- Table 2.5 below summarizes the operational conditions in terms of the liquid degree of saturation and corresponding air conductivity for the each of the non-agglomerated Casino samples under a nominal application rate of 10 L/h/m^2 (2.8 x10^{-4} cm/s). Also included in Table 2.5 is the threshold saturation (S*) for each of the samples. For this solution application rate:
    - The operational liquid saturation of the Casino samples is: 55% for Met 02-05, and 23.2% for the Met 11-17.
    - The operational degree of saturation is about the same as the saturation threshold for these composites which may limit the effectiveness of natural aeration (under irrigation rate of 10 L/h/m^2). A smaller irrigation rate will improve the natural aeration on these composites.
    - It is noted that the operational degree of saturation is basically the same as the threshold saturation value at which the air conductivity starts its rapid reduction – which indicates that any upset condition (strong precipitation, variability in the irrigation rate, increased level of fines, localized compaction, etc.) resulting in increased saturation would produce a marked reduction in the air conductivity**.** Empirical evidence shows that the rate of dissolution decreases by more than a factor of two as oxygen decreases by a factor of two.
    - Given the Au and Ag as well as the Cu grades, it is expected that the oxygen demand associated to cyanide leaching will be small. The available information indicates that aeration requirements may be larger for Met 11-17 given its higher Cu content than for composite Met 02-05.

Table 2.5 – Operational conditions at 10 L/h/m^2

Sample	S* (%)	S (%)	K_a (cm/s)
Met 02-05-L0	55.4	55.0	5.0 x 10^{-3}
Met 11-17-L0	22.0	23.2	4.5 x 10^{-1}

A couple of additional remarks arising from the HCT results are as follows:

- The degree of saturation resulting from the solution irrigation rate combined with the residual porosity presented above provide an estimate of the dynamic moisture for each sample for a given solution application rate. For instance, for a solution irrigation rate of 10 L/h/m^2 the dynamic moisture for Composite Met 02-15 is: 48 liters of solution per cubic meter of ore (L/m^3), and 32 L/m^3 for the coarser composite (**Met 11-17**).
- Industrial experience from many different ore types and various minerals shows that, in most instances, the hydrodynamic performance controls the metallurgical performance of a percolation leaching process. In this particular case, **it appears that the key considerations for the adequate leaching of the non-agglomerated Casino ore are:**
    - The permeability for Composite Met 02-05 or a blend thereof, and

- Effective solution-to-ore contact for Composite Met 11-17 if not blended.

Accurate numerical modeling of the solution and gas movement through a heap leach requires, as a minimum, knowledge of:

- The relationship between hydraulic conductivity and the degree of saturation (top frame of Figure 2.8),
- The relationship between the air conductivity and the degree of liquid saturation (bottom frame of Figure 2.8) – not critical for the Casino composites evaluated as part of this effort; and
- The relationship between degree of saturation and the pore pressure (Figure 2.9), known in the hydrological community as the moisture characteristic curve.

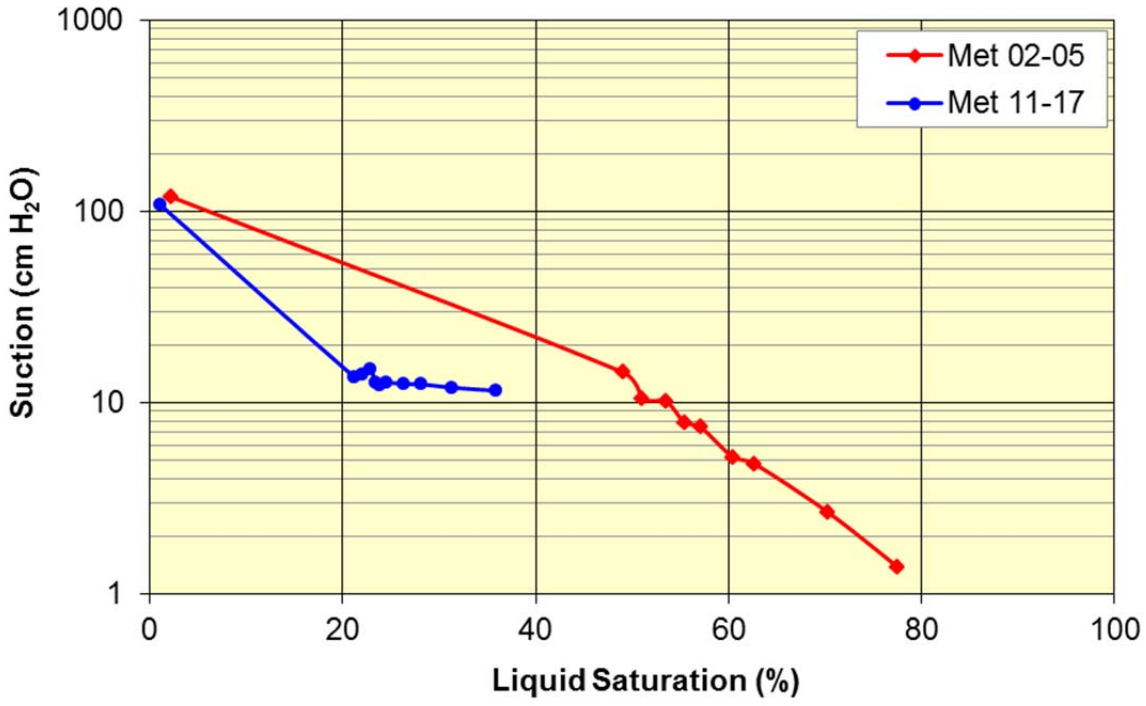

Figure 2.9 Casino – Moisture retention curve

It is noted that **the HCT is the only procedure that allows direct measurement of these properties concurrently and in a single sample in the context of multi-phase flow for the mining industry or otherwise.**

Because numerical analysis is not the focus of this characterization effort, the relationship between liquid saturation and pore pressure is not further discussed. However, it is worthwhile noting that the operational pore pressure for the Casino is 30 cm for Met 02-05 and about 12 cm for Met 11-17 at a solution application rate of 10 L/h/m^2. Availability of these data greatly facilitates modeling solution movement (wetting and draining) and reactive transport of the heap leach process.

3.0 PRELIMINARY METALLURGICAL PERFORMANCE

HGS continues to develop testing procedures for the optimal characterization of ore for leach. As part of this development, the HCT has been modified to included chemical testing of the feed and discharge solution to obtain a preliminary evaluation of the potential metallurgical performance of a sample. The resulting procedure is termed the Integrated Column Test (ICT) as it provides, for the first time in the history of leaching, all the hydrodynamic and critical metallurgical data on a single sample. It is our contention this integrated approach will greatly enhance our ability interpret the results of metallurgical tests, scale-up laboratory data, and build comprehensive numerical models of the leaching process.

The ICT procedure was applied to the Casino samples in order to generate a first estimate of metal extraction. Solution samples were collected and assayed for Au, Ag, Cu, NaCN and CaO in addition to the HCTs included on the original Scope of Work. It is noted, that this activity was undertaken as part of HGS development work therefore at no expense to WCG. As such, the results presented below are strictly preliminary and for information purpose only. It is noted however that the metallurgical data derived from the ICTs is in complete agreement with the conclusions derived from the physical, metallurgical, mineralogical and hydrodynamic characterization data presented in the above paragraphs.

The overall solution balance summarizing the metallurgical performance of composites Met 02-05 and Met 11-17 is presented in Figures 3.1 and 3.2, respectively. Table 3.1 presents the total metal recovery and reagent consumption. All the laboratory data and calculations of recovery could be made available to WCG in the future if necessary. The following paragraphs present a brief discussion of the more relevant findings from these data.

Table 3.1 – Preliminary metallurgical performance

	Recovery (%)			Consumption (kg/t)	
Sample ID	Au	Ag	Cu	NaCN	CaO
Met 02-05-L0	80.3	18.3	6.8	0.21	3.03
Met 11-17-L0	42.0	17.5	19.0	0.32	2.96

Inspection of the metal recovery and reagent consumption record for each of the composites indicates the following:

- As expected, Met 02-05 out performs the Au recovery of Met 11-17. It is noted that the Au recovery of Met 02-05 is quite fast (nearly 65% recovery in the first four days of operation) compared to that of Met 11-17 (25% recovery in seven days). The faster kinetics are likely associated to the finer size distribution of the former.
- The percent gold recovery for Met 02-05 is almost twice as high as that of Met 11-17 while the silver recovery for these composites is about the same (~18%).

- The last two days on the operation of the ICTs represent the flushing stage which in this particular case is shown to contribute about 10% of the Au recovery.
- It is noted, that copper extraction is higher in Met 11-17 (19.0% versus 6.8% in Met 02-05) which may explain the lower Au recovery of the former. Higher copper extraction can result in cyanide and oxygen consumption which tends to slow down the rate of gold dissolution. It would be important to completely determine the mineral composition of the copper species present in Met 11-17 to understand their potential impact on the performance of this composite at the industrial scale.
- The reagent utilization efficiency (g of Au dissolved by kg of NaCN) is 1.05 g/kg for Met 02-05 and 0.72 g/kg for Met 11-17 which indicates a more favorable leaching condition for the former.
- The reagent utilization efficiency of lime is 0.073 g/Kg for Met 02-05 and 0.078 g/Kg for Met 11-17.

Based on the conditions of the HCT it is concluded that leaching of these composites on a heap leach setting could result in Au recoveries of about 70% for Met 02-05 and about 30% for Met 11-17. **It is recommended that these preliminary results be compared to the larger scale column tests recently completed by Metcon in order to:**

a) Compare the calculated extractions, and more importantly;
b) Evaluate the potential scale-up factors required for the design of the industrial scale process.

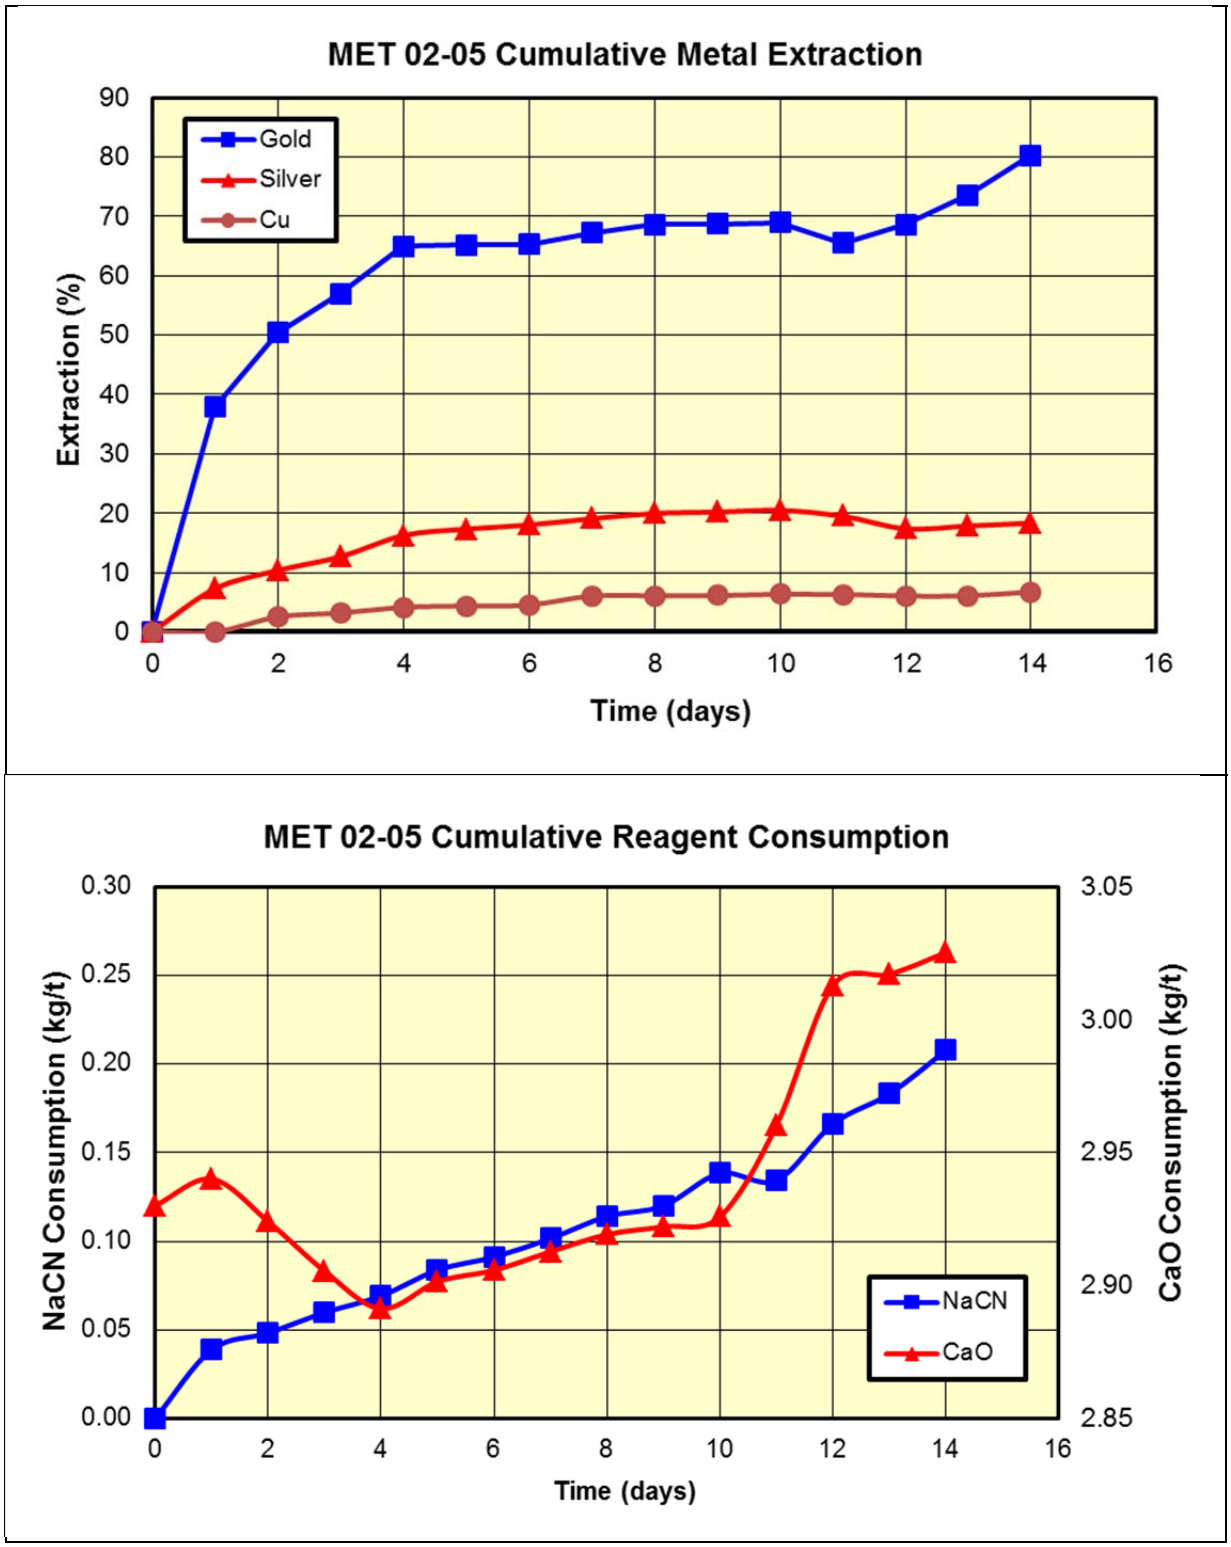

Figure 3.1 Met 02-05 – Preliminary metallurgical performance

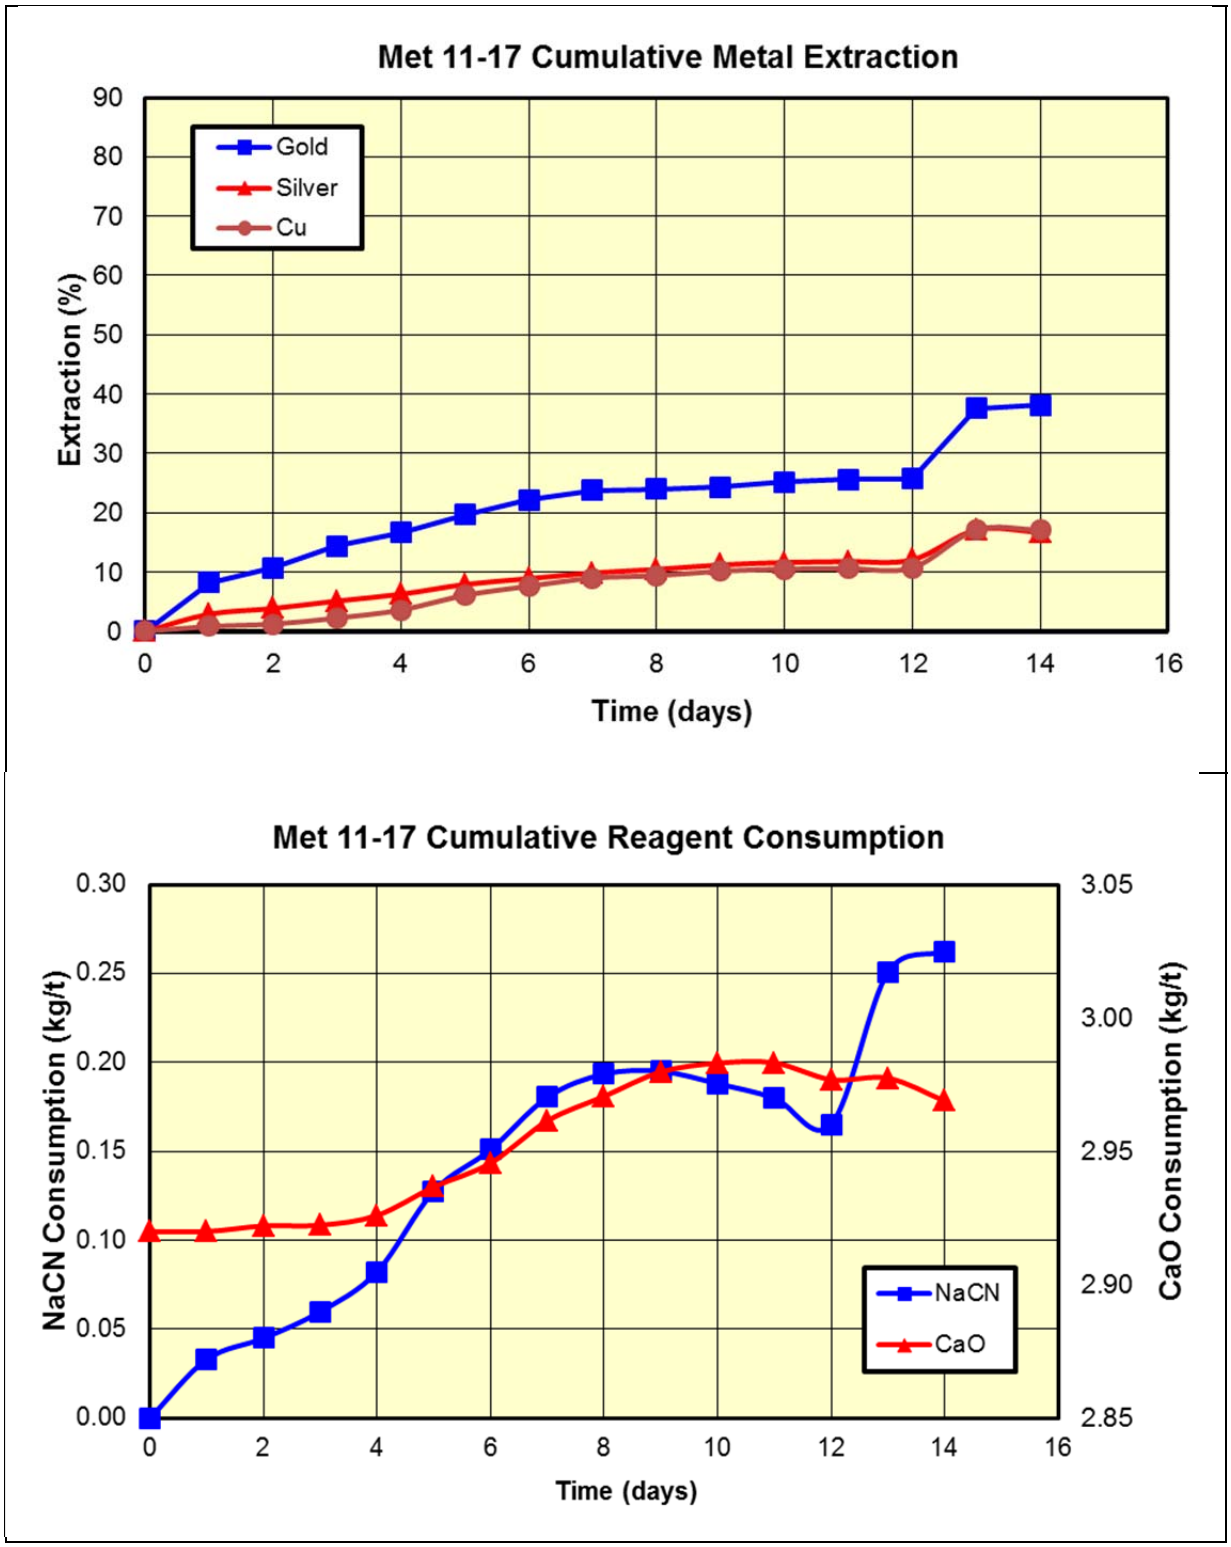

Figure 3.2 Met 11-17 – Preliminary metallurgical performance

4.0 CONCLUSIONS AND RECOMMEDATIONS

4.1 Conclusions

By necessity, the volume of rock analyzed by the work summarized on this document is small compared to the ore deposit. It is therefore critical that WCG develop a good understanding of the representativeness of these samples with respect to the ore body and the spatial distribution of the metallurgical composites with respect to the mine plan. This understanding will provide the basis for planning the mining sequence and identifying the opportunities for ore blending.

The main findings from the characterization activities and the data review presented in this document are as follows:

- There are significant physical, hydrodynamic, metallurgical and mineralogical differences between the two composites evaluated on this study. It is therefore important that a good understanding of their relative contribution and occurrence (location and timing) with respect to the mine plan be developed to assist with the conceptual design of the leaching process.
- Au and Ag are not uniformly distributed along the PSD of these composites. Met 02-05 has most of its metal value (35%) on the size fractions smaller than 1.7 mm and thus should be quite leachable. In contrast, Met 11-17 has most of its metal value (>25%) on rock fragments larger than 25.4 mm.
- The mineralogical characterization indicates that Au occurs primarily as sub-microscopic native gold.
- In addition bulk mineralogy indicates the gangue is composed predominantly by quartz and alumino-silicate minerals. The quartz fraction is quite different from each of the composites, 55.5% for Met 02-05, 41.7% for Met 11-17 and 36.8% for Met 19-20. Secondary minerals include Kaolinite ($Al_2Si_2O_5(OH)$) and swelling clays representing 5.5%, 6.0% and 7.7% for Met 02-05, Met 11-17 and Met 19-20, respectively.
- The competent nature of the Casino samples and their hydrodynamic performance would suggest that the bulk of the swelling clays are present within the crystalline structure of the feldspars and are not present as dispersed clays which tend to reduce he percolation capacity.
- Potential CN consuming minerals include metal sulfides including copper, iron, arsenic and zinc; iron oxide-hydroxides such as Limonite and Jarosite which can also act as preg-robbing; and secondary alumino-silicates and swelling clays.
- Shake leach tests conducted by FL Smidth leads us to believe that: the additional recovery on composites Met 11-17 and Met 19-20 at very high CN-concentrations results from the dissolution of sulfide minerals (sulfide encapsulation due to, but not exclusively, copper sulfides) which may be coating the Au minerals and dissolve in the presence of higher CN concentrations. On the other hand, the limited Au recovery in Met 02-05 is likely associated to silica encapsulation.
- The Casino ore is competent and contains a relatively low level of fines (< 4% minus 200-mesh) which results in a high percolation capacity and physically competent samples for the crush sizes (P_{100} 50 mm with a $\mathbf{P_{80}}$ of 30.6 mm for Met 02-05 and 43.6 mm for Met 11-17) evaluated in this study.
- This low level of fines (minus 200-mesh) is in contrast with the amount of swelling clays reported by the mineralogical characterization. The competent nature of the Casino samples and their hydrodynamic

performance would suggest that the bulk of the swelling clays are present within the crystalline structure of the feldspars. In other words, only small portion of the swelling clays are present in a dispersed fines which minimizes their negative impact on the hydrodynamic properties of these samples.

- The ST results show that heap height has a minimal effect on both the density and the conductivity of either composite which is indicative of a stiff, competent ore whose porous structure is able to withstand flooded conditions and the full lithostatic stress (up to 140 m) at its residual saturation.
- Notwithstanding the strong nature of the Casino samples;
    - Met 11-17 has a large macro-porosity which translates into gravity-dominated flow with limited horizontal movement of solution which typically leads to inefficient wetting and hence reduced metallurgical performance. This type of flow condition is responsible for lower metal extraction, inefficient reagent (CN, CaO and oxygen) utilization and protracted leach cycles.
    - At the 140-m lift height, only composite Met 11-17 satisfies the requirement that the minimum saturated hydraulic conductivity be larger than 1,000 times the application rate (assumed for this study as 6 L/h/m^2 based on the results from the hydrodynamic characterization presented in this document). The rationale behind the minimum K_s value of 1.7×10^{-1} cm/s considers the negative effect of slumping, decrepitation (weathering) of the ore during the life of the heap on the hydrodynamic properties of the ore.
    - The total porosity of the non-agglomerated Met 02-05 at a heap height of 71 m is 31% which compared to the minimal requirement of 30% may indicate that this particular condition may not support a heap height beyond 80 m.
    - For Met 11-17, the data suggest that it would support percolation leaching in a heap up to 140 m in height, but it may do so with significant solution channelization.
- **The results from the STs suggests that blending of the two composites (Met 02-05 and Met 11-17) even without agglomeration will improve the hydrodynamic (and potentially the metallurgical performance) of both composites.**
- **Similarly, despite the coarse nature and the limited amount of fines in the Casino ore, the results from the STs suggest that agglomerating these composites will result in a noticeable improvement of their hydrodynamic properties even for the very coarse Met 11-17.** Another important benefit from agglomeration with leaching solution (alkaline cyanide) is that the reagents are uniformly delivered to all the ore and the dissolution of minerals kick-started. This mode of reagent delivery is a significant improvement with respect to that attained on a typical ROM operation.
- **The ST data from the 2:1 blend of M 02-05 and M 11-17 indicate that this sample when agglomerated could support a heap height close to 140 m. These results show that ore preparation practices are therefore critical for an improved performance of the process.**
- An important fact that needs to be considered in the analysis and interpretation of the results is that all the samples considered in this report represent fresh ore. Leaching typically results in chemical-induced decrepitation (more so under acidic conditions than alkaline conditions) and exposure to ambient conditions lead to weathering both which negatively impact the hydrodynamic properties of the ore. **Given that the Casino heap leaching process is designed as a multi-lift operation, it would be important that hydrodynamic properties of the leached residue after three to four leach**

cycles be determined to define the potential impact of decrepitation to the long term operation of the heap.

- The results from the Hydrodynamic Column Tests (HCTs) show that composite Met 02-05 and Met 11-17 will easily support percolation leaching on the first several lifts (a 32-m heap was evaluated during this effort) with a solution application rate of up to 10 L/h/m^2. This conclusion is based on the following observations:
    - The data generated indicate that the degree of saturation associated to a 10 L/h/m^2 solution application rate would be below 56% for Composite Met 02-05, and 23.2% for Composite Met 11-17.
    - The macro-micro porosity partition for Composite Met 02-05 is 42:58, while that for Composite Met 11-17 is 74:26.
- It appears that the key considerations for the adequate leaching of the Casino ore **when not agglomerated** could be:
    - The permeability for Composite Met 02-05 or a blend thereof as the heap height increases beyond 70 m, and
    - Effective solution-to-ore contact for Composite Met 11-17 if not blended.
- The preliminary metallurgical performance of these two composites confirms that the conclusions based on the physical, hydrodynamic, metallurgical and mineralogical information regarding the potential metal recovery from the Casino composites are correct;
    - The metallurgical data show that gold recoveries of about 80% for Met 02-05 and 42% for Met 11-17. The corresponding silver recovery is about 18% for either of these composites. When the conditions of the HCTs are analyzed in the context of a heap leach operation, it is expected that Met 02-05 could yield gold recoveries of about 70% while Met 11-17 could produce gold recoveries of about 30%.
    - The better metallurgical performance of Met 02-05 compared to that of Met 11-17 is also confirmed by the better cyanide utilization efficiency (1.05 g/kg for Met 02-05 and 0.72 g/kg for Met 11-17).
- It is our contention, based on all the information presented in this document, that gold recovery from composite Met 11-17 **when not blended and agglomerated** may be hindered by gravity dominated flow and potentially by coatings of sulfide minerals (sulfide encapsulation due to, but not exclusively, copper sulfides) while ultimate recovery from Met 02-05 is likely associated to silica encapsulation.

