with road crossings have isolated fish populations in upper NFRC and upper South Fork Rose Creek from populations in the rest of the Rose-Anvil Creek system. Also, a culvert on West Vangorda Creek and a waterfall on the main stem of Vangorda Creek have prevented upstream migration so that fish are only found in the lower reach of Vangorda Creek.

	Open	100	90	40	85 (75 - 100)	85 (75 - 95)	15 (0 - 25)	70 (35 - 95)
Riparian Vegetation Types	descending dominance	willow, scattered black poplar, cinqfoil, some dwarf birch	willow, scattered poplar, then spruce	spruce, willow, black poplar	willow , moss, spruce, dwarf birch, berry shrubs, cinqfoil, rip-rap	willow, grasses, alder, moss, cinqfoil, equisetum, spruce	alder, willow, moss, equisetum, highbush cranberry, poplar, grass	alder, willow , grasses, poplar, forbs, berry shrubs, spruce, moss
Aquatic Vegetation (% areal coverage)	Emergent	0	0	0	0	0	0	0
	Submergent	0	0	0	0	0	0	0
	Floating	0	0	0	0	0	0	0
	Attached Algae	< 5	< 5	< 1	<10	0	0	0
Surrounding Land Use		U/S of old gravel pit haul road	Haul Road ~30m D/S of site	old gravel pit haul road	U/S mine road; forest	none; mature forest	forest	bridges/road crossings
Evidence of Anthropogenic Disturbance		modified channel, likely to ensure flow to culvert	none	culverts, pushed around substrate	rip-rap & metal culverts	none	none	bridges/road crossings
General Comments/Notes		Stream channel much smaller & shallower than Vangorda but substrate is comparable, in spots, to lower Vangorda. First sample taken 22m U/S of culvert, with next 2 samples taken U/S of that.	Assessed a very small portion of the stream, afterwhich the gradient was steeper with larger boulders. Mayflies noted when shocking. Conductivity will not calibrate, used Hanna meter instead. Site is more a pool/step kind of habitat with an increasing gradient that becomes a canyon type environment.	Sampled D/S of culverts. Loosely compacted substrate. U/S of road has alot of moss, channel narrows to < 9m. Small woody debris and some overhanging willow. LWD up on banks indicating Hgh water mark/flow.	Most sites have some orange fuzzy moss on rocks	Some sites in valley with access down steep hills	Lots of fines and small gravel making Hess sampling difficult	

[a] Numbers provided represent mean values with numbers in parenthesis representing the corresponding range for each respective description.

[b] Morphology type based on Rosgen (1994) classification. B= moderately entrenched, moderate-gradient, riffle-dominated channel with infrequently spaced pools, very stable plan and profile, stable banks; C= low-gradient, meandering, alluvial riffle-pool, channels with point-bars, broad, well-defined floodplains E= low-gradient, meandering, riffle/pool stream with low width:depth ratio and little deposition, very efficient and stable, high meander width ratio; G= entrenched, "gully" step-pool channel, on moderate gradients, with low width:depth ratio

Comments			Very bouldery substrate, difficult to kick net		Flow measured at X-14	No discharge data etc as creek too pushy to safely wade.			Substrate has a lot of moss on it					

There were no matches for VR and USFR. VR is a small stream with very soft water and is unlike any of the exposed sites. USFR is a steep sloped stream also with very soft water. Although it has some similar attributes with V5 and X2, it likely does not represent a very useful reference site. FC was indicated as the second best match for X2. FC is a small creek located at a much higher elevation and has extremely soft water. The substrate at X2, mostly cobbles and boulders, is

HABITAT INFORMATION FROM

WMEC (2008)

APPENDIX 1
GENERAL SITE DESCRIPTIONS

SITE: R1 Rose Creek

UTM: Down stream end 05 83 739 E, 69 12 390 N
Site Location: reach starts 10 meters upstream of the confluence of the north and south forks of Rose Creek and extends upstream for 110 meters.
Date Sampled: August 17 and 18, 2004, August 13 and 14, 2005
August 16 and 17, 2006, August 14 and 15, 2007
August 16 and 17, 2008

CHANNEL CHARACTERISTICS:

Surveyed Length:	3000 m
Average Channel Width:	4 meters
Average Wetted Width:	4 meters
Average Depth:	0.4 meters
Average Velocity	1.5 meters per second
% Pool, Riffle, Run / Glide:	65% riffles through boulders, 25% run and 10% small boulder and side pools
Cover	Dominant cover is boulder pools and perched boulders
Overhead vegetation	10% overhanging
Riparian Vegetation	Willow, dwarf birch, cinquefoil, with spruce adjacent

BED MATERIAL:

70% boulder, 20% cobble, 5% gravel, 5% sand with occasional bedrock outcrop in lower part of reach

BANK CHARACTERISTICS: Well defined channel with bedrock confining the channel on the left bank, the right bank has an open flood plain above an abrupt bank rise of 0.4 meters.

CHANNEL MORPHOLOGY CHARACTERISTICS: Uniform channel with a mostly flat bottom, some contour is provided by small pools near submerged bedrock along the left bank and boulders causing small cascades. A small island exists at the top of the reach. Flows within the South Fork of Rose Creek at site R1 in 2008 were similar to those of 2006. A long riffling run that extends approximately 800 meters upstream of the sample station was used as a collection area for angling Arctic grayling; this reach has similar morphology to the sample area although with more small pools and less velocity.

Photo 1: Rose Creek looking upstream at Site R1 from the bottom of the sample reach, 2008. The North Fork of Rose Creek enters on the left of the photo.

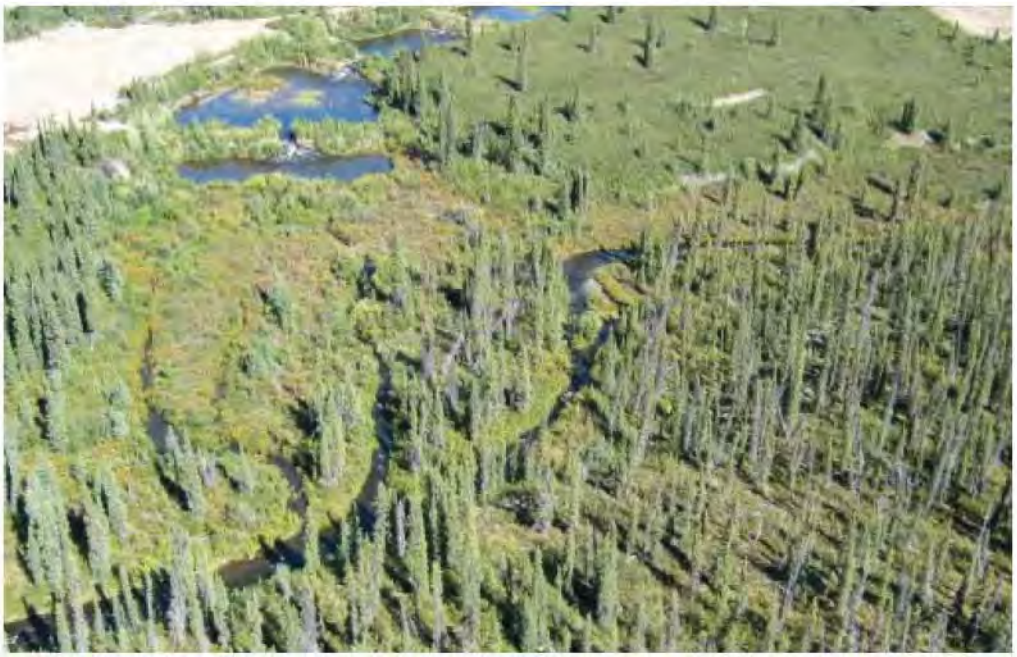

Photo 2: Ariel view of site R1 (on right) and the confluence with North Fork Rose Creek, 2007. The sample reach extends from the confluence to just below the first bend of the creek in the centre of the photo.