4.2 Recommendations

- Given the difference in the properties of the composites, the design of the leaching process should consider the opportunities for segregation and/or blending of the materials delivered to the heap to ensure the best operational conditions. A clear understanding of abundance and location of the various composites with respect to the mining plan would be a critical piece of information for this task.

- The understanding of the abundance and location of the individual composites (02, 05, 11, 117, 19 and 20) would be critical for the design of the leaching process. For instance, in composite Met 02-05, sample Met 05 has about 40% of the Au and Fe, 30% of the Ag and S, and 11% of the Cu than values reported for Met 02. Selection of blending should consider the hydrodynamic performance and the mineralogical characteristics of the individual samples to enhance the potential leaching performance of the composite.
- QEMSCAN results on the Casino composites show that Chalcopyrite is the dominant Cu-sulfide and that some Cu bearing Iron Oxides are present in M 11-17 and Met 19-20 but not in Met 02-05, which may explain the limited gold recovery on composite Met 11-17. The impact of copper mineralization on Met 11-17 on Au dissolution and cyanide consumption should be carefully considered during the selection of blending options.
- Given the competent nature of the Casino samples tested during this study, Met 11-17 in particular, it is recommended that additional hydrodynamic and metallurgical tests be conducted on this sample under the following conditions:
    - Crushed ore with a top size between 1.25" to 1.5" to be evaluated under the ST procedure to select the best candidate for Integrated Column Tests (ICTs). Given the amount of gold on the coarser fraction, this may result in better gold liberation – albeit the potential issue with the interference from the copper minerals.
- Given the more permeable and very coarse nature of Met 11-17, blending it with Met 02-05 even under a non-agglomerated condition increases the heap height supported by the latter composite. As indicated by the ST results, agglomeration of a 2:1 blend produces a much improved condition from the point of view of solution percolation and likely air movement.
- Future metallurgical testing of the blend (Met 02-05+Met 11-17) should focus on determining the potential negative impact of the copper minerals on the performance of Met 02-05.
- Even though the non-agglomerated Casino composites would support heap heights between 70 m to 140 m, the hydrodynamic characterization indicates that substantial benefits could be derived from blending and proper agglomeration of the samples. In addition to the improved hydrodynamic performance, agglomeration has the added benefits of uniform reagent delivery and kick-starting of the leaching process. It is recommended that agglomeration of the Casino composites be further considered.
- Another important parameter that needs to be considered is the moisture of the ore as-mined and during stacking. The moisture content of stacking determines the potential for compaction and particle size segregation. If the decision is made that the ore will not be agglomerated, it is recommended that some additional STs be conducted once the material is being placed on the heap at the *in situ* moisture content to confirm that no over-compaction of the ore would occur.
- Industrial experience shows that a permanent (multi-lift) heap design can be strongly impacted by excessive solution inventory. Although the Casino ore is quite permeable and shows favorable drainage characteristics, a trade-off study should be conducted comparing the financial benefits of a dynamic heap versus the multi-lift heap currently considered. Elevated solution and metal inventory would be more significant for Met 02-05 than for Met 11-17, so it should be explicitly considered in the context of the recommended trade-off study.

- The data presented in this document shows that the hydrodynamic performance of composites Met 02-05 and Met 11-17 would be more than adequate during the initial stages of the operation as clearly shown by the results of the HCTs for a heap height of 32 m; (i.e., four lifts of 8 m). Although the optimal irrigation schedule and application rate would be best determined via a three-dimensional numerical model which includes all the geometric characteristics of the Casino heap, the hydrodynamic and metallurgical properties of the ore presented in this document, the following design specifications are recommended:
    - Given the current crush size ($\mathbf{P_{100}}$ ~50 mm), a maximum distance between drippers of 30 cm and the solution application rate no larger than 10 L/h/m^2 for Composite Met 02-05 and no larger than 6 L/h/m^2 for Composite Met 11-17 are recommended.
    - The irrigation for both of these composites should follow a ramp-up irrigation scheme (RUI) whereby the average application rate for the first few days is 25% of the target rate and is maintained until solution discharge is equal to the solution application; the second flow step is 50% of the target and is continued until steady state flow (in=out) is achieved; the third flow step is 75% of the target flow rate and is continued to steady state flow at which point the full target application is applied on a continuous basis.
    - A rinsing period at the end of the leaching should be designed and instituted. Again, this is best done using the information presented in this document in combination of a 3-D flow model, however, based on the analysis so far it seems that the duration of the rinse cycle should be at least 10 days and at an irrigation rate of 200% the target irrigation.
- Given that the Casino is designed as a multi-heap leaching process, it is critical that the hydrodynamic properties of the leached residue be determined to define the potential impact of weathering, slumping and potential leaching-induced decrepitation to the long-term performance of the heap. It is recommended that leached residue, either from the recently completed columns at Metcon or from the future operation after three or four leach-cycles, be used for this purpose. If these results show a significant difference from the tests on the head samples, HCTs to be conducted to better assess the impact of leaching on the hydrodynamic properties of the Casino ore and the potential changes to the current heap design.
- Finally, It is recommended that the preliminary metallurgical results be compared to the larger scale column tests recently completed by Metcon in order to:
    i) Compare the calculated extractions, and more importantly;
    ii) Evaluate the potential scale-up factors required for the design of the industrial scale process.

Executive Summary

This report presents results of test work undertaken on two detox feed sample solutions from Casino Mining Corp's Casino Project. The aim of the test work was to determine the conditions to achieve a target of less than 1 mg/L CN_{WAD}. The two solutions were a PLS solution with higher cyanide and dissolved metal content and a RINSE solution that was approximately ten times more dilute than the PLS solution. Both solutions were tested using the SO_2/O_2 and H_2O_2 cyanide destruction processes.

An analysis of the samples received shows that the PLS Solution contained approximately 794 mg/L CN_{WAD}, 312 mg/L Cu, 0.28 mg/L Zn, 0.2 mg/L Fe and Nickel was below the detection limits of 0.1 mg/L. The RINSE Solution contained approximately 72 mg/L CN_{WAD}, 32 mg/L Cu, 0.1 mg/L Fe with Nickel and Zinc each below the detection limit of 0.1 mg/L.

When treating the PLS solution the extended confirmation test demonstrated that under the conditions of 3.5 $gSO_2/\ gCN_{WAD}$, pH 9.5, 182 minutes of retention time, and no copper addition the SO_2/O_2 cyanide destruction process was able to achieve an effluent with a CN_{WAD} content of approximately 0.3 mg/L. There were no conditions found where the H_2O_2 process achieved the target of less than 1.0 mg/L CN_{WAD} in the effluent.

The treatment of the RINSE solution through the extended confirmation test found that using 3.5 $gSO_2/\ gCN_{WAD}$, pH 9.5, 52 minutes of retention time, and no copper addition the SO_2/O_2 cyanide destruction process was able to achieve an effluent with a CN_{WAD} content of approximately 0.3 mg/L.

The alternative H_2O_2 process was also successful to achieve an effluent with a CN_{WAD} content of less than 0.2 mg/L using the conditions of 3.2 $gH_2O_2/\ gCN_{WAD}$, pH 9.5, 63 minutes of retention time, and no copper addition.

From this test work program the Gekko Cyanide Detox Group is able to modify the existing cyanide destruction circuit to be a robust cyanide destruction system that will be able to consistently meet effluent requirements.

1. Introduction

Gekko Systems was contacted to provide cyanide destruction test work for Casino Mining's Casino Project. The purpose of the test work was to determine the conditions that obtain the target of less than 1 mg/L CN_{WAD} on high cyanide PLS solution and a low cyanide RINSE solution.

The test work utilized the sulphur dioxide – air (SO_2/O_2) cyanide removal process (also known as the INCO process), and the hydrogen peroxide process. These processes require the presence of soluble copper (which acts as a catalyst), to oxidize cyanide (CN^-) to cyanate (OCN). The copper required is often present in the feed as a copper cyanide complex, or otherwise can be added as a solution of copper sulphate.

1.1. Definitions and Acronyms

These are the definitions and acronyms used in this document.

Term or Acronym	***Definition***
AAS	Atomic Absorption Spectrometry
CN^-_f	Free cyanide
CN_P	Cyanide measured by picric acid method
CN_T or CN_{TOTAL}	Total cyanide
CN_{WAD}	Weak Acid Dissociable Cyanide
Cu	Copper
$CuSO_4$	Copper Sulphate
DO	Dissolved Oxygen
Detox	Cyanide Detoxification
Gekko	Gekko Systems Pty Ltd
ICP	Inductively Coupled Plasma
O_2	Oxygen
SMBS or $Na_2S_2O_5$	Sodium Metabisulphite
pH	Solution Alkalinity
SO_2	Sulphur Dioxide
µm	Micrometre

2. Sample Receipt and Preparation

2.1. Sample Receipt

Approximately 60 litres of each PLS and RINSE sample were received at the Gekko facilities in Vancouver as 3 containers of “PLS” solution and 3 containers of “RINSE” solution on August 19th 2014.

2.2. Sample Preparation

The PLS solution was found to contain 793.8 mg/L CN_{WAD} when it was received and the RINSE solution contained 72.5 mg/L CN_{WAD}. Both samples underwent an ICP scan and a summary of the critical metals is provided in Table 1.

For full assay results see Appendix A.

Table 1: Critical Metals Summary of Detox Feed

Feed Analysis					
	CN_{WAD} mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L
PLS SOLUTION	793.8	312	<0.1	0.2	0.28
RINSE SOLUTION	72.47	31.5	<0.1	0.1	<0.1

3. Experimental Procedure

3.1. Laboratory Set-up

The experimental set up for the cyanide destruction tests comprised of a reaction vessel (overflowing at 1.5L) equipped with a Rushton turbine, baffles, a dissolved oxygen and pH probe, a cyanide sensing silver electrode (Dyna Probe) and a reagent reservoir for Sodium Metabisulphite ($Na_2S_2O_5$) or Hydrogen Peroxide (H_2O_2), and lime ($Ca(OH)_2$) addition. Figure 1 below shows the set up.

Figure 1: Laboratory Set-up

3.2. Test and Analytical Procedures

An initial batch test was performed to lower the detox feed CN_{WAD} levels to below 1.0 mg/L in the reactor, with the treated solution obtained from this test used as starting material for continuous treatment testing. In all subsequent tests, the solution remaining in the reactor at the conclusion of the treatment was used as the starting material for the next experiment.

To ensure adequate mixing within the reactor, the agitator was operated between 400 and 500 RPM. Reagent flow rates were set according to pre-selected feed conditions and continually monitored. Sodium Metabisulphite was used as the source of sulphur dioxide and hydrogen peroxide 50% w/w solution was used as the peroxide source. Air was injected into the reactor below the agitator to maintain the required dissolved oxygen level. No additional copper catalyst was required.

The cyanide destruction process was monitored on a continuous basis using a cyanide sensing silver electrode (Dyna Probe) that produces readings in mV. The dissolved oxygen levels and pH were also continuously monitored.

Representative samples of treated effluent were taken at each replacement for analysis. A minimum of three replacements of the detox reactor tank was used to produce a representative result. The effluents were filtered using a 0.45 µm membrane filter and immediately prepared for the colorimetric determination of CN_{WAD} using the buffered picric acid method (CN_P). All filtrates were tested for silver, copper, nickel, iron and zinc.

The cyanide concentration determined by the picric acid method includes all cyanide species except cyanide complexed with iron or gold in solution. Therefore, CN_P is greater than or equal to CN_{WAD} and is reported as CN_{WAD} in this report. If required, the total cyanide (CN_T) can be accurately estimated using the formula: $CN_T = CN_P + 2.795 \times Fe$ (mg/L).

4. Results

During the testing of the solution the process conditions were adjusted in successive tests to minimise the CN_{WAD} and residual base metals in the effluent and to optimise operating conditions. Two solutions were tested; a higher cyanide and higher metal content "PLS" solution and a lower cyanide and lower metal content "RINSE" solution.

4.1. PLS Solution

The PLS Solution contained approximately 794 mg/L CN_{WAD}, 312 mg/L Cu, 0.28 mg/L Zn, 0.2 mg/L Fe and no detectable Ni. The solution was detoxified using both the SO_2/O_2 and the H_2O_2 processes. The retention time was tested between the range of 86 minutes and 187 minutes for the SO_2/O_2 tests and for the H_2O_2 tests a range of 61 minutes to 194 minutes was tested. Retention time was investigated to determine the time required for cyanide destruction and possible reduction in reagent consumption. During the test work, the pH was controlled automatically by addition of lime to the pH set points of 8.5 and 9.5 for both processes. It was demonstrated that additional copper catalyst was not required for successful cyanide destruction.

A summary of all the conditions tested and results is provided in Table 2.

Table 2: Summary of PLS Solution Cyanide Destruction Tests

4.1.1. SO_2/O_2 Process Results

4.1.1.1. Effect of SO_2 Dosage

The sulphur dioxide dosage ratio was varied between 2.6 to 6.6 gSO_2/gCN_{WAD}. Table 3 provides a comparison between tests and shows that at a retention time of 174 minutes and a minimum addition of 3.5 gSO_2/gCN_{WAD}, the process was able to reduce the CN_{WAD} to <0.2 mg/L. Increases in SO_2 addition did not further reduce the CN_{WAD} content in the effluent. Reducing the SO_2 addition to 2.6 gSO_2/gCN_{WAD} caused an unstable reaction with the CN_{WAD} in the effluent slowly rising.

Table 3: Effect of SO_2 Dosage on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T3 - SMBS - PLS	6.2	0	184.0	9.5	0.56	0.30	0.2	1.1	0.0	0.0	0.0	0.30
T4 - SMBS - PLS	4.9	0	181.5	9.5	0.50	0.31	0.2	2.5	0.0	0.0	0.0	0.31
T17 - SMBS - PLS	3.5	0	173.6	9.5	1.44	<0.2	0.1	1.0	0.0	0.0	0.0	<0.2
T18 - SMBS - PLS	2.6	0	187.3	9.5	2.27	2.09	0.2	4.8	0.0	0.0	0.0	2.09

4.1.1.2. Effect of Retention Time

The retention time was varied between approximately 86 minutes to 187 minutes. A comparison between tests, as summarised in Table 4, shows that at the same SO_2 dosage ratio and pH, reducing the retention time from 174 minutes to 123 minutes resulted in a higher CN_{WAD} and dissolved copper content in the effluent.

Table 4: Effect of Retention Time on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T17 - SMBS - PLS	3.5	0	173.6	9.5	1.44	<0.2	0.1	1.0	<0.1	<0.2	<0.1	<0.2
T19 - SMBS - PLS	3.5	0	122.7	9.6	1.12	0.54	0.1	5.2	<0.1	<0.2	<0.1	0.5

4.1.1.3. Effect of pH

Table 5 illustrates the effect of pH on the cyanide destruction process. A pH between 8.0 and 9.0 is commonly used in the SO_2/O_2 process. In this test work, the pH was set to 8.5 and 9.5. It was found that increasing the pH resulted in a decrease in the cyanide level in the effluent and reduced the amount of copper dissolved in solution.

Table 5: Effect of pH on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T1 - SMBS - PLS	6.3	0	86.4	8.5	0.29	1.69	0.3	13.5	<0.1	<0.2	<0.1	1.7
T3 - SMBS - PLS	6.2	0	184.0	9.5	0.56	0.30	0.2	1.1	<0.1	<0.2	<0.1	0.3

4.1.2. H_2O_2 Process Results

4.1.2.1. Effect of H_2O_2 Dosage

The H_2O_2 dosage ratio was varied from 5.1 to 7.0 gH_2O_2/gCN_{WAD} and a comparison of the results can be found in Table 6. The tests found that even at a high dosage rate of 7.0 gH_2O_2/gCN_{WAD} the process was not able to achieve the target of less than 1.0 mg/L CN_{WAD} in the effluent. It is believed that the presence of fine metal hydroxide solids formed by the precipitation of base metals caused the peroxide to dissociate before it could oxidize the cyanide molecules.

Table 6: Effect of H_2O_2 Addition Rate on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T7 - H2O2 - PLS	5.1	0	194.6	9.5	0.16	37.98	0.2	51.2	-	<0.2	<0.1	38.0
T8 - H2O2 - PLS	7.0	0	175.2	9.1	0.42	40.50	0.3	66.3	-	<0.2	<0.1	40.5

4.1.2.2. Effect of Retention Time

The retention time was varied between approximately 61 minutes and 195 minutes. While increasing the retention time did produce a stable cyanide content in the effluent it failed to meet the target of less than 1 mg/L CN_{WAD}.

Table 7: Effect of Retention Time on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T5 - H2O2 - PLS	5.4	0	61.3	8.8	0.00	26.79	0.2	73.9	<0.1	<0.2	<0.1	26.8
T6 - H2O2 - PLS	5.8	0	116.4	8.6	0.00	12.33	0.2	30.8	-	<0.2	0.1	12.3

4.1.2.3. Effect of pH

Table 8 illustrates the effect of pH on the cyanide destruction process. A pH between 8.5 and 9.5 is commonly used in the H_2O_2 process. In this test work, the pH was set to 8.5 and 9.5. It was found that increasing the pH produced an unsteady reaction with an increasing CN_{WAD} content in the effluent as the test continued. A higher dissolved copper was also detected in the effluent.

Table 8: Effect of pH on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L

4.1.3. Extended Confirmation Test

A longer confirmation test was run to demonstrate that the reaction had achieved steady state conditions at an acceptable cyanide discharge level. The results are summarised in Table 9. The conditions selected for this test were based on the best results achieved during the test work optimisation program and selected as 3.5 gSO_2/ gCN_{WAD}, pH 9.5, 182 minutes of retention time, and no copper addition to match the conditions of Test 17. During the test it was observed that there was a problem with the addition of sodium metabisulphite causing the CN_{WAD} levels to rise. Once this was corrected the CN_{WAD} content in the effluent quickly recovered. The end result was an effluent that contained approximately 0.3 mg/L CN_{WAD}. Effluent from the final displacement also underwent cyanide speciation with the results provided in Table 10.

A full ICP-MS scan was conducted on the final solution as well as cyanide speciation which can be found in Appendix B.

Table 9: Summary of the Confirmation Test

Sample Description	CNp	Ag	Cu	Ni	Fe	Zn	pH	COMMENTS
	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L

Average Value	873	0.19	0.17	4.8

4.2. RINSE Solution

The RINSE Solution contained approximately 72 mg/L CN_{WAD}, 32 mg/L Cu, 0.1 mg/L Fe and no detectable Zn or Ni. The solution was detoxified using both the SO_2/O_2 and the H_2O_2 processes. The retention time was tested between the range of 32 minutes and 70 minutes for the SO_2/O_2 tests and for the H_2O_2 tests a range of 32 minutes to 63 minutes was tested. Retention time was investigated to determine the time required for cyanide destruction and possible reduction in reagent consumption. During the test work, the pH was controlled automatically by addition of lime to the pH set point of 9.5 for both processes based on the results from the PLS tests. It was demonstrated that additional copper catalyst was not required for successful cyanide destruction.

A summary of all the conditions tested and results is provided in Table 11.

Table 11: Summary of RINSE Solution Cyanide Destruction Tests

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L

4.2.1. SO_2/O_2 Process Results

4.2.1.1. Effect of SO_2 Dosage

The sulphur dioxide dosage ratio was varied between 3.7 to 5.4 gSO_2/gCN_{WAD}. Table 12 provides a comparison between tests and shows that at a retention time of 70 minutes and a minimum addition of 3.7 gSO_2/gCN_{WAD}, the process was able to reduce the CN_{WAD} to <0.2 mg/L. Increases in SO_2 addition did not further reduce the CN_{WAD} content in the effluent.

Table 12: Effect of SO_2 Dosage on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T9 - SMBS - RINSE	5.2	0	61.6	9.5	1.82	<0.2	<0.1	0.5	<0.1	<0.2	<0.1	<0.2
T10 - SMBS - RINSE	5.4	0	32.3	9.5	1.00	1.73	<0.1	1.5	<0.1	<0.2	<0.1	1.7
T11 - SMBS - RINSE	4.3	0	61.9	9.5	2.34	<0.2	<0.1	0.7	<0.1	<0.2	<0.1	<0.2

4.2.1.2. Effect of Retention Time

The retention time was varied between approximately 32 minutes to 70 minutes. A comparison between tests, as summarised in Table 13, shows that at the same SO_2 dosage ratio and pH, reducing the retention time from 62 minutes to 32 minutes resulted in a higher CN_{WAD} and dissolved copper content in the effluent.

Table 13: Effect of Retention Time on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T9 - SMBS - RINSE	5.2	0	61.6	9.5	1.82	<0.2	<0.1	0.5	<0.1	<0.2	<0.1	<0.2
T10 - SMBS - RINSE	5.4	0	32.3	9.5	1.00	1.73	<0.1	1.5	<0.1	<0.2	<0.1	1.7

4.2.2. H_2O_2 Process Results

4.2.2.1. Effect of H_2O_2 Dosage

The H_2O_2 dosage ratio was varied from 3.2 to 5.4 gH_2O_2/gCN_{WAD} and a comparison of the results can be found in Table 14. The tests found that the maximum cyanide destruction occurred at 4.5 gH_2O_2/gCN_{WAD} with 33 minutes of retention time achieving less than 0.2 mg/L CN_{WAD} in the effluent. Further reducing the H_2O_2 addition to 3.2 gH_2O_2/gCN_{WAD} required 63 minutes of retention time to achieve 0.95 mg/L CN_{WAD} in the effluent, slightly below the target.

Table 14: Effect of H_2O_2 Addition Rate on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L
T13 - H2O2 - RINSE	5.4	0	32.3	9.5	1.05	1.81	<0.1	0.8	<0.1	<0.2	<0.1	1.8
T14 - H2O2 - RINSE	4.5	0	33.1	9.5	0.42	<0.2	<0.1	0.3	<0.1	<0.2	<0.1	<0.2
T15 - H2O2 - RINSE	3.2	0	32.1	9.6	0.92	6.69	<0.1	1.8	<0.1	<0.2	<0.1	6.7
T16 - H2O2 - RINSE	3.2	0	62.8	9.5	1.52	0.95	<0.1	1.5	<0.1	<0.2	<0.1	1.0

4.2.2.2. Effect of Retention Time

The retention time was varied between approximately 32 minutes and 63 minutes. Increasing the retention time allowed for a lower H_2O_2 dosage that was still able to achieve the effluent target of less than 1 mg/L CN_{WAD} in solution. Results are shown in Table 15.

Table 15: Effect of Retention Time on Cyanide Destruction

Test	Conditions					Product Solution Analysis						
	Reagent:CN_{WAD} g/g	Cu addition mg/L	Retention Time min	pH	Lime:Reagent g/g	CN_P mg/L	Ag mg/L	Cu mg/L	Ni mg/L	Fe mg/L	Zn mg/L	CN_{TOT} mg/L

T15 - H2O2 - RINSE	3.2	0	32.1	9.6	0.92	6.69	<0.1	1.8	<0.1	<0.2	<0.1	6.7
T16 - H2O2 - RINSE	3.2	0	62.8	9.5	1.52	0.95	<0.1	1.5	<0.1	<0.2	<0.1	1.0

4.2.1. Extended Confirmation Test

A longer confirmation test was run to demonstrate that the reaction had achieved steady state conditions at an acceptable cyanide discharge level. The results are summarised in Table 16. The conditions selected for this test were based on the best results achieved during the test work optimisation program and selected as 3.5 gSO_2/ gCN_{WAD}, pH 9.5, 52 minutes of retention time, and no copper addition to match the conditions of Test 12. The test initially struggled due to an overdosing of lime that caused the pH to increase to 11.6 but was slowly able to recover and reduce the CN_{WAD} content of the effluent well below the target of less than 1 mg/L CN_{WAD}. The end result was an effluent that contained approximately 0.3 mg/L CN_{WAD}. Effluent from the final displacement also underwent cyanide speciation with the results provided in Table 17.

A full ICP-MS scan was conducted on the final solution as well as cyanide speciation which can be found in Appendix B.

5. Concluding Comments

From the results of the test work the following concluding comments can be made:

5.1. PLS Solution

- The analysis of the PLS feed solution showed it contained an average of 794 mg/L CN_{WAD} 312 mg/L Cu, 0.28 mg/L Zn, 0.2 mg/L Fe with Ni below the detection limit of 0.1 mg/L.

- Test work showed that only the SO_2/O_2 process was suitable for cyanide destruction of the PLS solution. It is believed that the H_2O_2 process failed due to the high amount of copper precipitate formed during the detox reaction. The presence of these solids would cause the hydrogen peroxide to decompose before it could oxidize the cyanide.

- A minimum dosage of 3.5 gSO_2/ gCN_{WAD} was able to achieve less than 0.2 mg/L CN_{WAD} in the effluent. Further reduction in SO_2 dosage resulted in an unstable reaction that failed to meet the targeted 1.0 mg/L CN_{WAD} and increasing the SO_2 addition did not achieve a lower CN_{WAD} content in the effluent.

- To minimize reagent consumption and improve effluent quality a retention time of approximately 180 minutes was required to achieve less than 1.0 mg/L CN_{WAD} in the effluent. Reducing the retention time failed to achieve the target even with higher SO_2 dosage.

- It was necessary to conduct the tests at pH 9.5 to remove residual copper from the solution.

- Under the conditions of 3.5 gSO_2/ gCN_{WAD}, pH 9.5, 182 minutes of retention time, and no copper addition the SO_2/O_2 cyanide destruction process was able to achieve an effluent with a CN_{WAD} content of approximately 0.3 mg/L.

5.2. RINSE Solution

- The analysis of the RINSE solution showed it contained an average of 72 mg/L CN_{WAD}, 32 mg/L Cu, 0.1 mg/L Fe and no detectable Zn or Ni.

- Test work showed that both the SO_2/O_2 and H_2O_2 processes could be used to reduce the CN_{WAD} content in the effluent to less than 1.0 mg/L

- A minimum dosage of 3.7 gSO_2/ gCN_{WAD} was able to achieve less than 0.2 mg/L CN_{WAD} in the effluent. Increasing the SO_2 addition did not achieve a lower CN_{WAD} content in the effluent.

- To minimize reagent consumption and improve effluent quality a retention time of approximately 60 minutes was required to achieve less than 1.0 mg/L CN_{WAD} in the effluent. Reducing the retention time failed to achieve the target even with higher SO_2 dosage.

- It was necessary to conduct the tests at pH 9.5 to remove residual copper from the solution.

- Under the conditions of 3.5 gSO_2/ gCN_{WAD}, pH 9.5, 52 minutes of retention time, and no copper addition the SO_2/O_2 cyanide destruction process was able to achieve an effluent with a CN_{WAD} content of approximately 0.3 mg/L.

- A minimum dosage of 4.5 gH_2O_2/gCN_{WAD} was required to achieve less than 0.2 mg/L CN_{WAD} in the effluent using 33 minutes of retention time. Reducing the dosage of hydrogen peroxide to 3.2 gH_2O_2/gCN_{WAD} required 63 minutes of retention time to achieve 0.95 mg/L CN_{WAD} in the effluent, slightly under the target of 1.0 mg/L CN_{WAD}.

- Under the conditions of as 3.5 gH_2O_2/ gCN_{WAD}, pH 9.5, 52 minutes of retention time, and no Copper addition the H_2O_2 cyanide destruction process was able to achieve an effluent with a CN_{WAD} content of approximately 0.3 mg/L.

6. Recommendations

The SO_2/O_2 process will be suitable for treatment of both solutions while the H_2O_2 process is limited to the conditions of the RINSE solution.

From this test work program the Gekko Cyanide Detox Group is able to design a full scale cyanide destruction circuit that will be able to consistently meet effluent requirements.

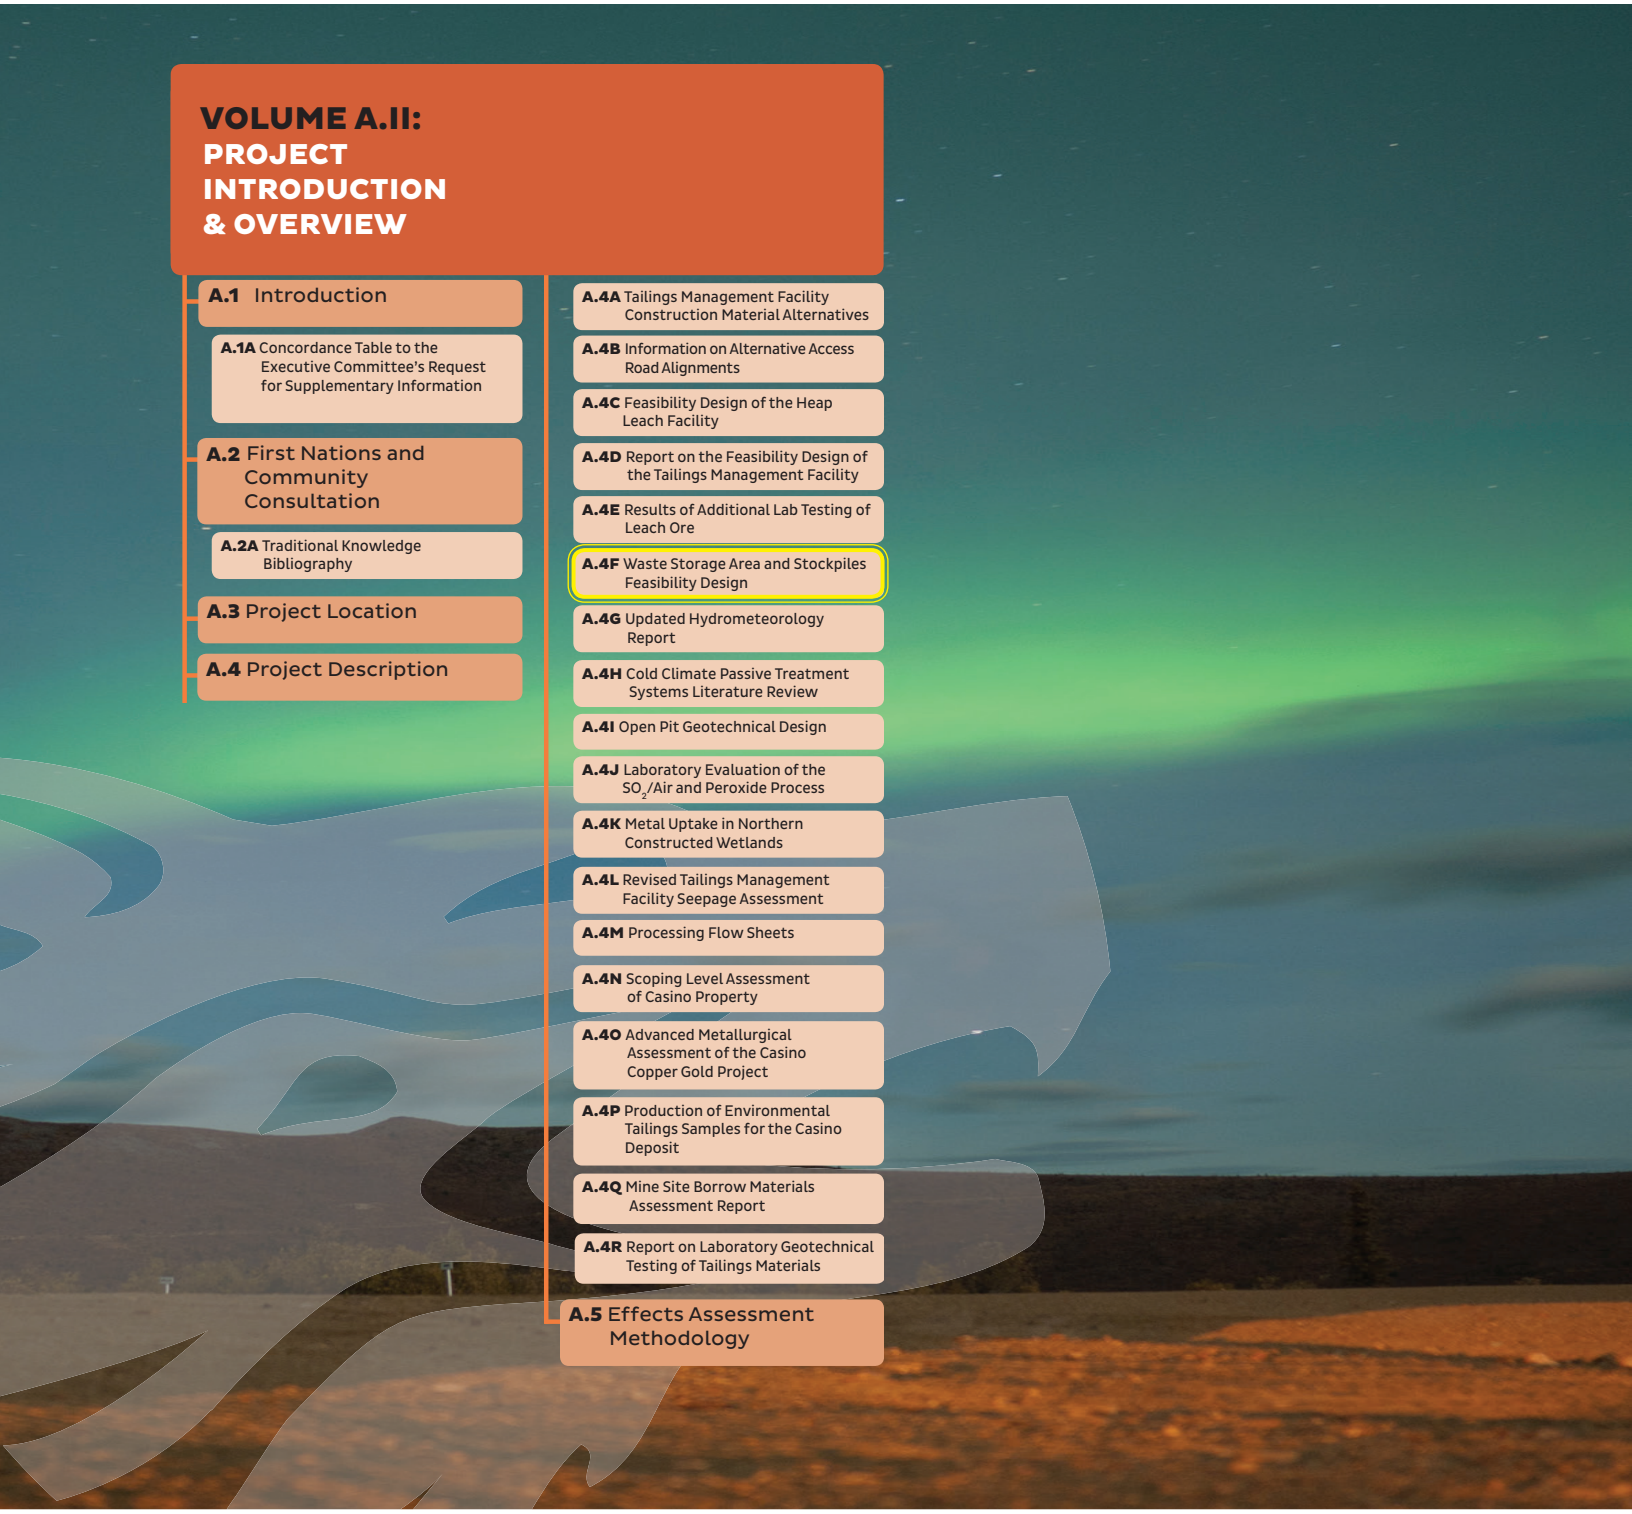
Appendix C – Disclaimer

Gekko has undertaken test work to characterize the response of your ore to certain separation techniques and/or to help your own experts make a decision as to whether you wish to purchase our product and, if so, the number and type.

It is important that you understand that:



- *You must have your own experts examine the detailed analysis in our report to decide its applicability to your project.*
- *We analyse only the sample you provide. Any one of a number of factors may cause that sample inaccurately to reflect the ore body. You must determine the extent to which the sample represents the ore body. That includes the detection limits and confidence intervals relevant to our results.*

At all times we endeavour to provide accurate test work outcomes but you should not use our results as a basis for your broader business decisions about your project.

If we have not exercised due care with our tests, the limit of our liability, both at common law and under any statute, will be to provide a further set of test results to you free of charge. You indemnify us with respect to all other loss and damage of every kind, including, without limitation:

- *damage to or loss of property;*
- *injury to or death of any person; and*
- *economic and consequential loss arising from the negligent act or omission of us or anyone else in connection with our test*

EXECUTIVE SUMMARY

The Casino Copper-Gold Project Feasibility design includes for the safe and secure management of mine waste materials, ore stockpiles and topsoil stockpiles.

Storage piles have been designed to accommodate the following materials:

- Potentially reactive (PAG and ML) waste rock and overburden
- Stockpiled ore (Low Grade ore, Supergene Oxide ore and Gold leach ore), and
- Topsoil/overburden materials.

The quantities and classification of mine waste and ore materials is based on the mine production schedule provided by Casino Mining Corporation.

The primary waste management facility for the project is the Tailings Management Facility (TMF). The TMF has been sized to provide sufficient capacity to store approximately 956 million tonnes of tailings (including cyclone sand tailings used as embankment fill) and co-disposal of up to 658 million tonnes of potentially reactive waste rock and overburden, comprising Potentially Acid Generating (PAG) and Metal Leaching (ML) materials. The findings of geochemical waste characterization studies indicate that almost all of the waste material is PAG and/or ML. These PAG and ML waste materials will be placed and stored subaqueously in a Waste Storage Area (WSA) located within the TMF.

Approximately 157.5 million tonnes of additional mined ore will be processed at a Heap Leach Facility (HLF) located south of the open pit. This gold ore will be stored in a temporarily stockpile near the crusher on the valley slope east of the open pit and at the northern end of the TMF. This stockpiled ore will report to the heap leach facility over a period of about 18 years, starting in the pre-production years (3 years prior to mill start-up) and continuing up to Year 15 of mill operations.

During mine operations approximately 144 million tonnes of Low Grade ore and 32 million tonnes of Supergene Oxide (SOX) ore will be stored in temporary stockpiles. The SOX ore will be stockpiled at a location between the open pit and plant site during the pre-production years and in Year 1 of mill operations, and report to the mill during Years 4 to 12 together with direct feed mill ore. Mined Low Grade ore will be stockpiled up to Year 17 in locations generally east and south of the plant site, on valley slopes above the TMF. Low Grade ore mined after Year 12 can also be stockpiled at the same location used for the SOX ore south of the open pit. The stockpiled Low Grade ore will be milled during the last four years of mine operations (Years 19 to 22).

It is anticipated that approximately 2 to 3 million tonnes of Non-Acid Generating (NAG) waste rock (leach cap material) will be produced during pre-production mining. This material will be used in the construction of the TMF Starter (Stage 1) embankment. Any NAG waste rock that is either unsuitable for use as a construction material or in excess of construction material requirements will be placed in the WSA or an adjacent surface dump.

The temporary storage of topsoil recovered during the construction of mine site facilities is required to ensure sufficient reclamation medium is available for mine closure. Topsoil recovered during construction will be stockpiled at select locations close to the material source.

General site characteristics including physiographic setting, hydrometeorology and seismicity are presented. Review of historical earthquake records and regional tectonics indicates that the Casino

Project site is situated in a region of low seismicity and moderate seismic hazard. A summary of geotechnical conditions at the WSA, ore stockpiles and topsoil stockpiles is also provided.

Specific design and operating requirements for the WSA, ore stockpiles and topsoil stockpiles are provided. The general arrangement and configuration of the Waste Storage Area and ore stockpiles is presented, including their development over the life of mine.

The WSA and temporary stockpiles have been designed to remain stable under both static and seismic loading conditions. Surface water and diversion ditching has been designed to divert surface flow around the ore stockpiles to minimise contact with the water. General requirements and expectations for reclamation and closure of the WSA and stockpiles are presented.

Quantity estimates for materials and work activities required for initial construction and ongoing operations of the ore stockpiles and topsoil stockpiles are provided, including foundation clearing and preparation of ore stockpile foundations, surface water management and sediment control.

1 – INTRODUCTION

1.1 PROJECT OVERVIEW

The Casino Copper-Gold Project is a venture by Casino Mining Corporation (CMC) to develop an open pit copper-gold-molybdenum mine in the Yukon Territory. The project is located in the Dawson Range Mountains of the Klondike Plateau approximately 300 km northwest of Whitehorse, Yukon, Canada, as shown on Figure 1.1. This area is somewhat unique in that the region was not glaciated during the Wisconsin Advance. The deposit is hosted by the Prospector Mountain Suite, a suite of igneous intrusive rocks with an intense hydrothermal alteration overprint. The deposit will be mined using open pit methods with a nominal mill throughput of approximately 125,000 tonnes/day (tpd) of ore over a 22 year operating life. During the 22 year operating period the deposit will be mined over a period of approximately 18 years using conventional open pit methods. The milling of ore stockpiled during the open pit operation will continue for the remainder of the mine life (approximately 4 years).

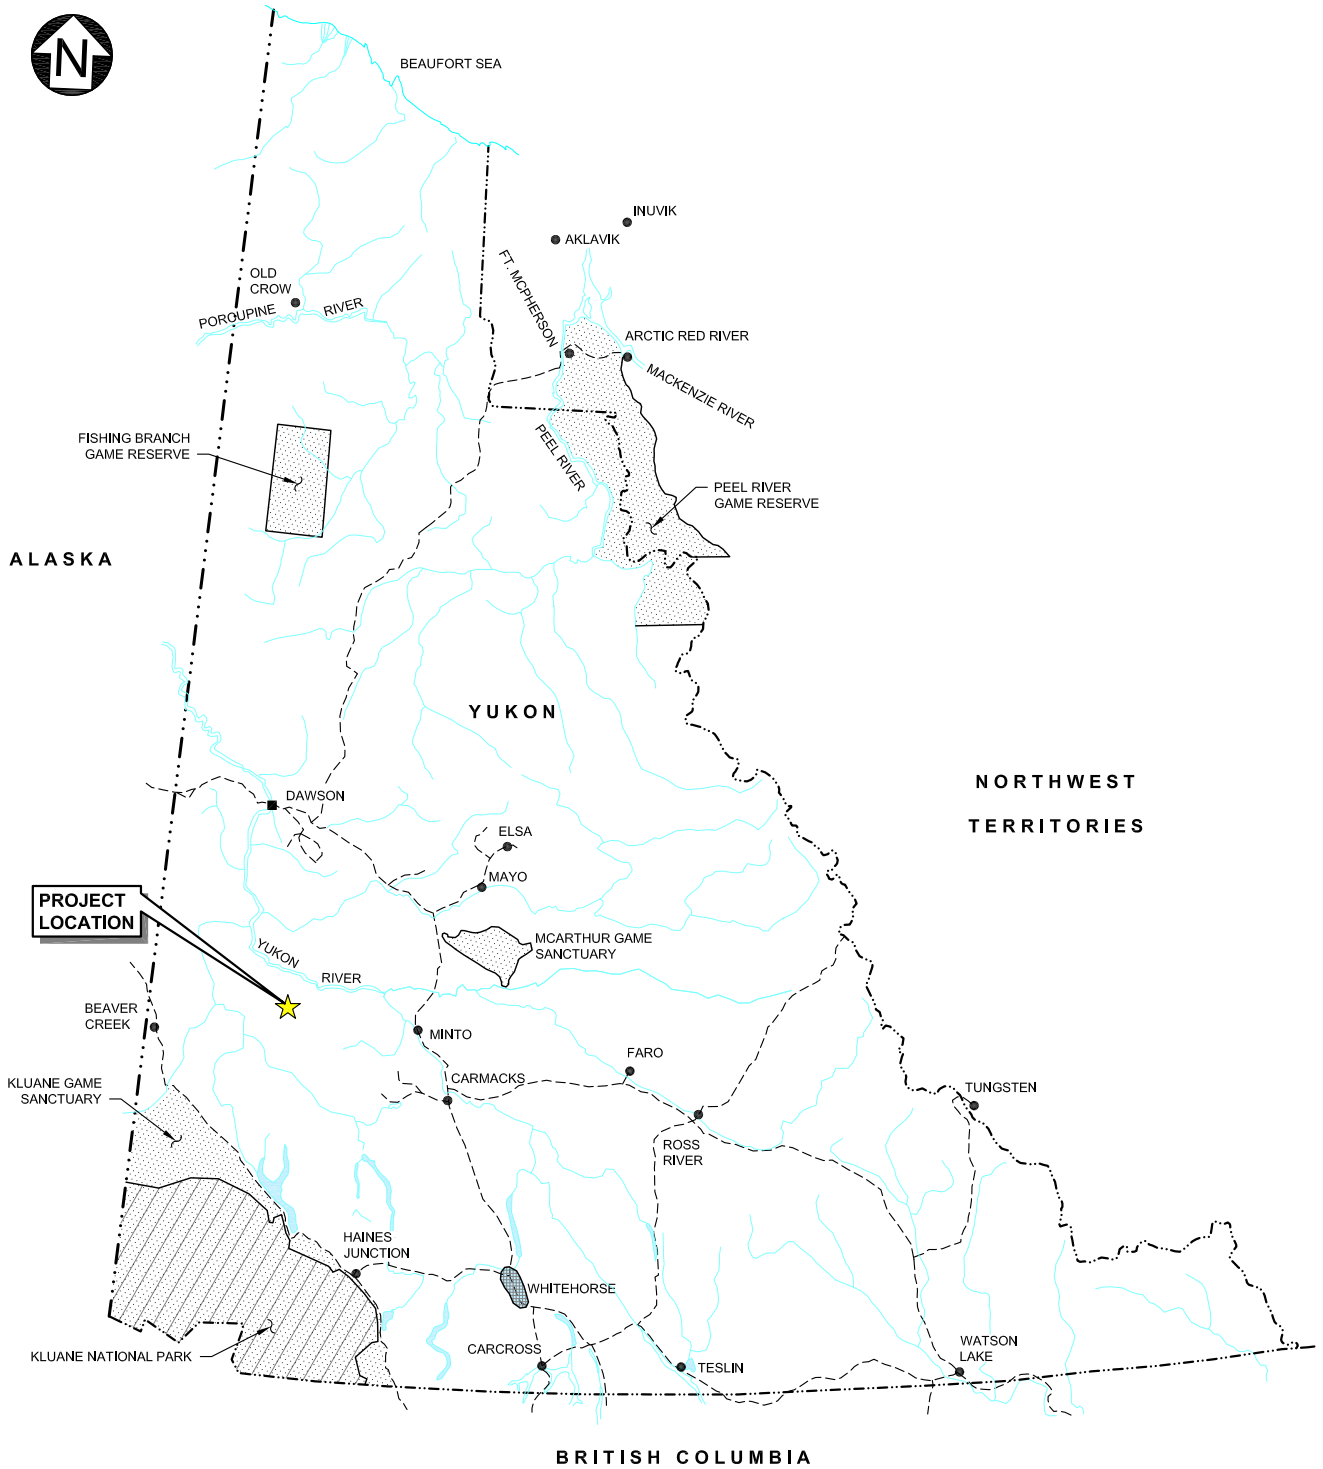
The proposed components of the project facilities include an open pit up to 600 meters deep containing a mineable reserve of approximately 965 million tonnes of mill ore. The primary waste management facility is the Tailings Management Facility (TMF). The TMF has been sized to provide sufficient capacity to store approximately 956 million tonnes of tailings (including cyclone sand tailings used as embankment fill) and co-disposal of up to 658 million tonnes of potentially reactive waste rock and overburden, comprising Potentially Acid Generating (PAG) and Metal Leaching (ML) materials. The findings of geochemical waste characterization studies indicate that almost all of the waste material is PAG and/or ML. These PAG and ML waste materials will be placed and stored subaqueously in a Waste Storage Area (WSA) located within the TMF. Details of the Feasibility design of the TMF are presented in the Knight Piésold Ltd. (KPL) report “Feasibility Design of the Tailings Management Facility” (Ref. No. VA101-325/8-10, December, 2012). A general arrangement of the project site is shown on Figure 1.2. Typical sections showing the development of the TMF and WSA during mine operations (Years 1, 4, 10 and 22) are provided on Figure 1.3.

Approximately 157.5 million tonnes of additional mined ore will be processed at a Heap Leach Facility (HLF) located south of the open pit. This gold ore will be stored in a temporarily stockpile near the crusher on the valley slope east of the open pit and at the northern end of the TMF. This stockpiled ore will report to the heap leach facility over a period of about 18 years, starting in the pre-production years (3 years prior to mill start-up) and continuing up to Year 15 of mill operations. Details of the Feasibility design of the HLF are presented in the KPL report “Feasibility Design of the Heap Leach Facility” (Ref. No. VA101-325/8-9, December, 2012). Heap leach facility operations will commence during pre-production stripping of the open pit.

During mine operations approximately 144 million tonnes of Low Grade ore and 32 million tonnes of Supergene Oxide (SOX) ore will be stored in temporary stockpiles. The SOX ore will be stockpiled at a location between the open pit and plant site during the pre-production years and in Year 1 of mill operations, and report to the mill during Years 4 to 12 together with direct feed mill ore. Mined Low Grade ore will be stockpiled up to Year 17 in locations generally east and south of the plant site, on valley slopes above the TMF. Low Grade ore mined after Year 12 can also be stockpiled at the

same location used for the SOX ore south of the open pit. The stockpiled Low Grade ore will be milled during the last four years of mine operations (Years 19 to 22).

It is anticipated that approximately 2 to 3 million tonnes of Non-Acid Generating (NAG) waste rock (leach cap material) will be produced during pre-production mining. This material will be used in the construction of the TMF Starter (Stage 1) embankment. Any NAG waste rock that is either unsuitable for use as a construction material or in excess of construction material requirements will be placed in the WSA or an adjacent surface dump.



The temporary storage of topsoil recovered during the construction of mine site facilities is required to ensure sufficient reclamation medium is available for mine closure. Topsoil recovered during construction will be stockpiled at select locations close to the material source. The topsoil stockpiles are comparatively low and flat with gently sloped faces.

The general layouts of the ore and topsoil stockpiles are included on Figure 1.2.

1.2 SCOPE OF REPORT

This report summarizes the geotechnical design of the Waste Storage Area (WSA), stockpiled ore and topsoil stockpiles. Specific aspects addressed in this report include the following:

- Site characteristics including physiographic setting, hydrometeorology and seismicity
- Geotechnical conditions at the WSA and stockpile areas
- Layout and design of the WSA within the TMF
- Layout and design of ore stockpiles
- Layout and design of topsoil stockpiles
- Surface water management, including sediment control measures, and
- Reclamation and closure.

2 – SITE CHARACTERISTICS

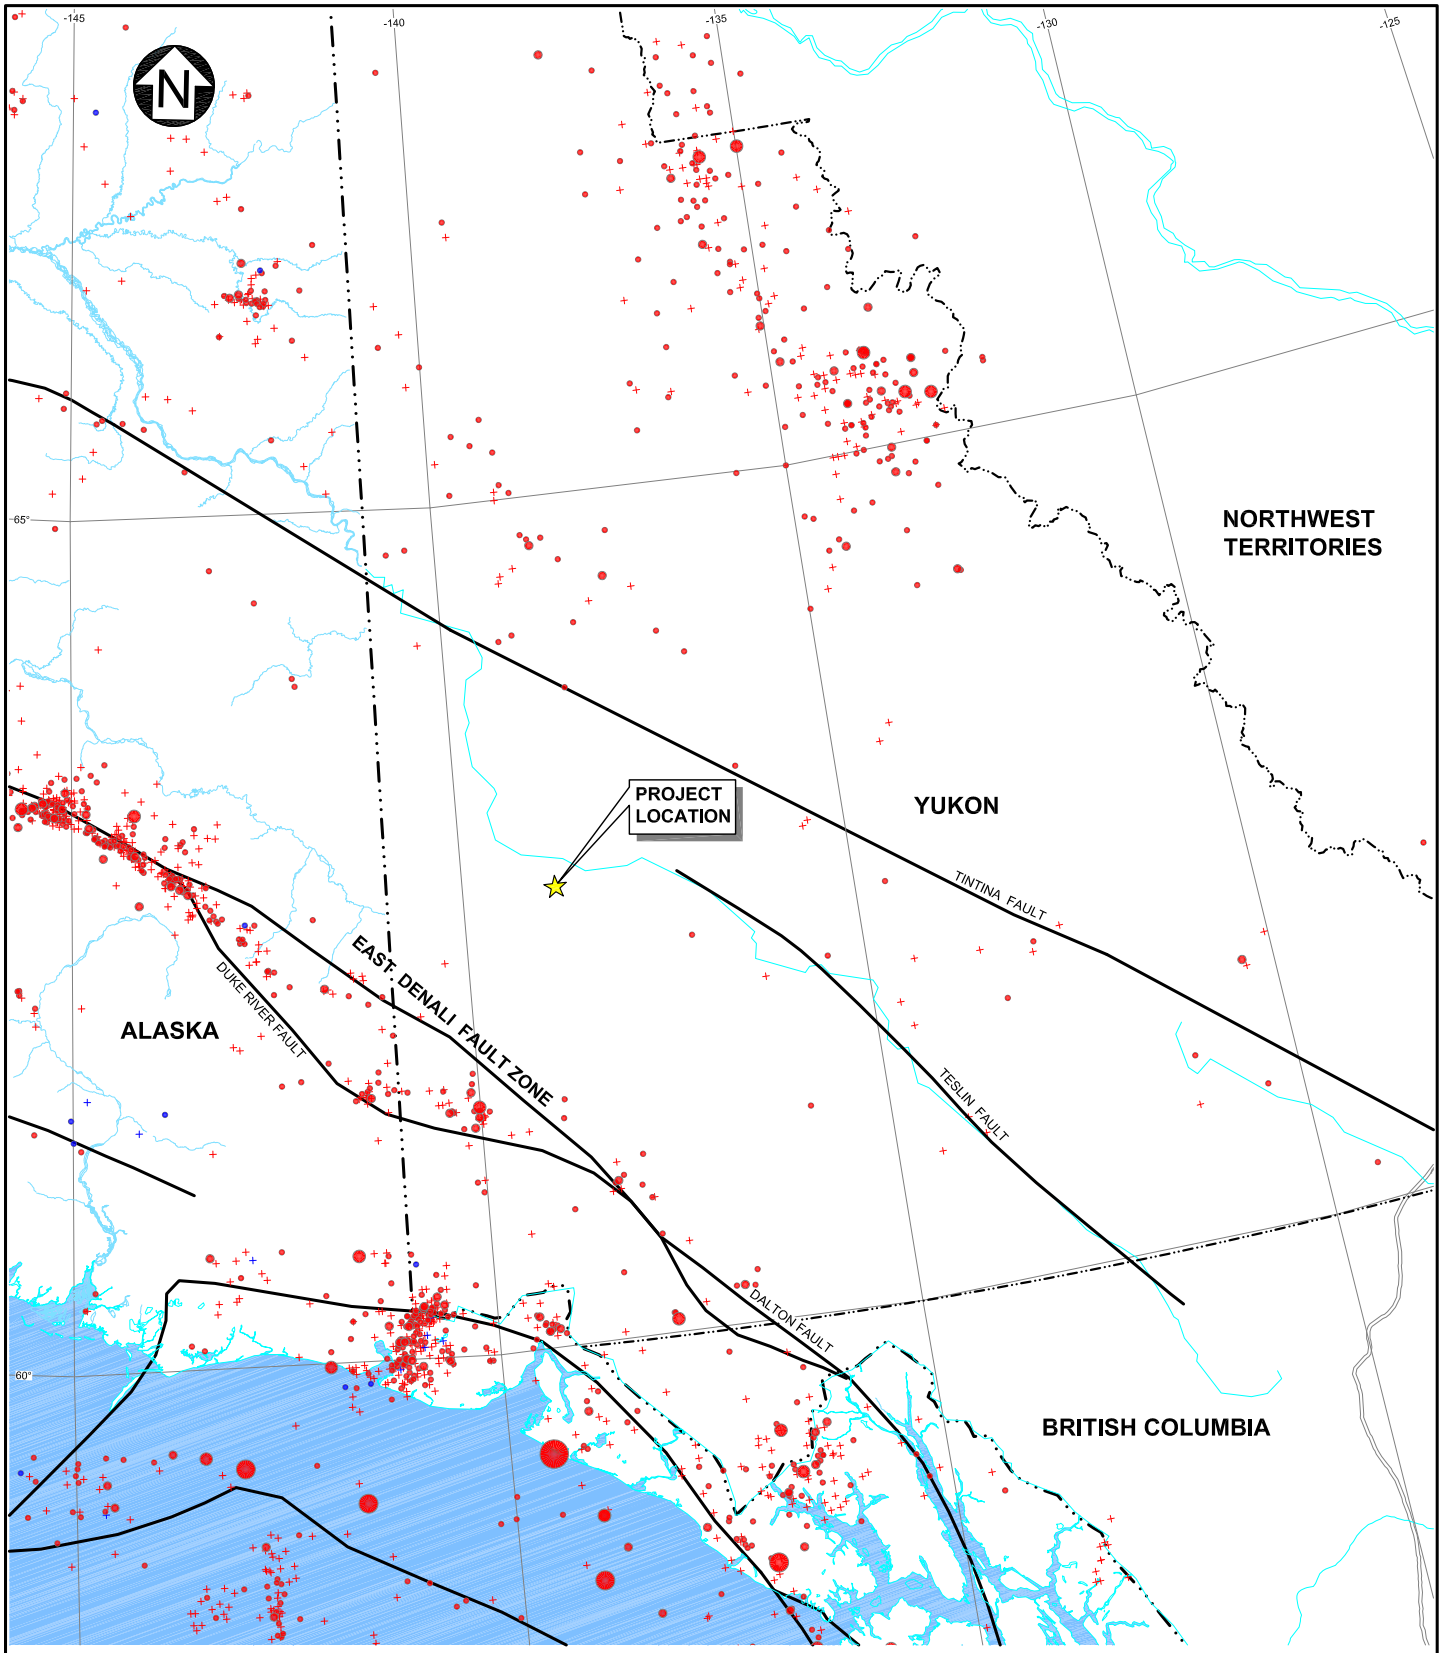
2.1 PHYSIOGRAPHIC SETTING

The project is located in the Dawson Range Mountains of the Klondike Plateau. The area is somewhat unique in that the region was not glaciated during the Wisconsin Advance. The characteristic terrain features are smooth, rolling topography, with moderate to deeply incised valleys. Major drainage channels extend below 1,000 m elevation. Most of the terrain lies between 900 m and 1,500 m elevation, except in the valley bottom of Casino Creek which drops to about 700 m elevation.