Source: WMEC 2008

SITE: R2 Rose Creek

UTM: down stream end 05 79 401 E, 69 14 972 N
Site Location: reach starts at the confluence of the tailing pond discharge channel with Rose Creek and extends downstream for 110 meters through the mix water zone.
Date Sampled: August 18 and 19, 2004 August 15 and 16, 2005
August 15 and 16, 2006 August 14 and 15, 2007
August 16 and 17, 2008

CHANNEL CHARACTERISTICS:

Surveyed Length:	110 meters
Average Channel Width:	14 meters
Average Wetted Width:	12 meters
Average Depth:	0.7 meters
Average Velocity	0.8 meters per second
% Pool, Riffle, Run / Glide:	30% pool, 30% riffle, 40% glide
Cover	Large woody debri, undercut banks and deep pools
Overhead vegetation	No overhead vegetation
Riparian Vegetation	Willow, dwarf birch and dead spruce

BED MATERIAL:

30% cobble, 50% gravel, 20% sand with sand and gravel increasing in deeper pools and exposed point bars mostly sand and gravel.

BANK CHARACTERISTICS: Sand and gravel point bars opposite of mud cut banks that rise 1.5 to 2.5 meters to an open flood plain.

CHANNEL MORPHOLOGY CHARACTERISTICS: Meandering channel with corner pools, small riffles and point bars adjacent to cut banks. Water levels in 2008 were similar to, 2006 and approximately 0.3 meters lower than the highest flows experienced in 2005.

Photo 3: The tailings pond discharge channel entering Rose Creek at the upstream end of the sample reach site R2 during August, 2008.

Photo 4: Site R2, Rose Creek. The downstream end of the diversion channel flows in to the photo from the right upstream of the out flow of treated water and the sample site. August 2007.

Source: WMEC 2008

SITE: R4 Rose Creek

UTM: down stream end 05 67 827 E, 69 21 736 N
Site Location: reach starts 80 meters upstream of the confluence of Rose Creek and Anvil Creek and extends upstream for 110 meters.
Date Sampled: August 12, 2004 August 17 and 18, 2005
August 16 and 17, 2006, August 17 and 18, 2007
August 19, 2008

CHANNEL CHARACTERISTICS:

Surveyed Length:	130 meters
Average Channel Width:	20 meters
Average Wetted Width:	14.5 meters
Average Depth:	0.5 meters
Average Velocity	> 1.0 meters per second
% Pool, Riffle, Run / Glide:	60% riffle, 15% boulder pool and 25% run
Cover	Boulder pools and overhead vegetation
Overhead vegetation	20% coverage
Riparian Vegetation	Alder and willow with spruce behind

BED MATERIAL:

5% large boulder, 20% boulder, 30% cobble, 40% gravel, 5% sand.

BANK CHARACTERISTICS: Open flood plain with gentle rise adjacent to well defined stepped banks that rise to a maximum of 2 meters to an open flood plain.

CHANNEL MORPHOLOGY CHARACTERISTICS: Mostly flat channel with one side typically deeper than the opposite side. Some exposed large boulders and a large side pool exists near the bottom of the reach. Water levels in 2008 were slightly higher than those of 2007 and similar to those of 2006.

Source: WMEC 2008

Photo 5: Rose Creek at site R4 during August of 2008. Water levels are slightly higher than in 2007 and similar to those of 2006.

Source: WMEC 2008

SITE: R6 Anvil Creek

UTM: down stream end 05 67 917 E, 69 21 804 N
Site Location: reach starts 100 meters upstream of the confluence of Anvil Creek with Rose Creek and extends upstream a further 100 meters.
Date Sampled: August 12, 2004
August 17 and 18, 2005

Anvil Creek just upstream of the confluence with Rose Creek (control site).
This reach is located at and begins 150 meters upstream of the confluence and then extends upstream for 100 meters. This site has not been sampled for fish since 2005 due to impracticalities with flow conditions. Site R6A, 500 meters upstream on Anvil Creek was established in 2006 as an alternate site for fish and benthic collections.

CHANNEL CHARACTERISTICS:

Surveyed Length:	100 meters
Average Channel Width:	15 meters
Average Wetted Width:	14 meters
Average Depth:	0.4 meters
Average Velocity	1.5 meters per second
% Pool, Riffle, Run / Glide:	15% rapid, 45% riffle, 20% run, 20% boulder pool
Cover	Turbulence, perched boulders and cobbles, and limited undercut and cut banks.
Overhead vegetation	< 5% cover
Riparian Vegetation	Willow with a sedge fringe and spruce adjacent

BED MATERIAL:

5% large boulder, 50% small boulder, 30% cobble, 15% sand

BANK CHARACTERISTICS: Well defined and stable banks rise to even 2 meter height on 50% slope.