The Tailings Management Facility (TMF), which incorporates the Waste Storage Area, is situated within the Casino Creek valley. The valley bottoms throughout the project area, with impeded drainage, have prominent permafrost features such as ice-rich peat plateaus, palsas, hummocky tussock fields and polygons. Ore stockpiles are generally situated on south to east facing slopes between the TMF and the open pit. These slopes are generally better drained and have frost susceptible soil. Topsoil/overburden stockpiles from stripping for the TMF Main Embankment are located on flatter slopes and hill top areas south of the TMF. Topsoil from stripping of the HLF area is stockpiled on a ridge located between the open pit and HLF at an elevation of about 1400 m.

2.2 HYDROMETEOROLOGY

The climate at the Casino Project area is characterized by long, cold, dry winters and short, warm, wet summers, with conditions varying according to altitude and aspect. Streamflow in the region is typically highest in May due to melting of the winter snowpack. Annual peak instantaneous flows commonly occur in this freshet period on larger rivers, but on smaller streams they may also occur in summer or early autumn due to intense rain or rain on snow events. Flows decrease throughout the winter and minimum flows typically occur in March or April.



The climate and hydrology at the Casino Project site have been assessed based on both short-term site data and longer-term regional data. Climatic data were collected on-site at the Project climate station located in the upper Casino Creek sub-watershed at an elevation of 1200 m. The period of site record extends from 1993 to 1994 and from 2008 to 2011. Preliminary streamflow data were collected by Hallam Knight Piésold in 1993 and 1994. A new data streamflow collection program was initiated by AECOM in 2008, with the installation of ten streamflow gauging stations. As of 2012, nine streamflow gauging stations are considered to be in active operation and continue to be operated at present by Knight Piésold Ltd (KPL).

The mean annual unit runoff for undisturbed catchments in the project area was estimated to be approximately 183 mm, based on the long-term estimates of streamflow for the hydrology station W4 on Casino Creek. The mean annual precipitation is estimated to be 510 mm, with 65% falling as rain and 35% falling as snow. The annual potential evapotranspiration value is estimated to be 300 mm, based on measured temperatures at the Project site climate station, and long-term regional temperature records. Details of the hydrometeorological analyses are presented in the KPL report “Updated Hydrometeorology Report” (Ref. No. VA101-325/8-11, July 9, 2012).

2.3 SEISMICITY

The region of the southwest Yukon Territory and northwest British Columbia is one of the most seismically active areas in Canada. The seismic hazard in the region is also influenced by the seismically active region of southeast Alaska. The coastal region has experienced many large earthquakes, including events with magnitudes in the range of magnitude 7.0 to 8.0. In 1958 a magnitude 7.9 earthquake occurred along the Fairweather fault (the northern extension of the Queen Charlotte transform fault). The most significant inland zone of seismicity follows the Dalton and Duke River segments of the Denali fault zone through the southwest Yukon. Farther inland there is only minor seismicity between the Denali and Tintina fault systems, including the region of the Casino Project site.

A probabilistic seismic hazard assessment has been carried out for the Casino project site to provide seismic parameters for design of project facilities. Details and results of the seismic hazard analysis are provided in the KPL report "Feasibility Design of the Tailings Management Facility" (Ref. No. VA101-325/8-10, December, 2012). Figure 2.1 shows the regional tectonics and historical seismicity of the Yukon and surrounding regions. Review of historical earthquake records and regional tectonics indicates that the Casino Project site is situated in a region of low seismicity and moderate seismic hazard.

3 – GEOTECHNICAL CONDITIONS

Geological information and geotechnical conditions for the WSA, ore stockpiles and topsoil stockpiles has been derived from interpretation of information and data provided by KPL site investigations at the project site in 1993, 1994, 2010, 2011 and 2012. These site investigations have included test pitting, geotechnical drilling, laboratory testing of recovered rock core and bulk soil samples, in situ permeability testing and geophysical surveys. The locations of site investigations in the area of the ore stockpiles are shown on Figure 3.1. The locations of site investigations in the area of the TMF, WSA and topsoil/overburden stockpiles located south of the TMF are shown on Figure 3.2.

Detailed results of previous geotechnical investigations at the Casino Project site are included in KPL reports:

- "Report on Preliminary Surficial Geotechnical Investigations" (Ref. No. 1831/1, March, 1994)
- "Data Compilation Report on 1994 Geotechnical/Hydrogeological Investigations" (Ref. No. 1832/2, February 22, 1995)
- "2010 Geotechnical Site Investigation Data Report" (Ref. No. VA101-325/3-4, November 2, 2010)
- "2011 Geotechnical Site Investigation Data Report – Waste Management Facilities" (Ref. No., VA101-325/8-5, December, 2012), and
- "2012 Geotechnical Site Investigation Data Report – Waste Management Facilities" (Ref. No., VA101-325/8-14, December, 2012).

A summary of the geotechnical conditions for the Waste Storage Area, ore stockpile areas and topsoil stockpile areas are provided in the following sections.

3.1 WASTE STORAGE AREA

The waste storage area is located in the upstream part of the TMF impoundment area, in Casino Creek valley. The WSA is underlain by the following geotechnical units:

- Overburden:
  - Topsoil
  - Silty SAND to GRAVEL with some cobbles, trace clay (residual soil and colluvial veneer) along valley ridges and upper slopes
  - SILT and SAND with some gravel and cobbles, trace clay (colluvial apron) and interbedded SAND and gravelly SAND with some cobbles (alluvium) along the lower slopes and valley bottom
- Weathered Bedrock, and
- Fresh Bedrock.

The ridges and upper slopes of Casino Creek valley are characterized by well drained colluvial and residual sandy soils, supporting stands of tall spruce and poplar. The colluvial veneer is locally overlying residual soils near the top of the slopes. The colluvium is relatively thin along the upper part of particularly south facing slopes, and generally absent on ridges where residual soils predominate.

The colluvial veneer along the slopes of the valley is comprised of a fine to medium grained sand with some silt, supporting coarse gravel and cobble sized broken rock fragments. The thickness and

organic content generally increase down-slope. On north-facing slopes, the colluvial veneer is mostly frozen.

Along slopes and ridges in Casino Creek valley the depth to bedrock varies from about 0.5 to 7.5 metres, with an average overburden thickness of between 2 and 3 metres. The depth to bedrock is considerably larger near the valley bottom, where slopes are gentler. An overburden thickness of up to 23 metres has been observed in the valley bottom near the proposed Main Embankment, and conditions are expected to be similar in the waste storage area. This material is classified as colluvial apron, which has a higher fines and organic content than the colluvial veneer. The colluvial apron is mostly frozen, with excess ice and massive ice layers. The colluvial apron is underlain by alluvium close to Casino Creek. The alluvium is coarse grained and comprised of interbedded sands and gravelly sands with cobbles, and is mostly unfrozen due to the presence of Casino Creek.

Dawson Range Batholith (Mid-Cretaceous) is the main country rock in the WSA area and is dominantly granodiorite in composition. Quartz monzonite and diorite are less abundant.

Permafrost is discontinuous along Casino Creek valley and is restricted primarily to valley bottoms, north-facing slopes and local shaded areas.

3.2 ORE STOCKPILE AREAS

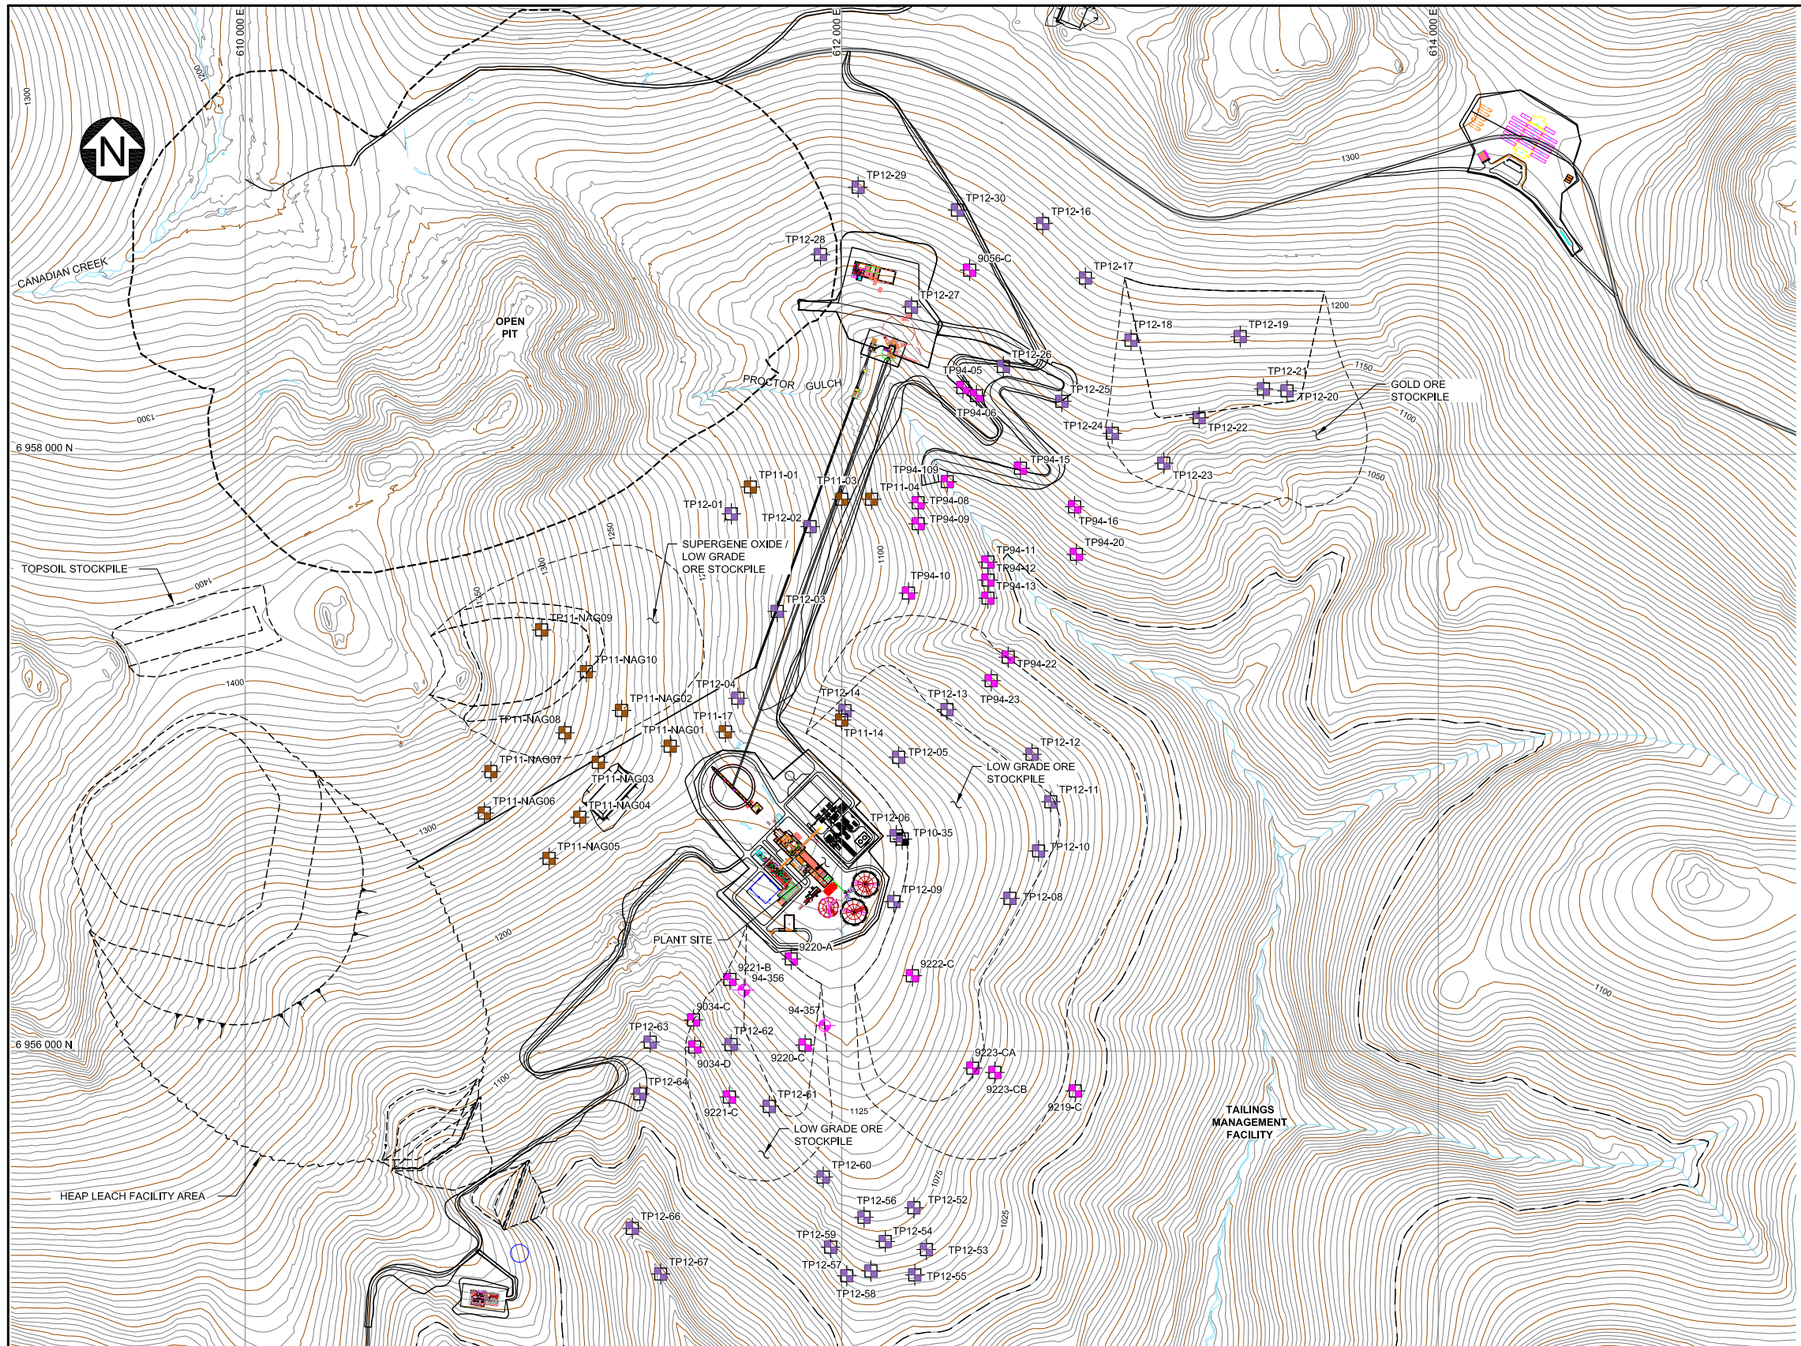
The proposed ore stockpiles are located on south to east-facing slopes near the plant site and open pit. Vegetation in these areas is comprised primarily of deciduous black spruce with thin moss and forest litter cover. Soil profiles throughout the areas typically comprise a thin veneer of organic rich topsoil and colluvium overlying in situ weathered residual soils or competent bedrock. The ore stockpile areas have the following generalized stratigraphy:

- Overburden:
  - Topsoil with many cobbles and boulders
  - Silty to gravelly SAND with some cobbles and boulders (Residual Soil and Colluvium)
- Weathered Bedrock, and
- Fresh Bedrock.

The topsoil thickness is typically less than 0.3 m, and comprises dry to moist organic-rich sandy silt with peat layers. Coarse talus blocks are found throughout the stockpile areas and are common at higher elevations such as the proposed gold ore and supergene oxide stockpiles. The underlying soil generally consists of loose silty sand to sandy silt with some gravel, cobbles and boulders (Residual Soil and Colluvium). It typically ranges in thickness from 0.3 to 3 m.

The overburden is often underlain by up to two meters of weathered bedrock. The bedrock is locally completely weathered and friable. Total depths to competent bedrock range from about 0.5 to 4 m with an average depth of approximately two meters. However, the depth to bedrock is greater in the Gold Ore stockpile area located east of the open pit. All test pits were refused on dense frozen soils at this location, and no bedrock was encountered. The overburden thickness typically exceeds five meters in the area of the Gold Ore stockpile.

The bedrock is predominantly comprised of medium strong, slightly weathered Dawson Range Batholith Granodiorite, with locally Quartz Monzonite.



Discontinuous zones of permafrost were recorded throughout the stockpile areas. Thin ice lenses were found in the overburden and interstitial ice crystals were observed in completely weathered bedrock.

Other areas are characterized by well-drained colluvial and/or residual sandy soils supporting stands of tall spruce and poplar.

A perched water table was observed directly below ground surface in several test pits with frozen soils. The maximum depth at which the groundwater table was observed was approximately two to three metres below ground surface in all Ore stockpile areas. In the majority of the test pits no water level was observed.

3.3 TOPSOIL STOCKPILE AREAS

Limited site investigations have been performed to date at the proposed locations of the topsoil stockpiles, north of the HLF and south of the TMF. The topsoil stockpiles are located at hilltop areas, which are characterized by a thin layer of topsoil, underlain by residual soil and bedrock. The residual soil generally consists of loose silty sands and gravels, with some cobbles and boulders. A maximum overburden thickness of approximately 3 m is expected. Permafrost is generally limited or absent in hilltop areas.

4 – WASTE STORAGE AREA AND STOCKPILES DESIGN

4.1 DESIGN BASIS

All mine waste rock and overburden material generated by open pit operations is to be stored in an environmentally sound, safe and secure manner in a permanent storage facility.

The current mine production schedule indicates that a total of approximately 658 million tonnes of waste rock and overburden will be produced over the life of the mine. A geochemical waste characterization program has been completed by Others to predict the potential reactivity of waste rock and overburden materials from the open pit. The findings of these studies indicate that almost all of this waste material comprises Potentially Acid Generating (PAG) and Metal Leaching (ML) materials. These PAG and ML waste materials will be placed and stored subaqueously in a Waste Storage Area (WSA) located within the Tailings Management Facility (TMF). The TMF has been sized to provide sufficient capacity to store approximately 956 million tonnes of tailings (including cyclone sand tailings used as embankment fill) and subaqueous disposal of 658 million tonnes of potentially reactive waste materials. Tailings and potentially reactive waste rock and overburden materials will be deposited in the TMF concurrently over the mine life.

In addition to the WSA, temporary ore stockpiles and a number of topsoil stockpiles will be located at engineered storage sites.

Approximately 157.5 million tonnes of gold ore will be processed at the Heap Leach Facility (HLF). This gold ore will be stored in a temporarily stockpile near to the crusher and will report to the heap leach facility over a period of about 18 years, starting in the pre-production years (3 years prior to mill start-up) and continuing up to Year 15 of mill operations. Heap leach facility operations will commence during pre-production stripping of the open pit.

During mine operations approximately 144 million tonnes of Low Grade ore and 32 million tonnes of Supergene Oxide (SOX) ore will be stored in temporary stockpiles. The SOX ore will be stockpiled during the pre-production years and in Year 1 of mill operations, and report to the mill during Years 4 to 12 together with direct feed mill ore. Low Grade ore will be stockpiled up to Year 17 and milled during the last four years of mine operations (Years 19 to 22).

It is anticipated that approximately 2 to 3 million tonnes of Non-Acid Generating (NAG) waste rock (leach cap material) will be produced during pre-production mining. This material will be used in the construction of the TMF Starter (Stage 1) embankment. Any NAG waste rock that is either unsuitable for use as a construction material or in excess of construction material requirements will be placed in the WSA or an adjacent surface dump.

The temporary storage of topsoil recovered during the construction of mine site facilities is required to ensure sufficient reclamation medium is available for mine closure. Topsoil recovered during construction will be stockpiled at select locations close to the material source.

A summary of the annual mine production schedule is presented in Table 4.1. Table 4.2 summarises the annual production and handling schedule of stockpiled ore.

The WSA and temporary stockpiles will be designed to remain stable under both static and seismic loading conditions. The minimum acceptable factor of safety for waste and ore stockpiles under static conditions is 1.3 for short-term operating conditions and 1.5 after closure and reclamation. All ore and topsoil stockpiles will be removed before or at closure of the mine. In the event of a premature mine closure it is anticipated that the stockpiled ore would need to be hauled to the TMF for disposal, or potentially re-handled for processing at the mill for delivery to the TMF as tailings. Details of the closure plan are being developed by Others.

The design earthquake defined for seismic stability assessment of the stockpile slopes is the 1 in 500 year earthquake, with a corresponding peak ground acceleration of 0.08g (mean hazard value on soft rock/very dense soil) and earthquake magnitude of 8.0. A factor of safety under seismic conditions of less than 1.0 is acceptable provided that any predicted deformations resulting from seismic loading are not significant, and would not impact mine site facilities, including the WSA and TMF.

The 1 in 100 year 24-hour storm event is defined as the design storm event for the sizing of surface runoff and diversion ditches for ore stockpiles. The 24-hour precipitation depth associated with this storm event was estimated according to the Rainfall Frequency Atlas of Canada (Hogg and Carr, 1965) as presented in the KPL report "Updated Hydrometeorology Report" (Ref. No. VA101-325/8-11, July 9, 2012).

A summary of the design basis for the WSA and stockpiles is presented in Table 4.3.

4.2 DESIGN AND OPERATION

Storage piles have been designed to accommodate the following materials:

- Potentially reactive (PAG and ML) waste rock and overburden
- Stockpiled ore (Low Grade ore, Supergene Oxide ore and Gold leach ore), and
- Topsoil/overburden materials.

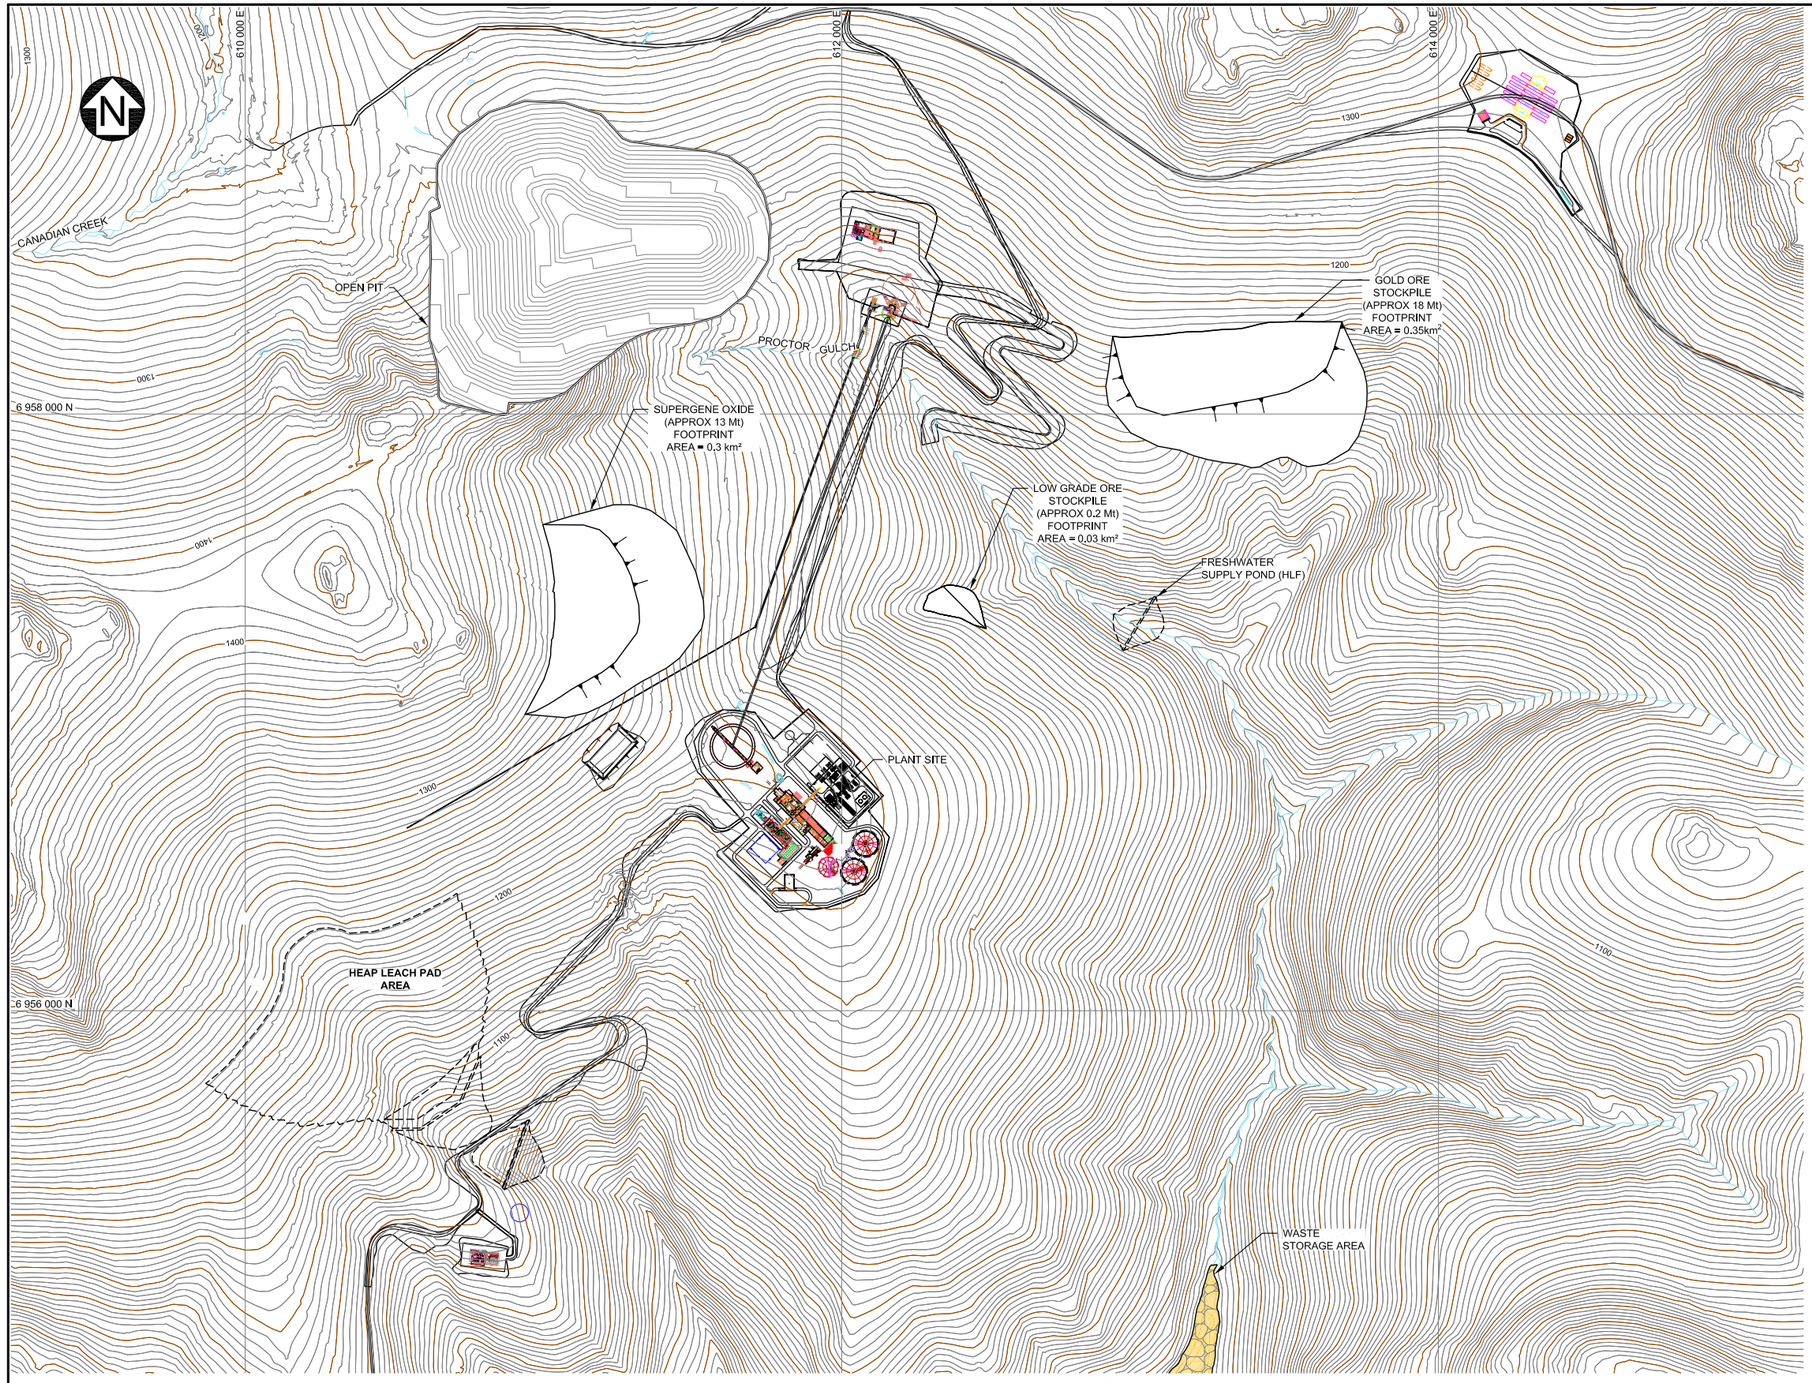
The location and configuration of the Waste Storage Area and ore stockpiles is presented on the overall site general arrangement plan shown on Figure 1.2**.** A plan view of the WSA and stockpiles development over the life of mine is shown for Year -1 (Pre-production), Year 1, Year 4, Year 10 and Year 22 (Final) on Figures 4.1 to 4.5 respectively. Figure 4.6 shows typical slope configurations for the ore stockpiles and topsoil stockpiles.

The specific design and operating requirements for the WSA, ore stockpiles and topsoil stockpiles are described in the following sections.

Knight Piésold CONSULTING

TABLE 4.3

CASINO MINING CORPORATION
CASINO COPPER-GOLD PROJECT



SUMMARY OF DESIGN BASIS FOR WASTE STORAGE AREA AND STOCKPILES

Print Dec/19/12 14:10:47

ITEM	DESIGN CRITERIA
Mine Production	• Total ore milled = 965.2 million tonnes (Mt) • Mine Operating Life = 22 years (+ 3 pre-production years) • Mill throughput= ~125,000 tpd • Heap Leach operations= ~157,5 million tonnes of gold ore
Stockpiled Ore	• Topsoil from embankment foundation preparation will be stockpiled for reclamation. • Low grade ore stockpiled during operations ◦ Maximum size = 143.8 Mt • Supergene Oxide ore stockpiled during operations ◦ Maximum size = 32.4 Mt • Gold Ore stockpiled during operations (reports to Heap Leach Facility) ◦ Maximum size = 39.4 Mt
Potentially Reactive Waste Rock and Overburden	• Produced from years 1 to 19 and stored in Waste Storage Area (WSA). • Total waste production is 658 million tonnes (overburden and waste rock) at variable rate.
Non Reactive Waste Rock (Leach Cap material)	• Approximately 2 to 3 million tonnes produced in pre-production years • Used for TMF Stage 1 (Starter) Embankment construction
Seismic Criteria	• Design Earthquake: 1/500 year event • Magnitude = 8.0 • Peak ground acceleration = 0.08g (Mean hazard value for soft rock / very dense soil conditions)
Stability Criteria	• The minimum acceptable factors of safety for each case considered are as follows: ◦ Short term (during mine operations) 1.3 ◦ Long term (closure) 1.5 (all stockpiles processed or removed to TMF prior to closure) ◦ For seismic loading condition, a factor of safety less than 1.0 is acceptable provided that any predicted deformations are minor, and would not impact mine site facilities, including the WSA and TMF.
Water Management	• Diversion ditches constructed upstream as required to minimize contact water with ore stockpiles. • Design storm event for ditch sizing is the 1 in 100 year event.
Closure Criteria	• Final crest of WSA to be levelled and contoured as required to provide long term stability. • Footprint of ore stockpiles to be covered with suitable topsoil and revegetated. • Stockpiled topsoil / overburden material used for reclamation of TMF and HLF.

4.2.1 Waste Storage Area

Approximately 658 million tonnes of potentially reactive (PAG and ML) waste rock and overburden material from the open pit will be placed into the WSA. The WSA will be operated to maintain a minimum separation between the WSA and the TMF embankments of approximately one km. This separation will allow development of a NAG tailings beach between the TMF embankments and the WSA. The tailings deposit will provide a low permeability transition zone between the coarse, permeable waste rock and the TMF embankments. This low permeability zone will function as a seepage limitation and control measure.

Development of the WSA is based on the mine production schedule presented in Table 4.1. It will be developed with a similar rate of rise as the tailings. The on-going maximum elevation of the WSA will be maintained at an elevation above the potential flood level of the TMF supernatant pond. The crest will be maintained several metres higher than the tailings and supernatant pond to provide a dry, stable surface for access and placement of material. The crest of the WSA will be covered with tailings and submerged by the supernatant pond in the later years of the mine life when stockpiled low grade ore is being milled after open pit mining is complete. Based on the current mine production schedule, approximately four years of tailings deposition will occur after final placement of waste rock in the WSA.

Waste rock deposition shall satisfy short and long term stability requirements. An overall slope of 1.5H:1V has been assumed for design purposes, but steeper slopes may be achieved in practice.

The following are recommended methods of construction and operation to ensure on going stability and performance of the WSA:

- Waste rock and overburden will be transported from the open pit using haul trucks. The material may be end dumped over the face or spread by dozers over the crest of the waste dump.
- Trial sections may be constructed in the field during the initial stages of development to monitor waste pile stability and foundation performance.
- Waste rock shall be end dumped over the crest to allow for maximum segregation of the coarser material at the base of each bench. For overburden materials, end dumping short of the crest and dozing over may be required.

These methods may be updated and revised, as necessary, based on field observations and performance monitoring during the initial stages of WSA development.

Details of the design and operation of the TMF, including the co-disposal of waste rock and overburden materials within the WSA, are provided in the KPL report “Feasibility Design of the Tailings Management Facility” (Ref. No. VA101-325/8-10, December, 2012).

4.2.2 Ore Stockpiles

Stockpiled ore will be placed on the south to east facing slopes between the TMF and the open pit, and will expand progressively over the mine life. The stockpiled ore will vary over the mine life, as shown in Table 4.2, with a peak of approximately 144 million tonnes of Low Grade ore stockpiled in Year 17. The stockpiled ore will be milled over the later years of the mine life. Low Grade ore mined after Year 12 can be stockpiled at the same location used for the SOX ore stockpile, located south of the open pit. SOX ore stockpiled in pre-production and Year 1 of mill operations will report to the mill in Years 4 to 12.

The following are recommended methods of construction and operation to ensure stockpile stability and to allow easy recovery of the ore. These methods may be updated and revised, as necessary, based on field observations and performance monitoring during the initial stages of waste pile construction.

Pre-Production

- Clear vegetated areas and strip the foundations prior to loading to remove the organic layer and to initiate the melting of any permafrost or frozen soils
- Strip topsoil to windrow for use during reclamation
- Remove any ice rich, frost susceptible and unsuitable soft or thawed and saturated materials in the foundation prior to ore placement, and
- Construct diversion and runoff collection ditches where required.

Operations

- Ore material will be transported from the pit using haul trucks. The material will be end dumped and spread by dozers over the crest of the pile.
- Load the ore stockpile in lifts starting at the toe and working progressively upslope. Each lift may be developed at the angle of repose for the material (approximately 1.3H:1V). However, benches should be left along the toe of each successive lift to establish a maximum overall slope angle of 2H:1V.
- The lifts should be loaded and developed in a direction parallel to the slope wherever possible to avoid stress concentrations associated with “nose” configurations where the axis of the pile extends outward and perpendicular to the slope.
- Trial sections should be constructed in the field during the initial stages of development to monitor pile stability and foundation performance.

The prepared base of the stockpiles will function as a working platform during the re-handling of the ore for milling.

Unsuitable soils excavated from the footprint of the ore stockpiles can be placed within the TMF. It is recommended to excavate down to competent bedrock in areas where permafrost or frozen soils are encountered during construction. Bedrock is generally encountered at shallow depths throughout the stockpile areas with an assumed average depth of approximately two meters, and will provide a solid foundation that is not susceptible to frost effects. However, the depth to bedrock is deeper (over 5 metres) in the area of the gold leach ore stockpile. For this area, and any other areas where the depth to competent bedrock is deep, it may be preferable to develop the stockpile configuration to provide suitable stability by buttressing at the toe of the pile.

Diversion ditches will be required upstream of the ore stockpiles to minimize the contact of runoff water with the ore. Details of the surface water management strategy are described in Section 4.4.

4.2.3 Topsoil Stockpiles

Topsoil materials will be stripped during development of the plant site, the open pit, ore stockpiles, HLF and the TMF embankments. The topsoil will be placed in stockpiles for use in reclamation activities. The stockpiles will generally be located within two kilometres of the material source. Topsoil salvaged from the base of ore stockpiles will be windrowed around the toe of the piles. The location of the various topsoil stockpiles is shown on the general arrangement plan on Figure 1.2.

Initial construction and ongoing development of mine site facilities will require that topsoil and organic material be salvaged from select areas of ground disturbance. Soil salvaging and stockpiling operations will require a variety of management practices to ensure that soils are handled and stored properly during all phases of the mine development. Soil management practices to be carried out for soil stripping, salvage and stockpiling are summarized below:

- Wet conditions will be avoided when possible during soil salvage operations.
- Excessive traffic will be avoided during the salvage process to minimize admixing, compaction and rutting.
- Traffic will be confined to established routes to avoid unnecessary compaction of soil in undisturbed areas.
- Soil will be stockpiled in locations to minimize the possibility of further disturbance.
- Stockpile locations will, where possible, be located a sufficient distance away from operations to protect soils from contamination from risk of spills or metal deposition.
- Protective ditches will be constructed where practical around stockpiles to prevent any spill reaching stockpiles.
- Erosion will be managed by limiting the height and slope of stockpiles. Erosion control measures will be implemented including prompt vegetation establishment on topsoil stockpiles to reduce exposure of bare soil.
- Where possible soil stockpiles will be oriented to reduce wind erosion and located to reduce wind exposure.

These methods may be updated and revised, as necessary, based on field observations and performance monitoring during stockpile development. Toe berms to ensure stockpile stability may be required, based on foundation conditions and the strength characteristics and condition of the stockpiled material.

The topsoil stockpiles will be limited to a maximum height of about 20 m (crest to downstream toe), with consideration of site-specific ground conditions, and constructed as wrap around dumps in an ascending sequence. This construction method is used to improve overall stability as each constructed lift will act as a buttress for the toe of the next lift. In addition, the topsoil stockpiles will be constructed such that the overall slope angle will average 14 degrees (4H:1V). These flat overall topsoil stockpile slopes will minimize the risk of slope instability, reduce erosion potential and improve the amenability for vegetation growth. The use of topsoil for concurrent reclamation activities will reduce the quantity of material required to be stockpiled. Figure 4.7 shows the slope configuration for the topsoil stockpiles.

It is anticipated that some overburden material will also be required for reclamation and erosion control of the downstream slopes of TMF embankments. Overburden and topsoil materials will be stockpiled separately.

4.3 STABILITY OF WASTE STORAGE AREA AND STOCKPILES

A stability assessment has been carried out for the WSA, topsoil stockpiles and ore stockpiles.

The stability of the WSA is not a concern, as the slope of the waste material adjacent to the tailings deposit is buttressed by the tailings, with only a few metres height of the waste pile above the surface of the tailings. Acceptable slopes and benching of the waste rock will depend on the

elevation difference between the waste rock, tailings and supernatant pond during operations, as well as the condition of the tailings. An overall slope of 1.5H:1V has been assumed for design purposes, as shown on Figure 1.3, but steeper slopes may be achieved in practice. Any sloughing and ravelling of waste material into the tailings and supernatant pond will not impact the integrity of the TMF. The tailings embankments are typically over one kilometre from the WSA and it is anticipated that there will be a significant tailings beach width (over 200 metres) that slopes upward between the pond and embankments.

To provide stability the slopes of the topsoil stockpiles are comparatively low and flat, with gently sloped faces with an overall slope angle of about 14 degrees (4H:1V). Toe berms to ensure stockpile stability may be required, based on the foundation conditions encountered and the strength characteristics and condition of the stockpiled material.

Numerical stability analyses have been carried out for the ore stockpiles. Two sections have been considered:

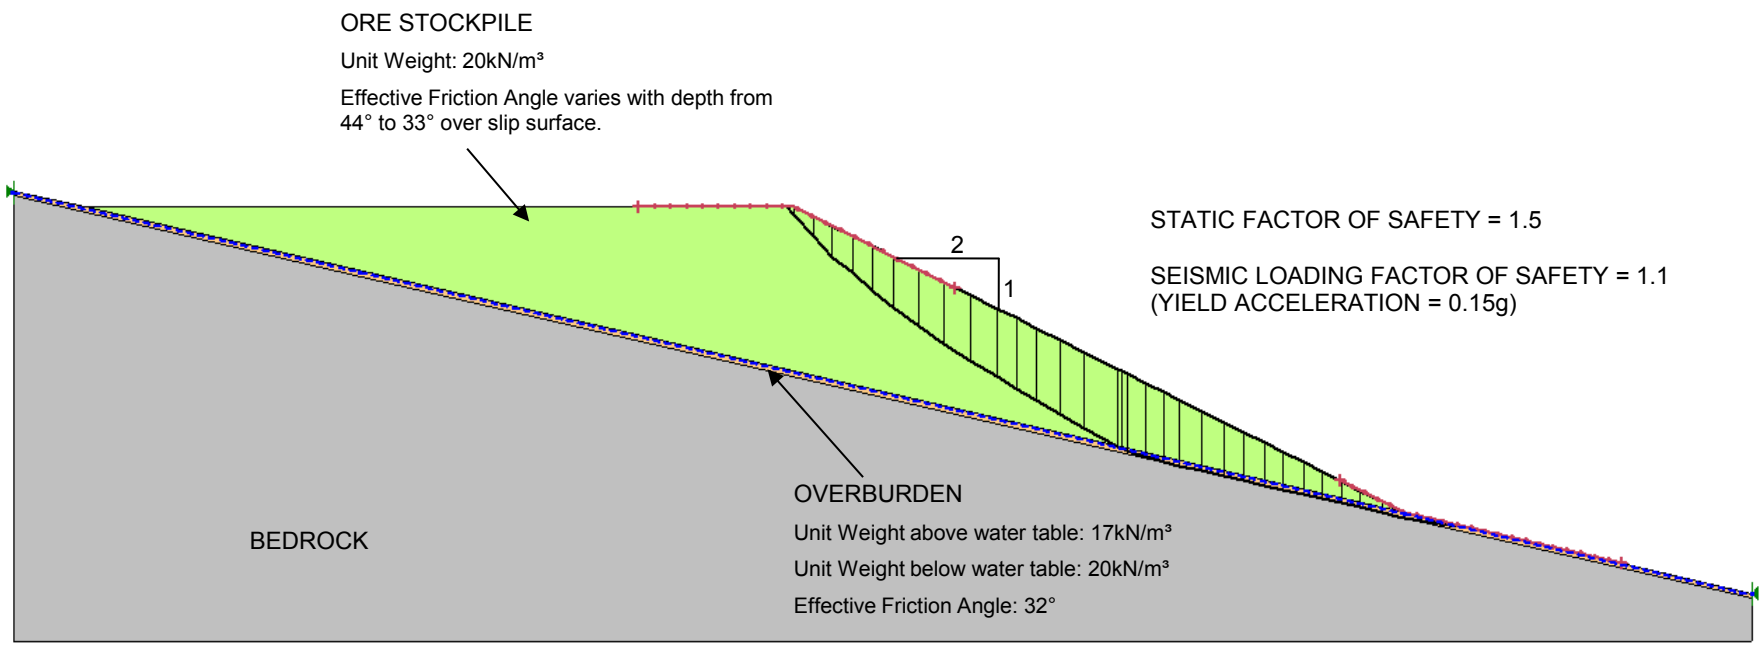
- Low Grade ore stockpile, with an overall slope of 2H:1V and overburden thickness of 3 metres, representing the stockpile located south of the open pit, and
- Gold Leach ore stockpile, with an overall slope of 2H:1V and overburden thickness of 10 metres (located in an area where the thickness of the overburden is typically greater than 5 metres).

The conditions and stability of the other Low Grade ore stockpiles are similar to or better than those identified for the Low Grade ore stockpile south of the open pit, based on consideration of overburden thickness and ground slope.

Figures 4.7 and 4.8 show the stockpile sections and material parameters used in the stability analyses for the Low Grade ore stockpile and Gold Leach ore stockpile respectively. Both sections are based on the maximum stockpile height achieved during operations.

The stability analyses for the ore stockpiles were carried out using the limit equilibrium computer program SLOPE/W. In this program a systematic search was performed to obtain the minimum factor of safety from a number of potential slip surfaces. Factors of safety were calculated using the rigorous Morgenstern-Price method of analysis. In accordance with standard industry practice, the minimum acceptable factor of safety for waste and ore stockpiles under static conditions is 1.3 for short-term operating conditions and 1.5 after reclamation and abandonment. Seismic loading was modelled by performing a pseudo-static analysis. A factor of safety under seismic conditions of less than 1.0 is acceptable provided that any predicted deformations resulting from seismic loading are not significant, and would not impact mine site facilities, including the WSA and TMF.

The design earthquake has been taken as the 1 in 500 year return period event, consistent with the Operating Basis Earthquake (OBE) defined for the TMF. The corresponding mean peak ground acceleration is 0.08g. A design earthquake magnitude of 8.0 has been selected based on a review of regional tectonics, potential seismic source zones in the region and historical seismicity.



The following parameters and assumptions were incorporated into the stability analyses:

- The unit weights used for the stockpiled ore and foundation soils were based on typical values for similar materials. An average bulk unit weight of 20 kN/m^3 was used for the stockpiled ore materials. Unit weights of 17 kN/m^3 and 20 kN/m^3 were used for the foundation overburden soils above and below the water table respectively.

- The effective friction angle of the overburden materials at the base of stockpile is assumed to be 32 degrees for cleared foundations (all unsuitable and ice rich soils are assumed to be removed).
- The shear strength for stockpiled ore material has been defined using a conservative strength function that defines the variation of shear strength with normal stress. The strength function is based on published information on the shear strength properties of granular rock fill materials (Leps, 1970).
- The phreatic surface was assumed to be one metre below the base of the ore stockpile. This is based on information provided by test pitting during the site investigation programs.
- There are no excess pore water pressures generated by thawing of foundation materials. It is assumed that appropriate foundation preparation and/or excavation have been conducted in any areas with ice rich and frozen soils.

The minimum calculated static factor of safety is 1.5 for the Low Grade ore stockpile and 1.4 for the Gold Leach ore stockpile (about 1.35 for small shallow slip surfaces). These results indicate that the proposed configuration of the stockpile slopes is adequate to maintain short term (operational) static stability (factors of safety greater than 1.3). The potential slip surface and minimum static factor of safety calculated from the analyses are included on Figures 4.7 and Figure 4.8. In the event of a premature mine closure it is anticipated that the stockpiled ore would need to be hauled to the TMF for disposal, or potentially re-handled for processing at the mill for delivery to the TMF as tailings. Details of the closure plan are being developed by Others.

The seismic stability assessment of the ore stockpiles has included an estimation of potential seismically induced deformations from the design earthquake. To account for the possible amplification of ground accelerations as seismic waves propagate through stockpile, an amplification factor of 1.5 was assumed, resulting in an estimated average maximum acceleration of 0.12g within the waste rock pile. Potential deformations under earthquake loading have been estimated using the simplified methods of Newmark (1965) and Makdisi-Seed (1977). Predicted deformations calculated for the design earthquake are negligible. The consequences of a stockpile slope failure due to earthquake shaking is minimal and restricted to minor displacement of the surface of the stockpile slopes (ravelling). There would be a negligible impact on the integrity of the stockpile and little, if any, impact on other mine site facilities.

NOTES:

1. PHREATIC SURFACE ASSUMED TO BE AT A DEPTH OF 1 METRE BELOW BASE OF STOCKPILE.
2. AVERAGE OVERBURDEN THICKNESS OF 3 METRES ASSUMED.
3. STOCKPILE SECTION REPRESENTS MAXIMUM HEIGHT OF LOW GRADE ORE STOCKPILES (190 METRES FOR STOCKPILE LOCATED SOUTH OF OPEN PIT).

4.4 SURFACE WATER MANAGEMENT AND SEDIMENT CONTROL

The surface and diversion ditching system which discharges to the TMF basin, is designed to divert surface flow around the ore stockpiles to minimise contact with the water. The collection of seepage from the toe of the ore will not be required. The diversion ditching system consists of a series of ditches constructed along the upslope side of the stockpiles and are designed to meet the following design criteria:

- Design storm conveyance: 1 in 100 year 24-hour duration storm event
- Minimum freeboard = 0.3 m
- Maximum design storm flow depth = 0.5 m
- Minimum ditch grade = 0.01 m/m
- Minimum channel side slope = 2H:1V

Evaluation of the estimated surface runoff for the 1 in 100 year 24-hour storm event was undertaken using the Hydrologic Engineering Centre Hydrologic Modeling System (HEC-HMS). HEC-HMS simulates the precipitation-runoff processes of dendritic drainage basins and uses site specific data to accurately capture the specific climate and catchment conditions, including storm precipitation intensity distribution, snowmelt, catchment slope, drainage and precipitation losses.

Two different ditch systems are required for the diversion runoff: 'earth lined' and 'erosion protected'. The earth lined ditch sections are those portions of ditch with shallow grades and low flow velocities. The erosion protection ditch sections will require either riprap or synthetic lining to prevent ditch scouring and erosion when conveying runoff water at steeper grades and higher velocity flows. Based on the topography at Site, the total ditch widths range between three to four metres for protected ditch sections and four to five metres for the shallow-grade earth lined sections.

Sediment control fencing will be placed around the down-gradient perimeter sections of the stockpiles to prevent sediment discharge from the stockpiles.

4.5 RECLAMATION AND CLOSURE

Reclamation of ore stockpile footprints will be required for mine closure. As much as practical the reclamation will be carried out concurrent with mine operations.

It is anticipated that reclamation of the footprint of ore stockpiles will take place in the later years of mine operations and post mill closure as stockpiled ore is milled and the stockpile footprints are exposed. Reclamation will be conducted in conjunction with on-going environmental monitoring to ensure that sediment control and water quality objectives and criteria are met. A general arrangement of the project site at the end of operations (Year 22) is shown on Figure 4.5 including the location and configuration of the final WSA within the TMF.

The WSA will be fully contained within the final TMF at closure. No closure activities will be required on the WSA to ensure long-term geotechnical stability and integrity. The final configuration of the TMF and WSA provides a tailings layer approximately 3 metres thick over the surface of the WSA (assuming a horizontal tailings surface) with a 4 metre deep supernatant pond over the tailings layer at the end of operations (Year 22). A minimum cover of 2 metres of water is recommended to ensure geochemical containment of the WSA materials.

Topsoil and overburden materials stockpiled south of the TMF will be used for reclamation of the TMF beach and the downstream slope of the TMF Main Embankment. For the West Saddle Embankment a small quantity of topsoil and overburden will be stockpiled nearby and used for reclamation of the downstream slope. The topsoil stockpile located south of the open pit will be used for reclamation of the Heap Leach Facility. The windrow topsoil located at the toe of the ore stockpiles will be used to reclaim the stripped area of the stockpile foundations.

A closure and reclamation plan for the project is being developed by Others.

5 – SCHEDULE OF QUANTITIES

Quantity estimates for the materials and work items required for initial construction and for ongoing operations of the ore stockpiles and topsoil stockpiles are presented in Table 5.1. Quantities have been estimated for the following components of stockpile development and operation:

- Foundation clearing and preparation of ore stockpiles foundations
- Surface water management ditching, and
- Erosion and sediment control.

The estimated maximum footprint area for each of the ore stockpiles is included on Figure 4.5.

An average depth of 0.3 metres was assumed for stripping and grubbing of ore stockpiles footprints. Excavation of unsuitable overburden materials was assumed to a depth of 3 metres for the Low Grade ore and SOX ore stockpiles. Excavation of unsuitable overburden materials to a depth of 5 metres was assumed for the Gold Leach ore stockpile, where the depth of overburden is greater.

The Feasibility level quantities were measured on the basis of the designs and dimensions shown on the relevant Figures of this report. These quantities have been developed to enable costing to be conducted to a level of accuracy of ± 15 percent. It is understood that the all capital costs and operating costs will be prepared by Others.

The cost estimate will also need to include the following items:

- Site haul roads to ore/topsoil stockpiles and the WSA
- Haulage of ore and topsoil materials to/from stockpiles
- Haulage of potentially reactive mine waste rock and overburden materials to the WSA, and
- Excavation of unsuitable (ice-rich and frost susceptible) soils from the ore stockpiles, and haulage and placement of these materials into the TMF.

CASINO COPPER-GOLD PROJECT

UPDATED HYDROMETEOROLOGY REPORT
(REF. NO. VA101-325/8-11)

EXECUTIVE SUMMARY

This hydrometeorology report provides climatic and hydrologic information for the Casino Copper-Gold Project in Yukon Territory, Canada. Specific climatic estimates are provided for the Project climate station situated at 1,200 m elevation, along with guidance on scaling these estimates to different elevations within the Project area. Hydrologic estimates are provided for nine gauging stations in the two watersheds that drain the Project area (Dip and Britannia Creek watersheds). The climatic and hydrologic estimates presented in this report are based on the available measured site data, in conjunction with regional regression analyses, which have been used to generate long-term synthetic data series for key climatic parameters and streamflow.

This report supersedes an earlier version, dated June 15, 2010 (KPL, 2010), which presented data collected up to 2009. This updated version incorporates an additional two years of climate and streamflow records (2010-2011) collected in the Project area and provides refined estimates of climatic and hydrologic parameters. Overall, the updated estimates for key parameters are in agreement with previously estimated values.

The estimated values for key climatic parameters, referenced to the Project site climate station at 1,200 m elevation, are presented below:

CLIMATIC PARAMETERS (1,200 M ELEVATION)	VALUE
Mean Annual Temperature	-3 C
Mean January Temperature	-17 C
Mean July Temperature	12 C
Extreme Minimum Temperature	-50 C
Extreme Maximum Temperature	30 C
Mean Annual Precipitation	510 mm
Mean Annual Rainfall	330 mm
Mean Annual Snowfall (Water-Equivalent)	180 mm
Mean Annual Rainfall/Snowfall Distribution	65% / 35%
2-Year 24-Hr Rainfall	29 mm
200-Year 24-Hr Rainfall	56 mm
Mean Annual Wind Speed	2.2 m/s
Maximum Wind Gust Speed	11.1 m/s
Prevailing Wind Direction	Southwesterly
Mean Annual Relative Humidity	68%
Mean Annual Potential Evapotranspiration	300 mm
Mean Annual Maximum Snow Water-Equivalent	140 mm
Mean Monthly Snowmelt for May (Water-Equivalent)	120 mm

Temperature and precipitation can be adjusted to reflect conditions at different elevations according to the following guidelines:

CLIMATIC PARAMETER ELEVATION ADJUSTMENTS	VALUE
Mean Monthly Temperature (April through October)	-0.6 C per 100 m
Mean Monthly Temperature (November through March)	Increases with elevation
Mean Annual Precipitation	+5% per 100 m

The streamflow and unit runoff results for gauging station W4 on Lower Casino Creek are presented below:

HYDROLOGIC PARAMETERS (LOWER CASINO CREEK (W4), DRAINAGE AREA 82 KM^2)	VALUE
Mean Annual Discharge	0.48 m^3/s
Mean Annual Unit Runoff	5.8 $l/s/km^2$
Mean Annual Runoff (Depth Equivalent)	180 mm/yr
Mean Monthly Discharge for May	1.37 m^3/s
Mean Monthly Unit Runoff for May	16.7 $l/s/km^2$
Mean Monthly Unit Runoff for May (Depth Equivalent)	45 mm/mo.
Natural Catchment Runoff Coefficient	0.4
2-Year Instantaneous Peak Flow	12 m^3/s
200-Year Instantaneous Peak Flow	40 m^3/s
10-Year, 7-Day Low Flow	0 m^3/s
10-Year Dry Monthly Flow	0.37 m^3/s
10-Year Wet Monthly Flow	3.01 m^3/s

Potential climate change effects have not been considered explicitly in any of the hydrometeorological estimates presented above, except for peak flows. Appropriate allowances for potential climate change effects should be made where necessary.

CASINO MINING CORPORATION
CASINO COPPER-GOLD PROJECT

UPDATED HYDROMETEOROLOGY REPORT (REF. NO. VA101-325/8-11)

SECTION 1.0 - INTRODUCTION

1.1 PROJECT DESCRIPTION

The Casino Copper-Gold Project is located in the Dawson Mountain Range of the Klondike Plateau approximately 300 km northwest of Whitehorse, Yukon Territory, as shown on Figure 1.1. The Casino Project is situated in the Dip Creek and Britannia Creek watersheds. Dip Creek drains southwest, eventually flowing into the White River, which is a tributary of the Yukon River. Britannia Creek drains north directly into the Yukon River.

The Project ore body is situated on a ridge between the Dip Creek and Britannia Creek watersheds. More specifically, the ore body straddles the drainage divide between the Casino Creek sub-watershed (tributary to Dip Creek) and the Canadian Creek sub-watershed (tributary to Britannia Creek). The Project includes an airstrip located in Dip Creek valley and a barge landing on the Yukon River near the Britannia Creek confluence. Access roads to these features will follow the Casino and Dip Creek valleys (to the airstrip) and the Canadian and Britannia Creek valleys (to the barge landing). The main access road to the Project area will connect to Carmacks.

1.2 REGIONAL SETTING

The Project is located within the Boreal Cordillera ecozone, which comprises much of the southern Yukon and a large portion of northern British Columbia, and more specifically within the Dawson Range ecoregion (NRC, 2010). The Boreal Cordillera ecozone is broadly characterized by the presence of several mountain ranges, including the Dawson Range, that trend in the north-westerly direction and include extensive plateau regions. The plateaus consist of flat or gently rolling upland terrain separated by broad valleys and lowlands.