CHANNEL MORPHOLOGY CHARACTERISTICS: Channel mostly flat but the mid channel areas are elevated with deep flows occurring towards the banks. Water levels in Anvil Creek were 0.5 meters deeper during 2005 investigations than those of 2004 and 0.2 meters higher again in 2006. This site has not been sampled since 2005.

Source: WMEC 2008

Photo 6: Looking upstream to the top of the sample reach at site R6, from the edge of the confluence with Rose Creek, 2005.

SITE: R6A Anvil Creek

UTM: down stream end 05 68 768 E, 69 21 412 N
Site Location: reach starts 1.35 km by creek channel (800 meters direct) upstream of the confluence of Anvil Creek with Rose Creek and extends upstream a further 100 meters.
Date Sampled: August 16 and 17, 2006 August 17 and 18, 2007
August 19, 2008

Anvil Creek upstream of the confluence with Rose Creek (control site).

CHANNEL CHARACTERISTICS:

Surveyed Length:	130 meters
Average Channel Width:	14 meters
Average Wetted Width:	9 meters
Average Depth:	0.7 meters
Average Velocity	>1 meter per second
% Pool, Riffle, Run / Glide:	10% rapid, 15% riffle, 20% run, 40% race, 15% pool
Cover	Large boulders, pools and LOD and undercut bank.
Crown Closure	< 5% cover
Riparian Vegetation	Alder, spruce, willow mix with grasses, sedge and cinquefoil

BED MATERIAL:

80% small boulder, 15% cobble, 5% gravel, with sand deposits at downstream point bar.

Source: WMEC 2008

BANK CHARACTERISTICS: Consistent well defined and stable banks rise abruptly 0.7 to 1.0 meter height.

CHANNEL MORPHOLOGY CHARACTERISTICS: The channel is partially entrenched by a small hill on the upper right bank, becomes confined and deep centered before spreading to over 50 meters wide at a small side channel in the lower portion of the reach on the right bank. The reach ends with a shoot rapid entering a deep corner pool with undercut banks.

Photo 7: Reach R6a sample site, flowing right to left. August, 2008. The corner pool in the lower end of the reach is the location used to capture Arctic grayling samples.

Source: WMEC 2008

SITE: B1 Blind Creek

UTM: down stream end 05 36 680 E, 68 96 005 N
Site Location: reach starts immediately upstream of the bridge and extends upstream for 100 meters; reaches below the bridge have been used for fish sample collections.
Date Sampled: August 14 and 15, 2004 August 19 and 20, 2005
August 18 and 19, 2006 August 17 and 18, 2007
August 19 and 20, 2008

CHANNEL CHARACTERISTICS:

Surveyed Length:	350 meters
Average Channel Width:	15.5 meters
Average Wetted Width:	14 meters
Average Depth:	0.7 meters
Average Velocity	0.4 meters per second
% Pool, Riffle, Run / Glide:	100% glide
Cover	Fine organic debris, cut banks (up to 40%), small woody debris against shore and a beaver lodge
Overhead vegetation	10% cover
Riparian Vegetation	Alder, willow with some spruce, with high bush cranberry, raspberry and cinquefoil adjacent

BED MATERIAL:

Sand silt and organic debris overlaying 60% cobble, 40% gravel.

BANK CHARACTERISTICS: Shallow point bars occur opposite of cut and eroding banks near gentle corners. Cut banks rise between 1 and 2 meters to an open flood plain.

CHANNEL MORPHOLOGY CHARACTERISTICS: Uniform channel with a deep side opposite of a side of deposition. Flows in Blind Creek were slightly higher in 2006 than during 2005 sampling which were very similar to those encountered during 2004.

Source: WMEC 2008

Photo 8: Collecting minnow traps in Blind Creek near the weir site during August of 2008.