The climate is characterized by long, cold, dry winters and short, warm, wet summers, with conditions varying according to altitude and aspect. Streamflow in the region is typically highest in May due to melting of the winter snowpack. Annual peak instantaneous flows commonly occur in this freshet period on larger rivers, but on smaller streams they may also occur in summer or early autumn due to intense rain or rain on snow events. Flows decrease throughout the winter and minimum flows typically occur in March or April.

The locations of regional climate and streamflow gauging stations operated by the Meteorological Service of Canada (MSC) and the Water Survey of Canada (WSC), respectively, are shown on Figure 1.2.

1.3 REPORT CONTENT

The climatic parameters presented in this report consist of the following:

- Temperature
- Rainfall, snowfall, and total precipitation
- Wind speed and direction
- Relative humidity
- Evapotranspiration, and
- Snowfall, snow accumulation, and snowmelt.

Climatic data were collected on-site at the Project climate station located in the upper Casino Creek sub-watershed at an elevation of 1,200 m. The period of site record extends from 1993 to 1994, and from 2008 to present. The site temperature and precipitation data were compared to the long-term record from the MSC climate station at Pelly Ranch, located 80 km to the east at an elevation of 454 m. Linear regression analyses of temperature and precipitation between the Casino and Pelly Ranch climate stations are described in Section 2.0 of this report along with the results of the analysis: a 54-year synthetic series of monthly temperature and precipitation at the Casino station, from which summary statistics have been computed.

Hydrologic information consists of streamflow, unit runoff, and runoff coefficient. Preliminary streamflow data were collected by Hallam Knight Piésold in 1993 and 1994. A new data collection program was initiated by AECOM in 2008, and continues to be operated at present by Knight Piésold Ltd. (KPL). KPL (2012) provided a comprehensive analysis of all available streamflow data and described a regional regression analysis used to generate a 33-year synthetic daily streamflow series for each of the nine gauging station locations in the Project area. Summary statistics of the 33-year streamflow series are presented in Section 3.0 of this report.

The following key hydrologic statistics for each gauging station presented are:

- Mean annual and monthly discharge and unit runoff
- Peak flows for various return periods from 2 years to 200 years
- 10-year, 7-day low flow
- 10-year wet and dry monthly flows, and
- Runoff coefficient (Lower Casino Creek station only).

SECTION 2.0 - CLIMATE

2.1 DATA SOURCES

2.1.1 Regional Climate Stations

Regional climate stations are operated by the MSC for several locations within the Klondike Plateau region and within 150 km of the Project location. The locations of selected stations are shown on Figure 1.2. The period of record, elevation, and mean annual temperature and precipitation at each station are provided in Table 2.1.

The MSC operated a climate station (Casino Creek, 2100310) within the general Project area, with measured data recorded between 1969 and 1995, with no years of complete record. The station elevation was 1,100 m. Based on the incomplete data for this station, the mean annual precipitation is approximately 400 mm with a mean annual temperature of -4 C.

Seven regional stations, listed in Table 2.1, have greater than 20 complete years of record. These stations are all situated in low-elevation settings (around 370 m to 650 m). Of these stations, Pelly Ranch is located closest to the Project area (approximately 80 km to the east of the Project area). Mean annual precipitation at the seven long-term stations ranges from around 290 mm to 420 mm, and mean annual temperature values ranging from around -3 C to -6 C.

2.1.2 Regional Climate Maps

Natural Resources Canada (NRC) maps of mean annual precipitation and lake evaporation in Yukon Territory are presented on Figures 2.1 and 2.2, respectively. The Project location lies in the middle of a broad zone of relatively low precipitation aligned northwest-southeast between large mountain ranges to the southwest (the St. Elias Mountains near the Pacific Coast) and the northeast (the Mackenzie Mountains along the Northwest Territories border), as shown on Figure 2.1. The zone of less than 400 mm mean annual precipitation roughly coincides with the Klondike Plateau. More specifically, the Project location is shown to lie in an area with less than 300 mm of mean annual precipitation, although this map (Figure 2.1) is based on relatively few regional climate stations and has a low resolution that does not account for local orographic effects. Mean annual lake evaporation in Yukon Territory is shown on Figure 2.2 to be more dependent on latitude than topography, although this map also does not account for local elevation effects. The Project location is shown to lie in an area with slightly less than 300 mm in mean annual lake evaporation.

2.1.3 Project Site Climate Station

In 1993, Hallam Knight Piésold Ltd. was retained by Pacific Sentinel Gold Corp. to undertake an environmental monitoring program for the Casino Project, which included both meteorology and hydrology monitoring programs. The field techniques followed during the program were presented in the report “Casino Project Baseline Environmental and Socioeconomic Studies” (HKPL, 1993). The data collection program involved the installation of a climate station near the Casino exploration camp, which measured both temperature and precipitation. This station

operated from 1993 to 1995. A new Project climate station was established at approximately the same location on October 3, 2008, and has been operational since that time. The active climate station is maintained by RWDI Air Inc. The location of the Project climate station in the upper Casino Creek sub-watershed is shown on Figure 2.3. The station elevation is approximately 1,200 m.

The climate station apparatus consists of a 10 m high, free-standing tower equipped with instrumentation, a datalogger and a logger enclosure (RWDI, 2012). The station records air temperature, rainfall, wind speed and direction, relative humidity, barometric pressure, and snow depth. The datalogger is equipped with a satellite modem and can be accessed remotely.

2.1.4 Project Site Snow Course

Yukon Environment has collected 33 years of snowpack data (1977-2011) at a snow course located near the Project site (snow course 09CD-SC01). The snow course is situated at an elevation of 1,065 m, and its location is shown on Figure 2.3. Snow depth and snow water-equivalent (SWE) are measured each year at the beginning of March, April, and May, followed by a measurement in mid-May.

2.2 TEMPERATURE

2.2.1 Region

Mean monthly temperature values for the long-term regional climate stations are presented on Table 2.2. These sites range in elevation from around 370 m to 650 m. Temperatures are warmest in July, with mean monthly temperatures ranging from 14 C to 16 C. Temperatures are coldest in January, with mean monthly temperatures ranging from -25 C to -28 C.

2.2.2 Project Site

2.2.2.1 Long-Term Synthetic Series Generation

The long-term temperature record at Pelly Ranch (2100880) was used as the basis for generating a long-term synthetic series of monthly temperature values at the Project site climate station. The Pelly Ranch record was missing nine months of temperature data between 2008 and 2011, so these were first estimated by regression analysis of monthly temperatures between Pelly Ranch and Dawson A, resulting in a 54-year infilled record available for modelling temperature at the Project site. Separate analyses were performed for each month in which estimated values were required at Pelly Ranch. Monthly temperatures were found to be well-correlated at Pelly Ranch and Dawson A, with coefficients of determination (R^2) values ranging from 0.91 to 0.97.

The concurrent temperature records from the Pelly Ranch and Project site climate stations were then correlated using a standard linear regression. The concurrent monthly temperature values for both stations used in the regression analysis are summarized in Table 2.3.

The concurrent monthly temperatures for the two stations were found to be strongly correlated in the warmer months (April through October), but more weakly correlated in the colder months (November through March). For April through October, the temperatures at the Project site were generally 1 C to 4 C cooler than Pelly Ranch, consistent with the higher elevation at the Project site. For November to March, the temperatures at the Project site were warmer compared to Pelly Ranch by an average of 5 C and up to 15 C. This is attributed to the settling of cold air in valleys during winter and the consequent temperature inversions that are often experienced between valley bottom sites (e.g. Pelly Ranch) and ridges (e.g. Project site) under such conditions. For the regression analysis, two relationships were developed, using a Pelly Ranch temperature threshold of -7 C to partition the data. For the warmer months with monthly temperatures above -7 C at Pelly Ranch (approximately April through October), the coefficient of determination (R^2) was 0.96. For the colder months with monthly temperatures below -7 C at Pelly Ranch (approximately November through March), the coefficient of determination (R^2) was 0.50. A 54-year synthetic series of monthly temperature values for the Project site climate station was generated by applying the two regression relationships to the Pelly Ranch monthly temperature record. For the period of record in which the Pelly Ranch data overlaps the Project site data, the actual measured data from the Project site were inserted into the temperature series for use in lieu of synthetic values.

2.2.2.2 Mean Annual and Monthly Temperature

The estimated long-term mean annual and monthly temperatures at the Project site climate station according to the synthetic temperature series are presented in Table 2.3. The mean annual temperature from the Project site temperature series is -2.9 C (round to -3 C). For comparison, the mean annual temperature recorded at the Project site climate station from 1993 to 2011 was -2.2 C. The mean July temperature at the Project site according to the synthetic temperature series is 11.6 C (round to 12 C), which is 2 C to 4 C cooler than the regional stations discussed in Section 2.2.1 and shown in Table 2.2. The mean January temperature at the Project site according to the synthetic temperature series is -16.8 C (-17 C), which is 8 C to 11 C warmer than the regional stations discussed in Section 2.2.1 and shown in Table 2.2.

2.2.2.3 Extreme Temperatures

The extreme maximum and minimum recorded temperatures at Pelly Ranch according to the 1971-2000 climate normals are 35 C and -60 C, respectively. According to the regression relationships described in Section 2.2.2.1, the corresponding maximum temperature at the Project climate station would be around 30 C. The corresponding minimum temperature at the Project station is more difficult to estimate due to the weaker correlation in winter temperatures, but it would be considerably warmer than -60 C.

The maximum and minimum temperatures recorded at the Project climate station between 2008 and 2011 are 26 C and -40 C, respectively. Based on the site data and the Pelly Ranch estimates, the estimated long-term extreme temperatures for the Project climate station are 30 C and -50 C.

2.3 PRECIPITATION

2.3.1 Region

Mean monthly and annual rainfall, snowfall and total precipitation values for the long-term regional climate stations are presented in Table 2.4. The mean monthly precipitation at all stations is greatest during the summer months of June through August, and lowest during the late winter months of February through April. Most of the precipitation falls in the form of snow during the months of November through March, and in the form of rain during the months of May through September. More snow than rain falls in the shoulder months of April and October, but mixed rain and snow conditions are common. The fraction of annual precipitation that falls in the form of rain/snow at these regional stations ranges from 56%/44% to 71%/29%.

2.3.2 Project Site

2.3.2.1 Long-Term Synthetic Series Generation

The long-term precipitation record at Pelly Ranch (2100880) was used as the basis for generating a long-term synthetic series of monthly precipitation at the Project site climate station. The Pelly Ranch record was missing nine months of precipitation data between 2008 and 2011, so these were first estimated by regression analysis of monthly precipitation between Pelly Ranch and two other stations: Dawson A and Mayo. Monthly precipitation at Pelly Ranch and the two other stations were not well-correlated, with coefficient of determination (R^2) values of 0.28 and 0.49 for Dawson A and Mayo, respectively. The missing monthly precipitation values at Pelly Ranch were estimated by taking the average of the values predicted by the Dawson A and Mayo regression relationships for each given month.

The concurrent precipitation records from the Pelly Ranch and Project site climate stations were correlated using a standard linear regression analysis. The rain gauge at the Project site climate station was not equipped to record snowfall, and rainfall measurements during the winter and shoulder months were likely affected from snow and ice interference. Therefore, only the Project site precipitation records for the months of May through September were considered in the regression analysis. It is assumed that any snow that fell during these months was captured in the rain gauge and recorded as the snow melted, so that the recorded rainfall in the months of May through September can be considered to represent total precipitation. The monthly precipitation values from Pelly Ranch and the Project site that were used in the regression analysis are summarized in Table 2.5.

The monthly precipitation at the two locations was found to be moderately well-correlated (R^2 = 0.63). A linear trendline forced through the origin had a slope of 1.66 (i.e. Project site precipitation exceeded Pelly Ranch precipitation by 66%). The elevation difference between Pelly Ranch (454 m elevation) and the Project site climate station (1,200 m elevation) is 746 m. If the difference in precipitation between the two climate stations were entirely attributable to orographic effects, then the corresponding orographic factor is 7% per 100 m elevation, which is close to the typical value for this region of 5% per 100 m. The 1.66 scaling factor was applied to the entire monthly precipitation record at Pelly Ranch to generate a long-term synthetic series of

monthly precipitation at the Project site climate station. In doing so, it was assumed that the observed precipitation ratio between the two sites in the months of May through September is also applicable to the winter months.

2.3.2.2 Mean Annual and Monthly Precipitation

The long-term estimated mean annual and monthly precipitation values at the Project site climate station according to the synthetic precipitation series are summarized in Table 2.5. The mean annual precipitation for the Project site based on the synthetic series is approximately 507 mm, of which 302 mm (60%) falls in the months of May through September. For comparison, the average precipitation for the months of May through September recorded at the Project site climate station from 1993 to 2011 was 329 mm. Mean monthly precipitation values at the Project site, according to the synthetic precipitation series, range from 17 mm in April to 91 mm in July.

The distribution of precipitation between rainfall and snowfall at the Project site was estimated by assuming that 100% of precipitation in the months of May through September falls as rain, 100% of precipitation in the months of November through March falls as snow, and 50% falls in each form in the shoulder months of April and October. The regional rainfall/snowfall distributions presented in Table 2.4 suggest that snowfall amounts may be greater than 50% in April and October, but it is expected that a significant portion of the snowfall in those months would melt relatively soon after falling so knowing the precise ratio of rainfall and snowfall in those months is not overly important. According to this distribution, 65% of annual precipitation falls as rain (329 mm) and 35% falls as snow (179 mm).

In order to reflect the uncertainty in the precipitation estimates, the recommended values for mean annual rainfall, snowfall, and total precipitation are 330 mm, 180 mm, and 510 mm, respectively.

2.3.2.3 Extreme 24-Hour Rainfall

The Rainfall Frequency Atlas of Canada (Hogg and Carr, 1985) provides a methodology for estimating the mean and standard deviations for the annual extreme 24-hour rainfall values. The resulting return period values were estimated using a Gumbel distribution. The results for the Project site climate station are presented in Table 2.6. The 24-hour rainfall depths range from 29 mm for a 2-year return period, to 56 mm for a 200-year return period.

For comparison, the maximum daily rainfall recorded at the Project site from 2009 to 2011 was 31.6 mm, which corresponds to a return period between 2 and 5 years according to the Rainfall Frequency Atlas. The maximum daily rainfall recorded at Pelly Ranch according to the 1971-2000 climate normals is 34.8 mm. Scaled by 1.66 to the Project site (according to the regression relationship for monthly precipitation), this would equate to 57 mm at the Project site, or close to a 200-year return period. Both of the above comparisons are taken to indicate that the extreme 24-hour rainfall estimates predicted by the Rainfall Frequency Atlas are reasonable.

2.4 WIND SPEED AND DIRECTION

Wind speed and direction are measured on-site at the Project climate station and data are available for the period from October 2008 through October 2011. A regional analysis to account for long-term variability in wind conditions was not deemed necessary.

The Project site wind speed data are presented in Table 2.7. The mean annual wind speed is 2.2 m/s (7.9 km/hr). The mean monthly wind speeds are higher in the spring, summer and autumn and lower in the winter. Monthly means range from 1.7 m/s in November and December, to 2.7 m/s in May. The maximum wind gust speed recorded between 2008 and 2011 was 11.1 m/s (RWDI, 2012). The predominant wind direction was southwesterly.

2.5 RELATIVE HUMIDITY

Relative humidity is measured on-site at the Project climate station and data are available for the period from October 2008 through October 2011. A regional analysis to account for long-term variability in humidity conditions was not deemed necessary.

The Project site relative humidity data are presented in Table 2.8. The mean annual relative humidity is 68%. Mean monthly relative humidity values are lowest in the spring (52% to 63% in the months of March through May) and higher throughout the rest of the year (67% to 76% in the months of June through February).

2.6 EVAPOTRANSPIRATION

In the 2010 hydrometeorology report (KPL, 2010), the Thornthwaite Equation was selected as the preferred method for estimating monthly and annual potential evapotranspiration (PET) at the Project site. The Thornthwaite equation (Thornthwaite, 1948) only requires mean monthly temperature as an input, as shown below. The equation assumes that PET is zero when the mean monthly temperature is below 0 C.

$$ET_0 = \begin{cases} 0, T < 0 \deg C \\ 16\left(\frac{10T_i}{I}\right)^a, 0 \le T \le 26.5 \deg C \\ -415.85 + 32.24T_i - 0.43T_i^2, T \ge 26.5 \deg C \end{cases}$$

Where:

PET_0 = Potential evapotranspiration (mm/month)
T_i = Mean monthly temperature (°C)
I = Heat index, sum of 12 monthly index values (i)
i = Monthly heat index
a = Empirically derived exponent, which is a function of I

And:

$$i = \left(\frac{T}{5}\right)^{1.514}$$

$$a = 6.75*10^{-7} I^3 - 7.71*10^{-5} I^2 + 1.79*10^{-2} I + 0.49$$

Monthly PET values based on measured temperatures at the Project site climate station, and long-term mean monthly PET values based on the synthetic temperature series for the Project site climate station, are presented in Table 2.9. Potential evapotranspiration values generally provide reasonable estimates of lake evaporation rates, and therefore the long-term values in Table 2.9 are assumed to be appropriate for estimating evaporation from lakes and ponds in the Project area.

The mean annual PET calculated for the period of site data collection is 321 mm. The estimated long-term mean annual PET is 304 mm. To reflect the uncertainties involved in estimating this value, the recommended value of mean annual PET at the Project site climate station is 300 mm.

2.7 SNOW ACCUMULATION AND MELT

The SWE measurements recorded at the Yukon Environment snow course 09CD-SC01 are presented in Table 2.10. The annual maximum SWE was typically recorded at the start of April or the start of May, with an approximately even distribution of occurrences between the two dates. The mean annual maximum SWE over the period of record is 141 mm. This value supports the estimated value of mean annual snowfall (180 mm) that was discussed in Section 2.3.2.2, since some of the snowfall is lost to sublimation or melt during the winter and early spring.

Monthly snowmelt in April and May was calculated from the SWE measurements by taking the difference of the values for April melt, and assuming that the entire snowpack was melted by the start of June. In years where the annual maximum SWE was recorded in May, the monthly melt for April was assumed to be zero. This method likely underestimates April snowmelt because it does not account for temporary snow accumulation and corresponding melt between the early April and early May measurement dates. Conversely, this method likely overestimates May snowmelt because the complete snowpack might not melt before the start of June in some years.

The estimated mean monthly snowmelt rates for April and May are 22 mm and 118 mm, respectively. These values represent 17% and 82%, respectively, of the annual melt after the date of maximum SWE accumulation.

The recommended, rounded value for mean annual maximum SWE is 140 mm. The recommended, rounded value for mean monthly snowmelt in May is 120 mm.

SECTION 3.0 - HYDROLOGY

3.1 REGIONAL STREAMFLOW ANALYSIS

The Water Survey of Canada (WSC) has operated nine streamflow gauging stations in the relative vicinity of the Project site (stations located within a 150 km radius and within the Dawson Range and Klondike Plateau) for varying periods over the past few decades. The locations of the regional WSC stations are presented on Figure 1.2.

All of the regional stations gauge flows from drainage areas much larger than the Project watersheds, and only five of the regional stations are currently active. Of the nine regional gauging stations, Big Creek has the smallest drainage area (1,750 km^2), and was deemed the most representative of the Project area streams. For this reason, Big Creek was selected as a regional surrogate for modelling streamflow at the Project area gauging stations. A more detailed rationale for the selection of the Big Creek gauging station is provided in KPL (2012).

A long-term synthetic flow series was developed for each Project station using a ranked regression modelling approach, which involved regressing ranked daily flows measured at the Project station against concurrent ranked daily flows from the WSC gauging station on Big Creek. The equations describing the regression trends were then applied to the 33-year streamflow record on Big Creek (1975-2010, excluding 1984, and 1994-1995), to produce synthetic daily flow series for the Project stations. A more detailed description of the regression analysis is provided in KPL (2012).

3.2 PROJECT AREA STREAMFLOW

3.2.1 Streamflow Measurement

Ten streamflow gauging stations have been operated in the Project area at various times since 2008. At present, nine streamflow gauging stations are considered to be in active operation, with one site deactivated in 2011 (W1) due to the development and natural destruction of a beaver dam, which interfered with the station's hydraulic control and caused the loss of the 2011 data. The locations of all active and discontinued stations are presented on Figure 3.1, and a simple schematic of the station network is provided on Figure 3.2. There are three stations in the Britannia Creek watershed (including the one deactivated station) and seven stations in the Dip Creek watershed. The latter can be further subdivided into four stations in the Casino Creek sub-watershed and three on the Dip Creek mainstem or the Victor Creek sub-watershed. The drainage areas at the Project gauging stations are provided in an inset table on Figure 3.1. Station W16, located on lower Dip Creek, has the largest drainage area of the Project gauging stations, at 384 km^2. Stations W18 and W11, located in the upper part of Casino Creek sub-watershed, have the smallest drainage areas, at 25 km^2 and 39 km^2, respectively.

An example measured streamflow hydrograph for the Lower Casino Creek gauging station (W4), including winter flow approximations and instantaneous discharge measurements, is shown on Figure 3.3. This hydrograph is indicative of the variable flows that occur in the Project area streams throughout the year, with multiple rain and snowmelt driven peak flow events throughout the spring, summer, and autumn, and low flows from late autumn through early spring.

3.2.2 Mean Monthly Discharge and Unit Runoff

The mean monthly and mean annual long-term synthetic flow estimates for the Project gauging stations are summarized in Table 3.1 (discharge) and Table 3.2 (unit runoff). The unit runoff results presented in Table 3.2 illustrate the following patterns:

- Mean annual unit runoff at the nine Project gauging stations ranges between 5.1 l/s/km^2 and 7.6 l/s/km^2, or 160 mm to 240 mm in annual runoff depth.
- The lowest unit runoff values (5.1 l/s/km^2 to 5.6 l/s/km^2) were estimated in the Britannia Creek watershed (stations W3 and W14), at the Lower Dip Creek station (W16), and in Upper Casino Creek (W11). The low unit runoff at the latter station is thought to be affected by surface flow losses to ground in the vicinity of the gauging station.
- Mean annual unit runoff at the gauging stations other than W11 in the Casino Creek sub-basin (W4, H18, and W18) range from 5.8 l/s/km^2 to 6.5 l/s/km^2, or 180 mm to 200 mm in annual runoff depth.
- Maximum monthly unit runoff occurs in May, corresponding with the month of maximum snowmelt, with mean values ranging between 13 l/s/km^2 and 29 l/s/km^2.
- In the Casino Creek sub-basin (other than station W11), mean May unit runoff ranges from 17 l/s/km^2 to 19 l/s/km^2.
- Mean monthly unit runoff at all stations is estimated to reach a minimum of 0.1 l/s/km^2 in the months of March and April.

At the Lower Casino Creek gauging station (W4), the key streamflow and unit runoff values are as follows:

- Drainage area: 82 km^2.
- Mean annual discharge: 0.48 m^3/s.
- Mean annual runoff: 5.8 l/s/km^2 or 183 mm/yr.
- Mean monthly discharge for May: 1.37 m^3/s.
- Mean monthly unit runoff for May: 16.7 l/s/km^2 or 45 mm/mo.

3.2.3 Peak Flows

Return period peak flows were calculated based on frequency analysis of the 33-year synthetic flow series for each station. These results were compared against an alternate set of peak flow estimates generated using a regional method (Janowicz, 1989). In general, the peak flow estimates generated by statistical analysis of the synthetic flow series exceeded the regional estimates based on Janowicz (1989). The latter are based on streamflow records from larger watersheds, which might not scale accurately to smaller watersheds with more flashy runoff response. A more detailed description of the peak flow analysis methodology and comparison of results are provided in KPL (2012).

The peak flows generated by statistical analysis of the synthetic series are recommended for adoption for Project design, with the inclusion of a 15% safety factor to account for potentially greater weather extremes and permafrost activity due to climate change. The recommended peak values for each station are presented in Table 3.3.

The highest peak flows per unit area were estimated for the Dip Creek and Victor Creek stations (W9, W16, R2), where the 200-year peak flow values equate to peak unit runoff values of 0.8 to 1.2 $m^3/s/km^2$. The 200-year peak flow values in the Britannia Creek watershed and Casino Creek sub-watershed equate to peak unit runoff values of 0.5 to 0.9 $m^3/s/km^2$.

These peak flow values contain considerable uncertainty due to the extent of rating curve extrapolation required to estimate high flows at the Project gauging stations, and uncertainties in the modelling of extreme flows based on the Big Creek record.

3.2.4 Low Flows

Janowicz (1990) provides a methodology for estimating 10-year 7-day low flows in Yukon Territory, based largely on streamflow records from larger rivers than are found in the Project area. Based on this regional methodology, non-zero flows are predicted in the Project area streams. However, site observations in late winter 2010 found that flows were zero or closely approached zero at all locations in the Project area. On this basis, the 10-year, 7-day low flow at all sites in the Project area is assumed to be zero.

3.2.5 Dry and Wet Monthly Flows

The variability of monthly flows at each Project station was characterized by calculating monthly average flows for a 10-year wet and 10-year dry return period. These monthly average flows were calculated based on the long-term synthetic flow series for each station using the Palisade Decision Tools @RISK statistical software.

For each month at each Project streamflow station, a statistical distribution was fit to the 33 monthly flow values in the synthetic flow series. The 10^{th} and 90^{th} percentile values of the distribution represent the 10-year dry and 10-year wet monthly flows, respectively. The results are presented in Table 3.4 (10-year dry) and Table 3.5 (10-year wet).

In May, the month with greatest mean monthly discharge, the 10-year dry and wet monthly discharge values at gauging station W4 (Lower Casino Creek) are 0.37 m^3/s and 3.01 m^3/s, respectively. They equate to 27% and 220% of the mean monthly discharge for May (1.37 m^3/s).

SECTION 4.0 - WATER BALANCE MODELLING INPUTS

4.1 GENERAL

This section defines additional hydrometeorological parameters required for engineering design and water balance modelling. These parameters help to quantify climatic variability, orographic effects and runoff coefficients for the Project area.

4.2 TEMPERATURE

The standard adiabatic lapse rate for temperature is -0.6 C per 100 m of elevation increase. This lapse rate can be applied to estimate temperatures in the Project area during the spring, summer, and autumn months. In the winter, temperature inversions are the norm, so temperature increases with elevation, but the relationship between elevation and temperature is not well-defined.

4.3 PRECIPITATION

4.3.1 Orographic Effect

The estimated orographic factor for precipitation is 5% per 100 m of elevation increase. This value is based on experience in assessing orographic factor elsewhere in Yukon Territory and British Columbia, and is in general agreement with the equivalent factor of 7% per 100 m between Pelly Ranch and the Project site.

4.3.2 Coefficient of Variation

The year-to-year variability of monthly precipitation in the Project area is quantified by coefficient of variation (Cv) values derived from regional data. The Cv represents the standard deviation normalized by mean. Cv values are typically required as input for stochastic water balance modelling. Monthly Cv values for precipitation in the Casino Creek Project area were estimated as the average monthly values of historical precipitation records for Beaver Creek A, Dawson A and Pelly Ranch. The estimated Cv values are summarised in Table 4.1.

4.4 EFFECTIVE RUNOFF COEFFICIENT

An effective runoff coefficient was estimated for the streamflow gauging station on Lower Casino Creek (W4). The Casino Creek sub-watershed contains no glaciers and therefore there is expected to be a reasonably direct relationship between annual precipitation and unit runoff. The effective runoff coefficient accounts for losses due to sublimation and evapotranspiration.

The effective runoff coefficient of 0.39 was calculated as the ratio of the mean annual unit runoff (183 mm) and mean annual precipitation at the mean elevation of the W4 drainage basin (475 mm). The recommended effective runoff coefficient is rounded to 0.4.

In May, the month with maximum snowmelt and streamflow, the calculated runoff coefficient is only 0.29. This is based on mean monthly snowmelt of 118 mm (no adjustment from snow course at 1,100 m elevation), mean monthly precipitation of 35 mm (adjusted from 37 mm at climate station), and mean monthly unit runoff of 45 mm at gauging station W4. The lower runoff coefficient in May might be related to springtime groundwater recharge, but also reflects uncertainties in the estimation of monthly snowmelt. It is recommended to use the rounded runoff coefficient of 0.4 in all months of the year.

SECTION 5.0 - CONCLUSIONS

The recommend values for key climatic parameters, referenced to the Project site climate station at 1,200 m elevation, are presented below:

CLIMATIC PARAMETERS (1,200 M ELEVATION)	VALUE
Mean Annual Temperature	-3 C
Mean January Temperature	-17 C
Mean July Temperature	12 C
Extreme Minimum Temperature	-50 C
Extreme Maximum Temperature	30 C
Mean Annual Precipitation	510 mm
Mean Annual Rainfall	330 mm
Mean Annual Snowfall (Water-Equivalent)	180 mm
Mean Annual Rainfall/Snowfall Distribution	65% / 35%
2-Year 24-Hr Rainfall	29 mm
200-Year 24-Hr Rainfall	56 mm
Mean Annual Wind Speed	2.2 m/s
Maximum Wind Gust Speed	11.1 m/s
Prevailing Wind Direction	Southwesterly
Mean Annual Relative Humidity	68%
Mean Annual Potential Evapotranspiration	300 mm
Mean Annual Maximum Snow Water-Equivalent	140 mm
Mean Monthly Snowmelt for May (Water-Equivalent)	120 mm

Temperature and precipitation can be adjusted to reflect conditions at different elevations according to the following guidelines:

CLIMATIC PARAMETER ELEVATION ADJUSTMENTS	VALUE
Mean Monthly Temperature (April through October)	-0.6 C per 100 m
Mean Monthly Temperature (November through March)	Increases with elevation
Mean Annual Precipitation	+5% per 100 m

The streamflow and unit runoff results for gauging station W4 on Lower Casino Creek are presented below:

HYDROLOGIC PARAMETERS (LOWER CASINO CREEK (W4), DRAINAGE AREA 82 KM^2)	VALUE
Mean Annual Discharge	0.48 m^3/s
Mean Annual Unit Runoff	5.8 $l/s/km^2$
Mean Annual Runoff (Depth Equivalent)	180 mm/yr
Mean Monthly Discharge for May	1.37 m^3/s
Mean Monthly Unit Runoff for May	16.7 $l/s/km^2$
Mean Monthly Unit Runoff for May (Depth Equivalent)	45 mm/mo.
Natural Catchment Runoff Coefficient	0.4
2-Year Instantaneous Peak Flow	12 m^3/s
200-Year Instantaneous Peak Flow	40 m^3/s
10-Year, 7-Day Low Flow	0 m^3/s
10-Year Dry Monthly Flow	0.37 m^3/s
10-Year Wet Monthly Flow	3.01 m^3/s

Potential climate change effects have not been considered explicitly in any of the hydrometeorological estimates presented above, except for peak flows. Appropriate allowances for potential climate change effects should be made where necessary.

NOTES:

1. THE CASINO SITE METEOROLOGICAL STATION, BOTH HISTORICALLY AND PRESENTLY, WAS ASSUMED TO COLLECT ONLY RAINFALL DATA DUE TO THE INSTRUMENT SET-UP, THEREFORE THE PRECIPITATION DATA COLLECTED IN THE MONTHS OF OCTOBER TO APRIL IS PRESENTED FOR INFORMATION PURPOSES ONLY BUT WAS NOT USED IN THE ANALYSIS OF MEAN ANNUAL PRECIPITATION FOR THE SITE.
2. IT WAS ASSUMED THAT PRECIPITATION COLLECTED DURING MAY TO SEPTEMBER FELL AS RAIN, SINCE THE AVERAGE MONTHLY TEMPERATURES DURING THESE MONTHS WAS ABOVE ZERO.
3. THE LONG-TERM PRECIPITATION VALUES WERE ESTIMATED BASED ON A REGRESSION ANALYSIS OF CONCURRENT CASINO AND PELLY RANCH DATA.

M:\1\01\00325\08\A\Data\Task 1100 - Hydrometeorology\[Snowpack & IDF.xlsx]Table 2.10

NOTES:

1. THE CASINO CREEK SNOW COURSE IS OPERATED BY YUKON ENVIRONMENT.
2. SWE = SNOW WATER-EQUIVALENT.
3. MONTHLY SNOWMELT WAS ESTIMATED BY SUBTRACTION OF CONSECUTIVE SWE MEASUREMENTS. MELT WAS ASSUMED TO BE ZERO IN CASES WHERE SWE INCREASED IN THE LATTER MEASUREMENT.
4. THE SNOWMELT ESTIMATES ASSUME THAT 100% OF SNOW MELTS BY THE END OF MAY, WHICH IS LIKELY NOT VALID IN ALL YEARS, ESPECIALLY IN THOSE YEARS WHERE MAXIMUM SWE OCCURRED IN MID-MAY.
5. MONTHLY SNOWMELT (%) REFERS TO THE FRACTION OF ANNUAL MAXIMUM SWE THAT MELTED IN A GIVEN MONTH.

Executive summary

In this review, we evaluate the challenges encountered and the adaptations required for the successful treatment of mine-impacted waters in cold climates with Passive Treatment Systems (PTSs). Engineered PTSs are modeled on natural wetlands, which have been shown to effectively treat water with high metal concentrations through natural attenuation. PTSs include constructed wetlands, bioreactors, and hybrid systems. Some of the challenges associated with implementing cold climate PTSs include cold temperatures, remote locations and limited access in winter, which can lead to freezing pipes and surface water, variable seasonal flow, and low productivity of microbial and macrophytic communities. Many adaptations have been implemented to address these cold climate challenges including burial of pipes to avoid hydraulic failure, insulation to avoid freezing surface waters, bypasses and overflows to maintain constant flow, summer establishment of microbial and macrophytic communities and the addition of liquid carbon sources to offset reduced organic matter decomposition in cold temperatures. While further investigation and development is necessary to fully understand the factors affecting cold climate PTSs, with sufficient research and planning PTSs can be successfully implemented in cold climates.

Acknowledgements

This review was funded by a NSERC Applied Research and Development grant held by Yukon College and Casino Mining Corporation. We would like to thank Andre Sobolewski of Clear Coast Consulting for his expertise and contribution to the document.

1. BACKGROUND

Passive treatment of mine impacted water has become increasingly common over the last 30 years. While natural attenuation of contaminants in wetlands, bogs and swamps has been well documented (McGregor, 2002; Sobolewski, 1997), recent advances in the design and construction of engineered passive treatment systems (PTSs) has resulted in more efficient contaminant removal (USEPA 2014; INAP 2010; Mays & Edwards, 2001; MEND 1996). PTSs consist of constructed wetlands (CWs), bioreactors, or some combination and/or variation on both of these components. Other types of PTSs exist, such as in-pit or in-pond treatment systems, but these are more specialized and will not be reviewed here.

Natural wetlands provide important information about the processes that drive PTSs, as well as, acting as water treatment systems in their own right. Natural wetlands and bogs have been removing contaminants from water for centuries (Gusek, 2008). From cupriferous and uraniferous bogs (Sobolewski, 2013) to bog iron ore deposits (Gusek, 2008), many examples of natural attenuation of metals in wetlands exist (e.g., Boyle, 1995; Wieder and Lang, 1982). Numerous studies have found evidence of metal retention in natural wetlands from natural and anthropogenic sources (Table 1). Natural wetlands can also give us an indication of the potential for the long-term performance of CWs. A wetland in Ireland has been assimilating metal-laden water from an abandoned Pb/Zn mine for over 120 years without interference (Sheoran and Sheoran, 2006). A natural wetland receiving drainage high in Fe, Zn and Mn from an iron ore mine in the Rocky Mountains was found to retain metals at a rate of 90%, 65% and 25%, respectively (August et al, 2002). The wetland received mine drainage for over a century and had accumulated large amounts of metal oxides and sulfides. This likely resulted in a decrease in efficiency overtime, as at the time of the study the wetland was found to be a sink for all metals during the winter, but then became a source for Zn and Mn during the summer when flows were higher. Similarly, a fen in Northern Manitoba treating Ni mine drainage was found to remove 96% of the Ni (Hambley, 1996). While higher levels of Ni were observed in the effluent in the spring and after heavy rains, sequential extractions of the soils indicated that 97% of the Ni captured by the fen would be unlikely to be remobilized. In another natural wetland receiving drainage from an abandoned Pb/Zn mine in Ireland, retention of 95% of Zn and 65% of As was observed (Beining and Otte, 1997). The wetland has been receiving mine drainage for over a century and is estimated to have reached only 30% of its capacity. A wetland receiving coal mining drainage high in Se removed 83% of the inflowing metal concentration (from 364 mg/L to 22mg/L) and selenium-reducing bacteria and SRB were found at high levels (Baldwin and Hodaly, 2003). Finally, a natural wetland established below the Silver King mine in Elsa, Yukon, was shown to completely remove Zn from mine drainage during winter months, even when temperatures decreased below -40°C (Sobolewski, 2003a). Evidence of sulfide generation was uncovered during this study, indicating that SRB were active and could account for metal removal.

Natural wetlands have been treating mine-impacted water in cold climates since mining activity began and while several studies indicate their efficacy and longevity, their effectiveness over long time periods and the effects of seasonal variation on efficiency still remains poorly documented. Understanding the effects of changes in water flow through the seasons would better inform PTS designers to adapt their own systems for cold climates. Natural wetlands also help to inform the scale necessary for treatment wetlands. The longevity of natural wetlands, particularly in cold climates, indicates that a well-designed PTS may last for decades to centuries.

Table 1: Natural wetlands shown to ameliorate mine drainage (Sobolewski, 1999, p.26).

Wetlands that only partly improve mine water quality

Mine	Location	Dominant plant Species	Acidic Drainage	Water quality parameter	Ref.
Abandoned tin, zinc mines	St Hilary Mining District, West Cornwall, U. K	*Juncus effusus, Phragmites australis*	No	Cu yes, Zn no	Brown, 1997
Carbonate mine	Montana	*Carex rostrata*	Yes	Al no, Fe yes, Pb yes	Dollhopf *et al.*, 1988
Coal mines	Eastern United States	*Typha, Scirpus* spp.	Yes	pH, Al, Fe, Mn	Kleinmann, 1996
Coal mine	Mpumalanga mining district, South Africa	*Typha,* spp.	Yes	pH, Al, Fe, Mn	Limpitlaw and Bloem, 1996
Dunka Mine	Minnesota, United States	Peat bogs	Yes	Cu, Ni	Eger *et al.*, 1994
Equity silver	British Columbia, Canada	Sedges	Yes	Cu	Mehling, 1985
Mt. Washington Mine	British Columbia, Canada	*Eriophorum angustifolium*	Yes	Cu, Al	Coombes, 1998
Natural wetlands at 35 coal mines	Pennsylvania, USA	*Mainly Typha,* spp., others also noted	Yes	pH, Al, Fe, Mn	Stark, 1990
Ranger Mine	Jabiru, Australia	*Eleocharis sphacelata Typha* species	No	U	Jones *et al.*, 1996
St. Kevin Gulch	Colorado, USA		Yes	Fe yes, Zn no	Walton-Day, 1994
Unnamed coal mine	Ohio, USA	*Sphagnum* spp.	Yes	pH, Fe, Mn	Huntsman, Solch and Porter, 1978
Tug Fork coal mine	West Virginia, U.S.A.	*Sphagnum* spp.	Yes	pH, Fe, Mn	Wieder and Lang, 1982

Wetlands which improve mine water quality to full environmental compliance

Mine	Location	Dominant plant Species	Acidic Drainage	Water quality parameter	Ref.
Abandoned Lead/ Zinc mines	Glendalough, County Wicklow, Ireland	*Molinia caerulea, Juncus acutiflorus*	Yes	As, Cd (?), Pb (?), Zn	Beining and Otte, 1996
Birchtree Mine	Manitoba, Canada	*Agrostis, Carex* spp. *Typha latifolia*	No	Ni	Hambley, 1996
Cluff Lake, Rabbit Lake	Saskatchewan, Canada	*Carex* species *Sphagnum* moss	No	U	TAEM, 1995; Sinclair, 1996
Con Mine	Northwest Territories, Canada	*Carex* species *Sphagnum* moss	No	CN^-, As	Ball, 1993
Hilton Mine	Mt. Isa, Queensland, Australia	Reeds, algae	No	Fe, Mn, Tl, Zn	Jones and Chapman, 1995
Pacific Mine	Utah, USA	?	No	Cd, Pb, Zn	Lidstone and Anderson, 1993
Quirke Mine	Ontario, Canada	*Typha latifolia*	Some	Fe, Ra-226	Davé, 1993
Silver Queen	British Columbia, Canada	Sedges	No	Zn	Higgs, 1996
Star Lake, Jolu	Saskatchewan, Canada	*Carex* species *Sphagnum* moss	No	CN^-, Cu	Gormely *et al.*, 1990
Tom's Gully Gold Mine	Darwin, Australia	*Melaleuca, Typha domingensis*	No	As, Co, Cu, Fe, Pb, Mn, Ni, Zn	Noller, Woods and Ross, 1994
United Keno Hill Mines	Yukon Territories, Canada	*Carex* species *Sphagnum* moss	No	Fe, Mn, Pb, Ag, Zn	Boyle, 1965
Woodcutter's Mine	Darwin, Australia	*Typha* species	No	Cd, Mn, Pb, Zn	Noller, Woods and Ross, 1994

In Yukon, Canada, effluent from hard rock mines can have neutral or acidic pH and be high in a suite of heavy metals, depending on the local geology (Nordin, 2010). Contaminated mine drainage

often requires treatment prior to discharge to the receiving environment. Yukon mines have expressed interest in implementing PTSs to treat contaminated drainage and in some cases have already begun research to develop such systems (i.e. Minto Mine, Casino Mine, Faro Mine, United Keno Hill Mine, Brewery Creek, Eagle Gold and Wolverine Mine). There are distinct advantages to PTSs in remote locations with limited access and power. Passive systems should ideally be able to function for decades with no power (Gusek & Wildeman, 2002). While most systems are not truly "walk-away" scenarios, they are generally lower maintenance than active systems (Johnson & Hallberg, 2005).

Some of the challenges facing PTSs in cold climates include hydraulic failure due to freezing in winter, reduced microbial activity, and increased water flows during spring melt. Many adaptations have been developed to overcome these challenges such as insulating and/or burying PTSs, maintaining constant flows through the use of bypasses and overflows, and providing carbon sources to feed bacteria during times of slower organic matter decomposition. There have been varying degrees of success, but hurdles have been overcome and many advances have been made in the use of PTSs in cold climates.

With the proliferation of PTSs around the world and the growing interest in Yukon, it is necessary to synthesize some of the successes and failures of PTSs, particularly in a northern context. This review aims to summarize many of the PTSs that have been used to treat mine-impacted water and address some of the challenges and future research directions associated with implementing these systems in cold climates. This review focusses primarily on PTSs for the treatment of mine-impacted water, although systems that treat other types of effluent are discussed where relevant cold climate adaptations have been used.

2. PASSIVE TREATMENT SYSTEMS

PTSs are generally defined as water treatment systems that require little or no maintenance once installed (Johnson & Hallberg, 2005). This is contrasted with active treatment systems (treatment plants), which use mechanical devices operated by workers and require continual flow control, reagent input, sludge/residual removal and power. More specifically PTSs can be described as water treatment systems that sequentially remove contaminants using biological or geochemical processes (Gusek & Wildeman, 2002). They are typically designed to last for decades and be less costly over the long term than active treatment systems. However, they can also require much more space and may be constrained by site limitations, such as topography (Johnson & Hallberg, 2005).

PTSs capitalize on natural attenuation processes that naturally occur in wetlands. Wetlands generally have an aerobic zone where plants thrive and oxidative conditions dominate. Below this is an anaerobic zone where reductive processes dominate and sulfate-reducing bacteria (SRB) thrive (Gusek, 2002). In each zone, different reactions occur that precipitate different contaminants. In the aerobic zone, hydroxide and oxide precipitation occurs and in the anaerobic zone sulfide and carbonate precipitation is catalyzed by microorganisms. Some contaminants like chromium, selenium or uranium are retained by reductive immobilization in these anaerobic environments. Filtration and adsorption by detritus are also important processes occurring in both zones. PTSs promote these processes by using organic materials as substrates for microbial activity, as well as, local native plant species as the living wetland layer. The chosen substrate is often waste material that can be obtained at low cost.

Additionally, organic material such as wood chips or sawdust can often be obtained on-site or nearby, reducing or eliminating transport costs (Gusek, 2002).

Metal removal in PTSs can be divided into abiotic or biotic processes. Technologies that rely on abiotic processes include anoxic limestone drains (ALDs), open limestone channels, diversion drains, vertical flow limestone drains and others. All these systems rely on limestone to neutralize acid drainage and remove aluminum and iron. They are often used in combination with other biotic passive treatments. For example, successive alkalinity producing systems (SAPS) or vertical flow limestone drains rely on the percolation of acidic water through a layer of compost, where the carbon dioxide produced by its microbial decomposition greatly enhances limestone dissolution (Kepler & McCleary, 1994). These systems are used to treat waters with high acidity, aluminum or ferric iron, which cannot be treated by other limestone-based PTSs.

Systems that rely on biotic processes can be divided into aerobic and anaerobic systems. Aerobic wetlands rely on oxidative processes to remove metals (primarily iron) and are most often constructed to treat mine water that has net alkalinity (Hedin et. al., 1994, Johnson & Hallberg, 2005). Anaerobic wetlands, or bioreactors, are used to treat neutral, metal rich water by reductive processes. They are typically applied at base and precious metal mines to remove metals that were originally present as sulphides and were released during the mining process (Sobolewski, 1999). Constructed wetlands and bioreactors are further detailed in Section **Error! Reference source not found.** and **Error! Reference source not found.** below.

The technology behind PTSs has evolved considerably over the last 20 years. A landmark development was the publication of an Information Circular by the former US Bureau of Mines (Hedin et al, 1994). This document presented for the first time design criteria that were field-validated, along with a decision-making flow chart that identified the different types of treatment required for different types of mine waters. The information circular focused on acid drainage from abandoned coal mines in Eastern Appalachia, where the authors had gained their experience. More recently, Gusek (2008) expanded this flow chart by including additional forms of treatment that were predominantly developed for abandoned base and precious mines in Western USA and Canada. This chart presents the multitude of PTS components and possible configurations available for industry and those involved in reclamation (Figure 1).

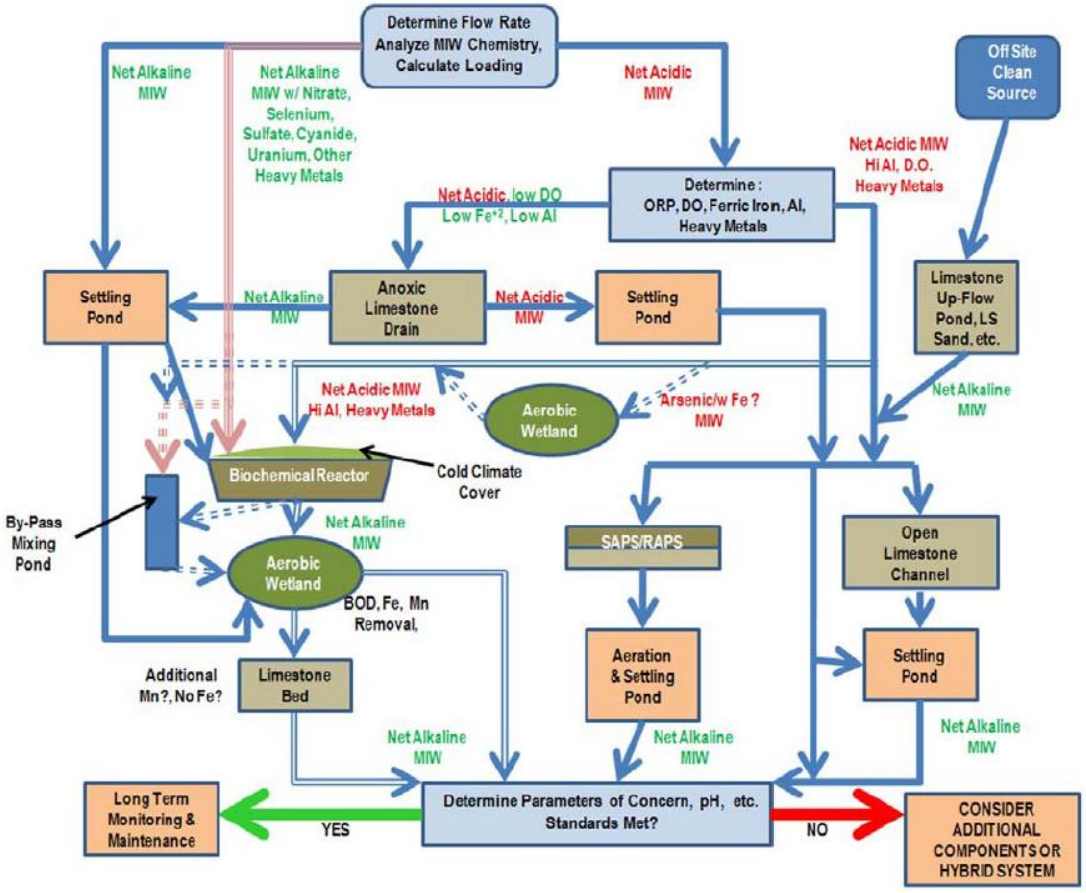

Figure 1: Flow chart for selecting PTS based on water chemistry and flow (adapted from Hedin et al, 1994 by Gusek, 2008, p. 4).

2.1. Constructed wetlands

Constructed wetlands (CWs) are defined as engineered wetlands that use natural processes associated with vegetation, soil and microbes to treat contaminated water (Mander & Jenssen, 2003). The basic processes that operate in CWs include nutrient uptake, bacterial degradation, filtration, oxidation, precipitation, sedimentation and adsorption (Sheoran & Sheoran, 2006). The characteristics of wetlands that contribute to their effectiveness in treating contaminated water include: high productivity, microbial diversity, organic matter accumulation, high reactive surface area and slow water flow (Sobolewski, 1999). It is these characteristics that designers seek to emulate when creating CWs, and many CWs are more efficient at removing metals than natural wetlands (Sheoran & Sheoran, 2006). CWs are used all over the world for treating various types of effluent. They have been used extensively in cold climates for municipal wastewater treatment (Mander & Jenssen, 2003) and in several northern settings for mine drainage (Nyquist & Greger, 2009; Sobolewski 1996a; Sobolewski 1996b; Duncan, 2002; Goulet & Pick, 2001).

Surface flow wetlands often consist of an excavated pond lined with an impermeable substrate, such as clay or geotextile and are filled with porous materials like peat (Eger & Eger, 1991), or sand (Nyquist & Greger, 2009), then fertilized (Sobolewski, 1996b) and planted with local wetland plants (Figure 2a). Sub-surface flow wetlands are similarly constructed but attempt to direct the flow through the root zone of the plants (Figure 2b). In both cases, the wetland bed is gently sloped so that water flows by gravity.

In Europe, sub-surface flow CWs are most often used to treat municipal wastewater (Galletti et al, 2010; Hiley, 2003; Vyzamal & Krasa, 2003), whereas in North America, they are most often used to treat mine drainage. Native wetland plants are generally chosen based on their ease of propagation and transplantation, water depth tolerance, root structure, and metal accumulation properties. Many studies have assessed the role of plants in CWs and most have found that plants uptake only a small fraction of the metals sequestered by a CW with most of the metal retention occurring in the roots (Noller et al, 1994; Sobolewski, 1999; August et al, 2002; Deng et al, 2004; Galletti et al, 2010; Mitsch & Wise, 1998; Nyquist & Greger, 2009; Taylor & Crowder, 1983; Vyzamal & Krasa, 2003; Ye et al, 2001) or on the surface of belowground biomass in a metal-rich plaque layer (Weis & Weis, 2004). It has been hypothesized that low translocation of metals from roots to shoots is a strategy of metal-tolerant plants (Taylor & Crowder, 1983; Deng et al, 2004). Metal uptake in plants varies considerably depending on the plant species, contaminants being treated, and the pH of water and sediment (Weis & Weis, 2004).

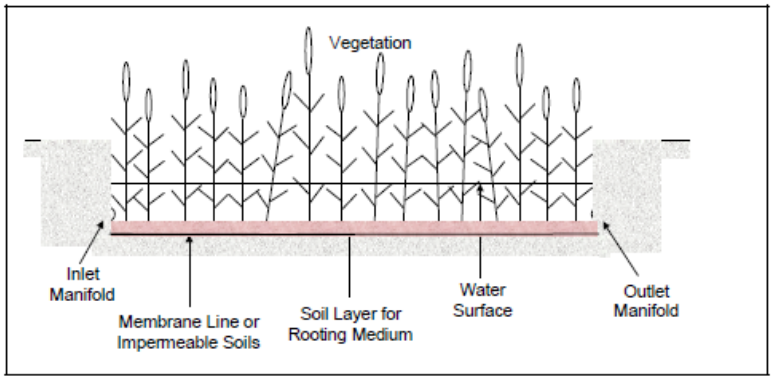

Figure 2a: Surface flow wetland (adapted from a drawing by SC Reed from EPA, 2000a, p. 1).

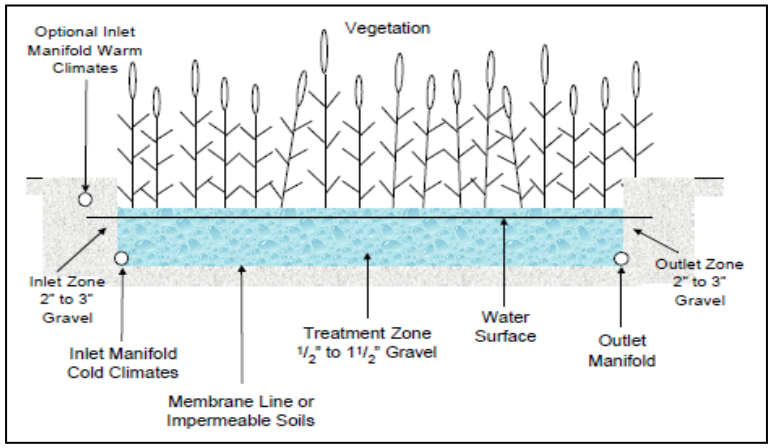

Figure 2b: Sub-surface flow wetland (adapted from a drawing by SC Reed from EPA, 2000b, p. 1).

2.2. Bioreactors

Bioreactors (or anaerobic wetlands) are PTSs that are contained in an excavation, pond, tank or even a mine shaft. It is filled with a solid reactive mixture made up of sand, gravel, compost, manure, wood chips, sawdust, or other organic material from nearby sources (Figure 3) (Schmidtova & Baldwin, 2011). The most effective reactive mixture generally contains an organic carbon source, a bacterial inoculum, a solid porous medium, a nitrogen source and a neutralizing agent (Zagury & Neculita, 2007). As mine water percolates vertically or horizontally through the substrate material, decomposing organic matter provides nutrients that fuel the activity of sulfate reducing bacteria (SRB) and other microorganisms that provide treatment (Hashim et al, 2011). The SRB then produce bicarbonates, which increases the pH while reducing sulphates to sulphides, which in turn precipitate with metals to form highly insoluble metal sulphides (Zagury & Neculita, 2007). Some bioreactors also rely on other anaerobic bacteria to remove nitrate (Reinsel, 1998) or selenium (Pahler et. al., 2007).

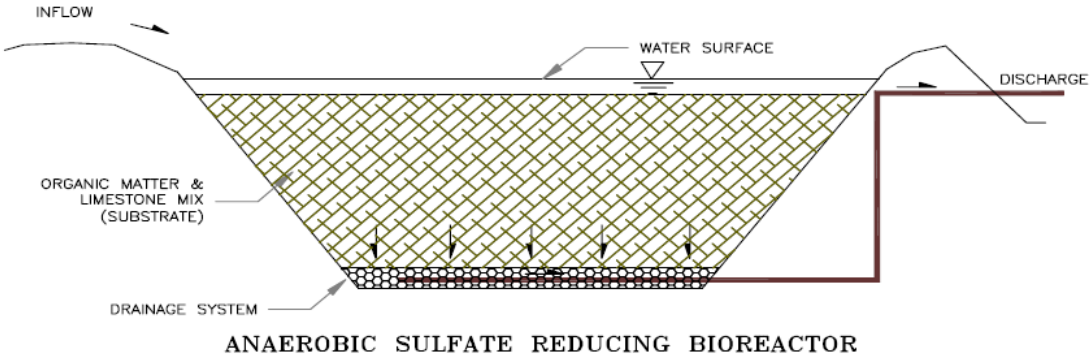

Figure 3: Typical bioreactor design (Gusek, 2002, p. 3).

Bioreactors can be used in combination with other PTS components such as limestone pretreatment to increase pH, constructed wetlands and aerobic cells (Figure 4). Bioreactors have been used at numerous mine sites in cold climates with limited access and power (Duncan et al, 2002; Ettner, 2007; Kuyucak, et al, 2006; Nordwick et al, 2007; Sobolewksi, 2010; Zagury & Neculita, 2007) due to low construction and operating costs (Schmidtova & Baldwin, 2011) and their ability to work year-round in sub-zero temperatures (Kuyucak et al, 2006).

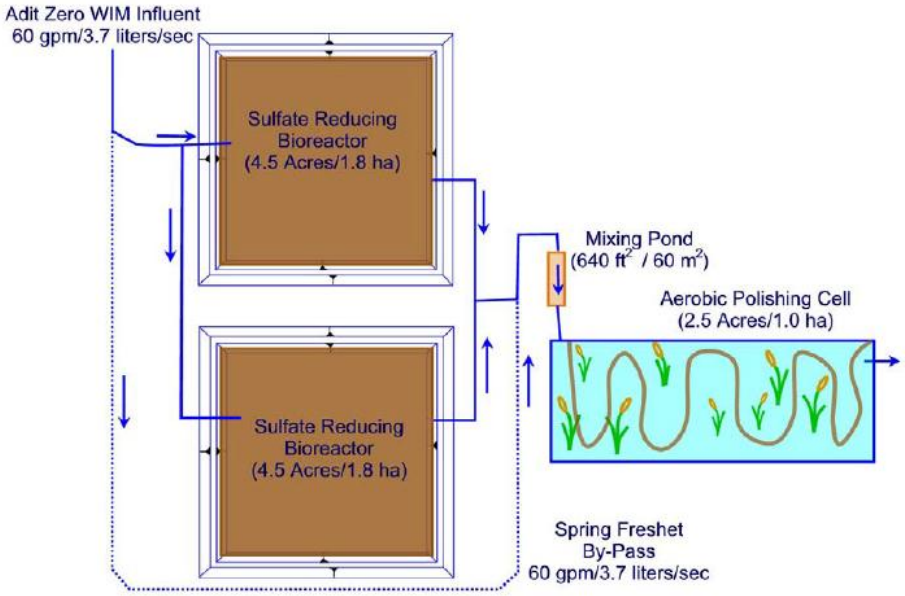

Figure 4: Hypothetical hybrid system with bioreactor and aerobic wetland components (Gusek & Conroy, 2007, p. 265).