SITE: V8 Vangorda Creek

UTM: down stream end 05 84 790 E, 69 00 606 N
Site Location: reach starts immediately upstream of a small foot bridge that crosses the creek at the site of the town of Faro sewage discharge pipe crossing and extends upstream for 100 meters
Date Sampled: August 14 and 15, 2004 August 17 and 18, 2005
August 17 and 18, 2006 August 15, 16, 17 and 23, 2007
August 17 and 18, 2008

CHANNEL CHARACTERISTICS:

Surveyed Length:	100 meters
Average Channel Width:	6.0 meters
Average Wetted Width:	3.3 meters
Average Depth:	0.5 meters
Average Velocity	1.5 meters per second
% Pool, Riffle, Run / Glide:	80% riffle (almost rapid), 20% eddy and side pools
Cover	Over head vegetation, large and small woody debri, flood washed shrubby vegetation and boulder pools
Overhead vegetation	20% cover
Riparian Vegetation	Alder and willow with occasional spruce and poplar

Source: WMEC 2008

BED MATERIAL: Exposed substrate consists of 50% boulder, 20% cobble, 15% gravel, 15% sand with occasional bedrock outcrop in upper part of reach. Most substrates loosely consolidated and highly silted. Creek channel was heavily modified by a high water event this season.

BANK CHARACTERISTICS: Well defined channel with newly eroded, but stable, banks that rise gently to a maximum of 2 meters. A small area of bedrock confines the channel on the left bank at the upstream end of the reach.

CHANNEL MORPHOLOGY CHARACTERISTICS: Very little meandering in an entrenched valley, unconsolidated materials from 2004 have been washed out and boulders protrude in most of the channel.

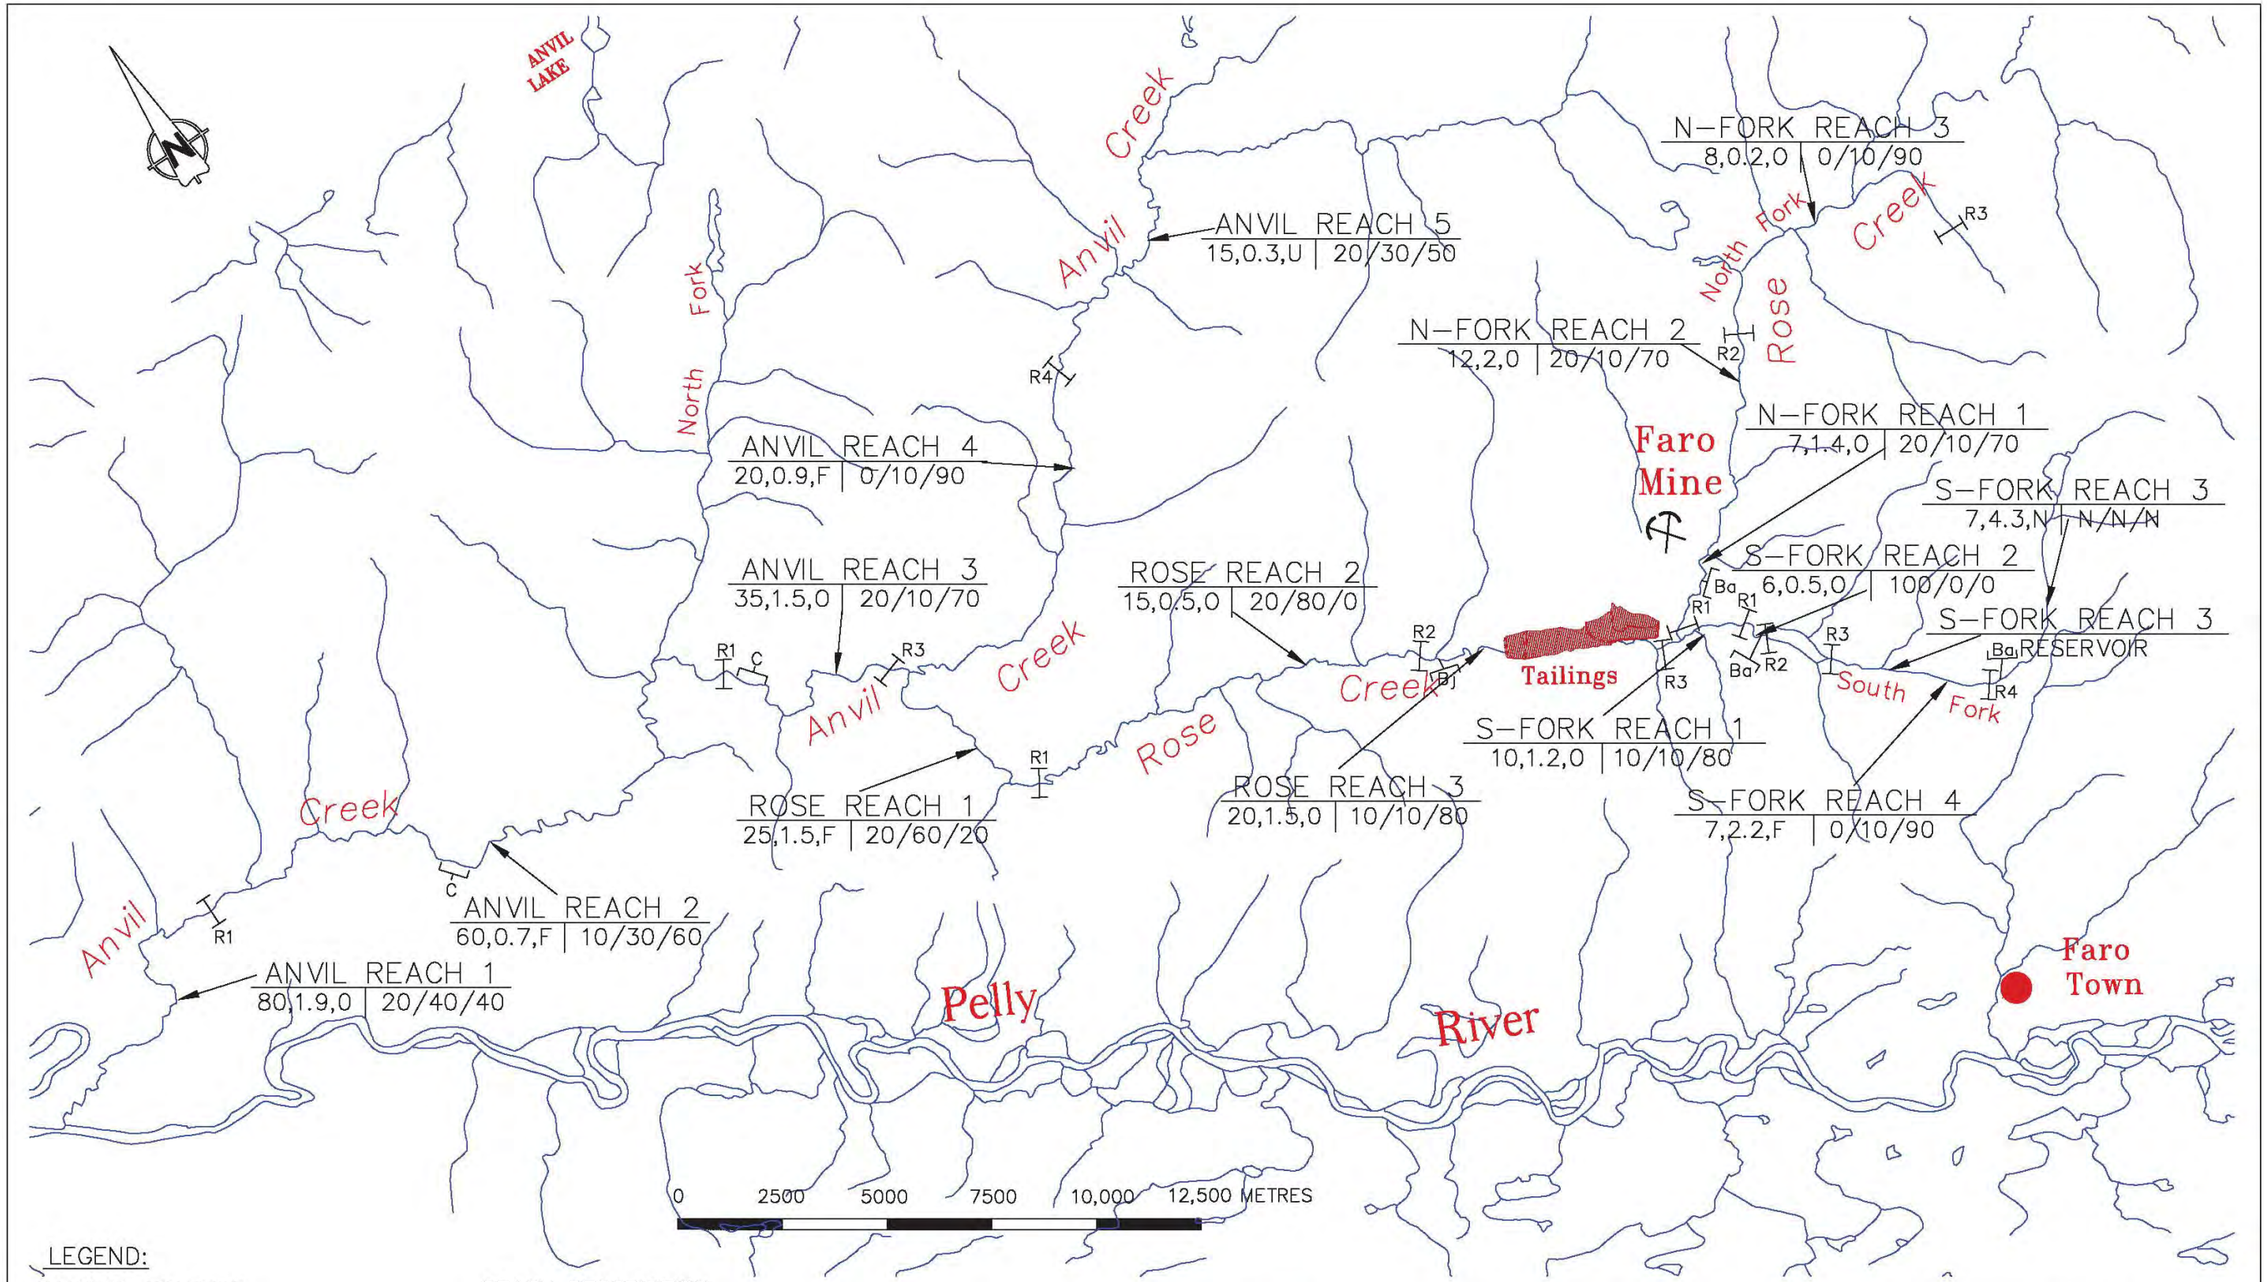

Photo 9: Rock slide at the upstream end of Vangorda Creek site V8 sample site during 2008. The materials that slid are surrounded by mineralized materials visible on the left side of the photo.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was at the 95th percentile of pooled reference station data; therefore the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics

Suspect value, excluded from summary statistics

Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Suspect value, retained in summary statistics
Suspect value, excluded from summary statistics
Value reported as below detection limit (DL) but DL was above water quality guideline, value was excluded from summary statistics
Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Tables 6H-1 and 6H-2 for information regarding the source, selection, and derivation of water quality criteria.

Value was reported as below detection limit (DL) but the DL was the maximum reported station value; therefore, the value was excluded from summary statistics

[a] values reported as less than the detection limit (DL) were used at 1/2 the DL for calculation

[b] Refer to Table 6H-3 for information regarding the source of drinking water quality guidelines

Figure C.1: Total versus dissolved iron at mine-exposed stations V8 and X14, 2008-2012.

ATTACHMENT D

SEDIMENT DATA

Table D.1: Rose-Anvil sediment chemistry data, mean values (n=3/area, unless otherwise noted) by year (1996 to 2008) for the 0.15mm fraction. Highlighted values exceeded Canadian Sediment Quality Guidelines.

[a] Qualitiative value is derived from a 'quick scan' of periphyton sample.

[b] Quantitative value is derived from actual cell counts from grided sample tray.

[c] Simpson's evenness is calculated on quantitative data only and is a value between 0 and 1, where 1 is an evenly dispersed population.

cP - probability metric value at exposure area is the same as the mean for reference areas.
ncP - probability metric value at exposure area is inside the range of reference values
Different from exposure mean (cP < 0.05) or range (ncP < 0.1).
Uncertain with respect to being similar to or different from reference (ncP 0.1 > p < 0.9).
Similar to reference mean (cP > 0.05) or within reference range (ncP < 0.9).

Table F.5: Benthic community characteristics of exposure areas sampled in 2010 relative to reference areas that were sampled in 2008 and 2010 (N = 7). Results are presented for traditional central (cP) t-tests and non-central (ncP) t-tests.