2.3. Pilot and full scale PTSs

Many PTSs are currently being employed to treat contaminants in northern and/or cold climate environments (Table 2). While many lab and bench scale experiments are documented in the literature, our focus is only on those that have reached pilot and full scale implementation. For the purposes of this review, full scale passive treatment projects are defined as those that are constructed on-site to deal with a large portion of the effluent being produced. Pilot scale projects are experimental PTSs and are generally implemented on-site to increase the likelihood of successful full scale design (Gusek, 2002). An overview of pilot and full scale PTSs studies is provided in Table 2 including the metal removal rates observed. Note that this survey is not fully comprehensive and only reflective of the available literature, as there are PTSs that have operated for years, but have never been documented.

Table 2: Overview of Pilot and Full Scale Passive Treatment Systems

Passive Treatment Type	Components	Target Contamination	Location	Scale	Duration	Removal rates	Reference
Bioreactor	Bioreactor cell	Zn, Fe, Mn, Ni, Cd, Cu,	United Keno Hill Mine, Yukon, Canada	Pilot scale	2 years	Zn (98-99%), Mn (99%), Sb (80%), As (58-80%)	Alexco, 2012
CW	HSSF wetland & aerobic polishing cell	Cu, Zn, Pb, Fe	Clear Creek/Central City, Colorado, USA.	Pilot scale	n/a	Cu (99%), Zn (98%), Pb (94%), Fe (86%)	Banks et al, 1997
CW	Aerobic wetland and permeable reactive barrier	Fe, Mn, Al, Ni	Northumberland, UK	Full scale	2 years (ongoing)	Fe (99%), Mn (66%), Ni (83%), Al (80%)*	Batty & Younger, 2004
Bioreactor	BCR, aerobic polishing cell, aeration cell	Se, Tl, Zn	Montana, USA	Pilot scale	4 months (ongoing)	Se & Tl (99.5%), Zn (97%)	Blumenstein & Gusek, 2008
CW	3 different wetlands constructed in duplicate	Cu, Fe, S, Se	Minto Mine, Yukon, Canada	Pilot scale	1 year (ongoing)	Cu (89%), Se (26%)	Contango Stategies, 2013
Hybrid	ALDs, sedimentation ponds, CW, SAPS	Fe	Howe Bridge SAPS, Pennsylvania, USA	Full scale	7 years	Fe (50-69%)	Demchak et al, 2001
Bioreactor	SAPS, settling pond, SAPS	Fe, Al	Filson SAPS, Pennsylvania, USA	Full scale	4 years	Fe (90%), Al (20-50%)	Demchak et al, 2001
Bioreactor	Holding pond, SAPS	Fe, Al	Sommerville SAPS, Pennsylvania, USA	Full scale	3 years	Al (30%), Fe (increased)	Demchak et al, 2001
Bioreactor	SAPS, settling pond	Fe, Al	McKinley SAPS, Pennsylvania, USA	Full scale	2 years	Fe (92%), Al (25-90%)	Demchak et al, 2001
Hybrid	2 vertical upflow anaerobic bioreactors, 3 HSSF wetlands, sand filter, holding pond	As, Zn, Cd	Teck Metals Smelter, Trail, BC, Canada	Full scale	5 years (ongoing)	91% to 100% net removal efficiency	Duncan et al. 2002; Duncan, 2010
CW	5 surface flow wetland systems	Ni	Dunka Mine, Minnesota, USA	Small scale	18 years (ongoing)	Ni (30-90%)	Eger et al, 1991; Eger & Eger, 2005; Eger & Beatty, 2013
Bioreactor	Pretreatment pond, 2 bioreactors, settling pond, flushing pond & aeration channel	Al, Cu, Fe, Ni, Se, Zn	Leviathan Mine, California, USA	Full scale	2 years (ongoing)	Al (99%), Cu (99%), Fe (95%), Ni (86%), Zn (98%), Se (20%)	EPA, 2005
Bioreactor	Vertical flow cell, limestone drain, settling pond	Fe, Al, Mn	Indiana County, Pennsylvania, USA	Full scale	7 years	Al (Up to 90%)	Eppley & Gusek, 2009

Cold climate PTSs are highlighted in grey.

3. NORTHERN ENVIRONMENTS

PTSs in northern environments are often located in remote locations with limited access and power, short growing seasons and cold winter temperatures, conditions which can present challenges for PTS design. These challenges however, are also often reasons for choosing PTSs, which can be constructed to operate year-round with little maintenance and no power.

For the purposes of this review, cold climates are described as those that may experience freezing conditions during the winter months. This definition allows the inclusion of any PTS that may experience seasonal variations in efficiency and may employ adaptations for cold temperatures. The main problems faced by PTSs in cold climates are hydraulic failure due to freezing, ice formation and insufficient biological activity at low temperatures (Wittgren & Maehlum, 1997; Mander & Jenssen, 2003). Due to the interest in implementing PTSs in cold climates and the need to develop site-specific systems, many adaptations for cold climate PTSs have been examined and case studies illustrating the implementation of cold climate PTSs are detailed in Section 3.2.

3.1. Cold climate effects

Seasonal variations occur in most PTSs due to changes in water flow, senescence of aquatic plants, metabolic activities of microorganisms and variations in temperature and pH. Some wetlands may lose efficiency during the winter months while still meeting water treatment objectives (Groudev et al, 2008). In other cases, no seasonal variation in effectiveness has been found due to complex relationships between oxidation, temperature and pH which maintain the treatment regime regardless of climatic conditions (Hedin, 2013). Some of the main cold climate conditions potentially affecting PTS effectiveness are discussed below.

3.1.1. Temperature

Water temperature changes diurnally and annually. Diurnal temperature changes by approximately 5°C, while annual changes vary depending on latitude and climate. For example, in warm seasons water temperature is approximately equal to air temperature. During periods of ice cover, water temperature is maintained near 0°C for the duration with no diurnal variation (Kadlec & Reddy, 2001). Water temperature directly affects microbial activity by reducing metabolic reaction rates (Oberholster et al, 2014). In addition, plant matter decomposition and adsorption has been shown to decrease as temperature is lowered (Kadlec & Reddy, 2001). The solubility of oxygen (Kadlec & Reddy, 2001) and carbon doxide (Hedin, 2013) is also strongly temperature dependent with greater solubility at lower temperatures. The increased oxygenation in winter can aid aerobic processes, although ice cover can impede oxygenation during the winter and create anoxic conditions (Fortin et al, 2000). Maintaining oxic conditions in sediments during winter has been recommended to increase Fe and Mn retention (Goulet & Pick, 2001). In a PTS in Pennsylvania, Hedin (2013) found there was greater mixing of unfrozen ponds in winter due to density gradients in the water column. Cool water on top continually sunk to the bottom which forced the CO_2-rich deep water to the surface where it degassed. This caused changes in pH and subsequently Fe oxidation rates (Hedin, 2013). This PTS is discussed in greater detail in Section 3.2.10. In general, lower temperatures in winter have the effect of slowing down both biotic and abiotic processes that are essential to the functioning of PTSs, however, in many cases temperature

and efficiency are not directly related. For example, at Silver King mine, Yukon, Canada samples were collected with distance from an adit into a natural wetland/muskeg in the months of December, January and February, when temperatures ranged from -26°C to -49°C (Sobolewski, 2003a). In all three months Zn concentrations dropped from 1.2 mg/L at the adit to 0.15-0.61 mg/L within 160 m from the adit into the wetland. Diagnostic sequential leach analysis was used to identify metal removal processes during these winter months and both Cd and Zn were found mostly adsorbed onto or coprecipitated with iron and manganese oxides (Sobolewski, 2003b). More discussion on cold climate impact on microbial activity is presented in 3.1.3.

3.1.2. pH

pH is very important in PTSs treating mine-impacted water as it affects the solubility, oxidation, adsorption and biological removal of metals (Sheoran & Sheoran, 2006). The solubility of many metals is pH-dependent, with metal solubility typically increasing to toxic levels at lower pH values (Figure 5). For certain metals, such as aluminum or iron, raising water pH to neutrality is usually sufficient to decrease their concentrations to acceptable levels. Other metals, such as cadmium, manganese or zinc, can be soluble at neutral pH and cannot be removed by simple pH adjustment. The solubility of certain contaminants, such as nitrate or selenium, is largely unaffected by pH. Finally, the solubility of certain gases, particularly carbon dioxide, is pH-dependent and changes in solution pH will affect their concentrations. CO_2 degassing has been found to increase at colder temperatures due to greater mixing of the water column (Hedin, 2013) and as CO_2 is released, pH increases. CO_2 degassing has also been found to improve iron and trace metal removal in PTSs likely due to the increase in pH (Nairn, 2013). Conversely, CO_2 solubility also increases at lower temperature which may have the effect of lowering pH.

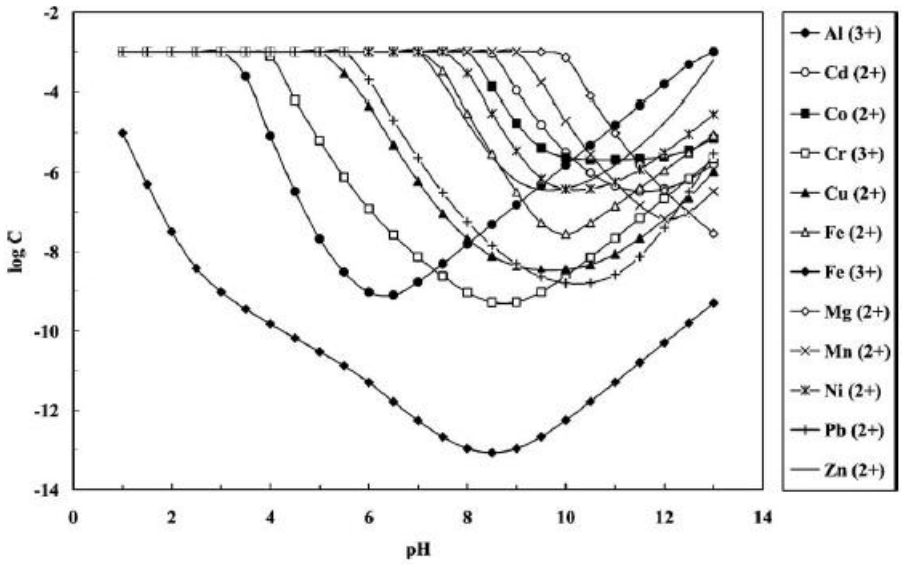

Figure 5: Solubility of different metal hydroxides based on chemical equilibrium calculations using the MINQL+ software. Stimulation conditions: T=25°C, $CI_i = 10^{-2}$ M and $(metal)_i = 10^{-3}$M (Blais et al, 2008, p.137).

Additionally, the precipitation of metals salts, such as aluminum or iron hydroxides can drive significant changes in pH. In some cases, the oxidation and precipitation of dissolved iron may be sufficient to acidify mine water to unacceptable levels. The alkalinity and acidity of water are essential parameters to consider in predicting overall changes in pH that might occur in PTSs.

Biological processes, such as the decomposition of organic matter and plant uptake of metals, are affected by water pH. The sulphate-reducing bacteria (SRB) that are responsible for metal removal, grow within a pH range of 5.5-8.5. Therefore, low water pH hinders their growth and ability to remove metals. Lowering pH has been shown to decrease sulfate reduction rates (Tsukamoto et al, 2004), which is why many PTSs employ pretreatment by ALDs or other limestone-based unit processes. Photosynthesis and respiration have the effect of increasing pH due to the removal of CO_2, therefore pH is likely to be greater in the summer due to growth of algae and plant biomass. pH has been found to have a positive effect on the bioavailability of some metals to some plant species (Deng et al, 2004). Numerous studies have found that temperature and seasonal variation affect pH in PTSs, however the relationship between temperature and pH is complex and requires further study.

3.1.3. Microbial activity

In general, microbial activity decreases with temperature. However, cold-adapted SRB have been studied extensively in the Arctic and Antarctic (Camenzuli et al, 2014; Robador et al, 2009; Sagemann, et al, 1998) and many have adaptations that sustain sulfate reduction rates at colder temperatures. Anaerobic bacteria have been found to grow very slowly below 15°C (Hiley, 2003), although in a CW in Ontario, SRB were found to thrive during winter. Goulet and Pick (2001) showed that the largest SRB populations in a wetland were in December when the water was ~1°C and determined that sulfate reduction rates were highest under those conditions. While sulfate reduction rates are generally lower at colder temperatures and cold-adapted SRB may have higher optimum growth temperatures, sulfate reduction rates may still be maintained at levels similar to those in temperate climates (Fortin et al, 2013). Cold-adapted SRB in the Arctic have been found to be more limited by organic substrate availability than by temperature (Sagemann et al, 1998). Fortin et al. (2013) suggest that decreased organic decomposition in cold temperatures caused the SRB to compensate by increasing their numbers, which maintained the sulfate reduction rates throughout the year. Panos et al. (2013) found that temperature has a large influence on the development of SRB; SRB did not develop at temperatures below 6°C. Despite this, Fe removal efficiency was still relatively high indicating other processes, such as adsorption, may be responsible for maintaining metal removal at lower temperatures (Panos et al, 2013). On the other hand, in a bioreactor at the Calliope mine (Section 3.2.8), results suggested that freezing SRB did not affect their activity during the rest of the year (Nordwick et al, 2006). In a pilot bioreactor in Wyoming, sulfate reduction rates were reduced by 20% in the winter when water temperatures were below 1°C, although this was not enough of a reduction to affect the treatment performance of the bioreactor (Gusek, 2002). In a column experiment on the performance of anaerobic bioreactors at low temperatures, Gould et al. (2012) found that Zn removal fell from 99% to 60% when the temperature was lowered from 20°C to 4°C. They compensated for the loss of efficiency by feeding the columns with liquid carbon (glucose and lactate/acetate) and achieved >95% Zn removal efficiency at 4°C (Gould et al, 2012). Liquid carbon sources can maintain microbial activity in bioreactors over the winter months when cold temperatures reduce organic matter decomposition (Sobolewski, 2010).

3.1.4. Water flow

In cold climates, water flow changes seasonally with large increases in flow in the spring when the snow melts and low flows throughout the winter. Drastic changes in flow present challenges to PTS designers. In a natural wetland in the Rocky Mountains, spring snowmelt caused an increase in the flow to the wetland, which decreased the concentration of metals. The wetland was found to be a sink for Zn and Mn in the summer and a source in the winter due to changes in flow conditions and microbial activity, with the greatest disturbances to treatment efficiency occurring during spring snowmelt (August et al, 2002). Higher flows during spring runoff and throughout the summer likely created more exposed mineral surface area and allowed more of the products of weathering to be flushed out. The higher flows, however, were offset by the increased retention of metals in the wetland. Similar flushing effects were experienced at a subsurface bioreactor constructed in a mineshaft in Montana (Nordwick et al, 2006). Oxygenated spring run-off infiltrated through the ground and mobilized historic metal precipitates creating higher metal concentrations in the effluent in the spring. At a bioreactor in Norway, Cu removal efficiency was found to be highest when water flows were low and constant during the summer (Ettner, 2007). Unlike the majority of sites that experience lower flows in the winter, at this site flows were found to increase in the winter, which resulted in a dramatic drop in removal efficiency. These factors must be accounted for in the design of PTSs.

It is clear that seasonal variations affect the efficiency of PTSs but more work is needed to elucidate the specific mechanisms occurring in cold climate PTSs. Understanding of a site's hydrology, climate, precipitation regime and seasonal water flows allows PTS designers to address site-specific limitations in cold climates. In addition, better understanding of seasonal variations and their effects on metal leaching and metal removal mechanisms will improve the efficiency and reliability of PTSs operating year-round in cold climates.

3.2. Cold climate case studies

Numerous PTSs have been constructed in cold climates at various scales. Below are highlighted case studies of PTSs that demonstrate adaptations in their design for year-round operation in cold climates. Some are successful full scale designs, while others reveal some of the obstacles that may be encountered by PTS designers in cold climates.

3.2.1. United Keno Hill Mine, Yukon – Constructed wetland

In 1995, a pilot wetland was constructed at UKHM and monitored over one year to assess the possibility of treating adit discharge with high levels of Zn (30 mg/L) and other heavy metals (Sobolewski, 1996; Burns, 2000). An area below the Galkeno 900 adit was excavated, fertilized and planted with *Carex aquatilis* collected from a nearby uncontaminated wetland. The plants were allowed to establish for approximately one month, then effluent was piped into a lined pond and then into the wetland. Plywood baffles were subsequently added to distribute the flow evenly throughout the wetland (Figure 6). Zinc removal rates reached up to 90% efficiency in the first season (Table 2), however, the concentration never dropped below 3 ppm, which is well above the 0.5 ppm discharge limit. Other heavy metals were below acceptable limits and more than 80-90% of Co, Ni and Mn were removed. Results from this CW indicated that longer hydraulic retention times within the pilot wetland would have increased the Zn removal efficiency. In addition, Sobolewski (1996) suggested that allowing

vegetation to more fully establish (>35% was unvegetated) would likely improve efficiency. Metal removal in the CW was directly correlated with sulfate reduction, suggesting that Zn was removed as a Zn sulfide precipitate. Wetland plants were analyzed from the natural wetland and the results suggested that contaminants uptake from the sediments into the plants was limited.

Figure 6: CW at Galkeno 900 adit with plywood baffles to help distribute flow evenly (Burns, 2000, p.38).

The CW at the Galkeno 900 adit was only operational for a short time and never reached a steady state before flow was redirected to a limestone treatment system inside the mine adit. The wetland was, however, subject to further analysis in 1999 (Burns, 2000). The author reported that four years after transplant, *Carex aquatilis* had fully covered the constructed wetlands. Below-ground seepage from a waste rock pile was observed to be travelling to the wetland so samples were taken to determine the levels and distribution of contaminants in the wetland. The metal concentrations in sediments decreased with distance from the seep while the concentrations in plants were relatively consistent, except for the concentration of Zn which decreased with distance from the seep. The data indicates that the wetland continues to attenuate metals in the discharge waters.

3.2.2. United Keno Hill Mine, Yukon – Anaerobic bioreactor

In 2008 at UKHM, a pilot horizontal flow bioreactor was constructed on-site at the Galkeno 900 adit (Figure 7 and 8) (Alexco, 2012). A pit was excavated, lined and then filled with waste rock. The pit contained 3 m deep waste rock with a 1.2 m soil cover on top to reduce ice formation in the bioreactor. In March 2011, there was up to 60 cm of ice in the bioreactor. All of the pipes and valves were buried at least 1 m belowground and those running under roadbeds were covered in heat trace. Baffles were installed to distribute the flow throughout the pit. The bioreactor was filled with untreated adit water and sucrose, methanol and/or milk solids were added to stimulate SRB growth in October 2008 and

January and July 2009. From October to July of 2009, the water was recirculated in the bioreactor in a closed circuit and strong sulfate-reducing conditions developed. The flow-through phase then began and constant additions of methanol were initiated. The flow rate was initially 0.5 L/sec (21 days residence time), which was then increased to 1 L/sec (10.5 days residence time) and then reduced to 0.75 L/sec for the rest of the operational phase. At low flows 99.8% of Zn was removed and at higher flow rates 97.8% was removed (Table 2). While the Zn discharge limit (0.5 mg/L) was met consistently at the low flow rate, it was sometimes exceeded at higher rates. It was observed that the residence time within the bioreactor was a major factor affecting metal removal efficiency. While Zn was the primary contaminant of concern, 80% of As was removed at a flow rate of 1 L/sec. Cd was removed to below detection limits and 97.5% of Ni was removed at low flows, but only ~50% was removed at higher flows. Iron and Mn were efficiently removed (99%) during the recirculation phase, but during the operational phase, when the reducing conditions were fully established, Fe and Mn were remobilized resulting in slow release of these metals over the course of operation. The bed of the bioreactor was composed only of waste rock, so sorption was not likely a factor in removing metals; sulfate reduction and metal sulphide precipitation were the primary mechanisms. Some of the engineering problems encountered included uneven distribution of flow and decreased contact with the substrate (i.e. so-called 'dead zones') and pump failure and power outages resulting in pipes freezing and the system having to be shut-down temporarily. A gravity fed system and/or back-up power would have helped to avoid the difficulties of maintaining a constant flow in the winter (Alexco, 2012).

Figure 7: Bellekeno pilot bioreactor under construction in 2008 (left) and after 5 years (right) (Alexco, 2012, p. 6).

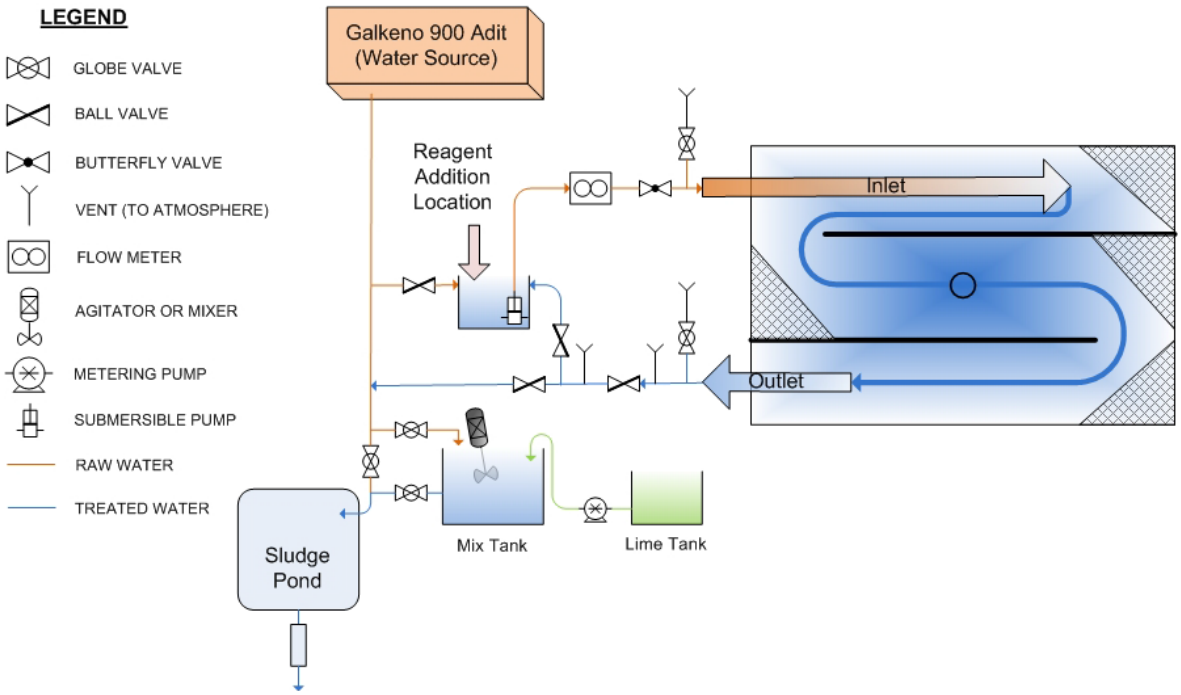

Figure 8: Layout of Galkeno 900 bioreactor (Alexco, 2012, p.7).

3.2.3. Tulsequah Chief & Smoky River Coal Mine, BC

At the Tulsequah Chief Mine (Cu, Pb/Zn) in Northern British Columbia, acidic rock drainage was successfully treated using a 66 m^3 anaerobic bioreactor built inside the mine adit (Sobolewski 2010). Wood mulch was used in the bioreactor; however, as the ambient temperature in the reactor was low (6-8°C), wood mulch decomposition was too slow to maintain anaerobic conditions. To overcome the issue, ethylene glycol was subsequently added to the influent to create reducing conditions, decreasing the dissolved oxygen levels and kick-starting SRB activity. A full scale five cell, 200 m long, bioreactor was then built based on the pilot test results and monitored over four years. The first three cells received a wood mulch/limestone mix to reduce acidity and the two final cells received sulfur prills (elemental sulfur in pellet form) and supported SRB. Ethylene glycol was dripped into cells one and four. The front three cells consistently removed Al and Fe, but also gradually accumulated sludge, which caused failure after four years of operation, while the final cells removed Cd, Cu and some Zn (Table 3). The bioreactor operated year-round without maintenance in the winter and was constructed in areas with limited space, access and power.

Table 3: Metal concentrations in drainage and discharge from Tulsequah Chief pilot and full scale bioreactors (adapted from Sobolewski, 2010).

Parameter	ARD	Pilot-scale bioreactor	Full-scale bioreactor
pH	3.0-3.7	6.0-6.7	6.1-6.7
Al (mg/L)	10-30	0.1-1.0	0.06-2.5
Cd (mg/L)	0.22-0.47	<0.050	0.07-0.30
Cu (mg/L)	16-30	0.1-1.0	2-7
Fe (mg/L)	20-120	0.1-2.0	0.04-4.0
Zn (mg/L)	56-120	30-50	42-77

3.2.4. Smoky River Coal Mine, BC

Two 5 m^3 pilot scale bioreactors were constructed in parallel at the Smoky River Coal Mine to treat Se-contaminated water in an area where access, space and power were severely restricted, (Sobolewski, 2010). The bioreactors were filled with gravel, wood chips, manure, lime and bonemeal, inoculated with Se-reducing bacteria and fed with ethylene glycol as a liquid carbon source. The liquid carbon source helped to sustain necessary microbial processes (Sobolewski, 2010). The bioreactors effectively removed 97% of the Se from September to November 2008 (Figure 9), even when temperatures dropped to 2°C. This case study, along with other studies previously mentioned (i.e. Galkeno 900 and Tulsequah Chief) demonstrates that addition of a liquid carbon source may allow anaerobic bioreactors to keep operating with high efficiency on northern mine sites under winter conditions.

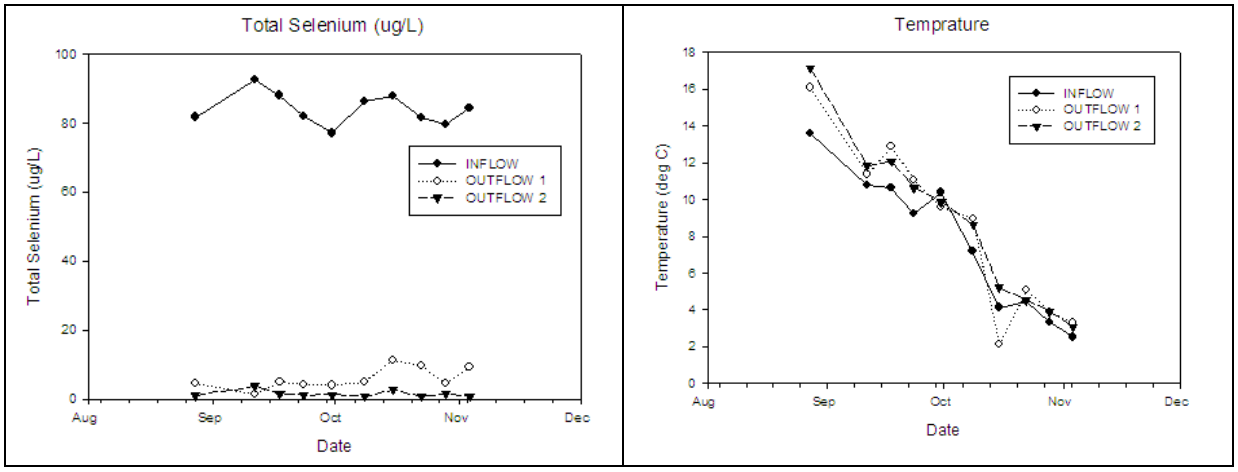

Figure 9: Selenium removal as a function of temperature at Smoky River Coal (Sobolewski, 2010, p. 2)

3.2.5. Kongens & Folldal Mines, Norway

In Norway, bioreactors have been tested for the treatment of acidic mine drainage at both active and abandoned mines in cold climates (Ettner 2007). A first pilot bioreactor system was constructed at the Kongens Mine in northern Norway in 1999, consisting of a pre-treatment limestone drain and four anaerobic cells filled with organic waste materials, rotted hay, sawdust, tree clippings and $CaCO_3$. However, the substrate was found to be inappropriate due to low hydraulic conductivity which caused clogging. Highlighting the importance of thorough design, the substrates were revisited and a new bioreactor system was constructed in 2002 using rotted hay, sand and coarse birch tree materials. In this reactor, up to 85% Cu 48% Zn, 98% Cd, 82% Pb, 71% Cr and 24% Ni were removed in this second pilot system, however Cu removal was significantly reduced in winter months. This reduction was correlated with a drastic increase in the flow rate in the bioreactor (Figure 10). To overcome this issue and avoid high flow variations, a full-scale bioreactor was constructed in 2006 which consists of two identical cells, one receiving a constant flow and the other receiving smaller, but variable flow rates.

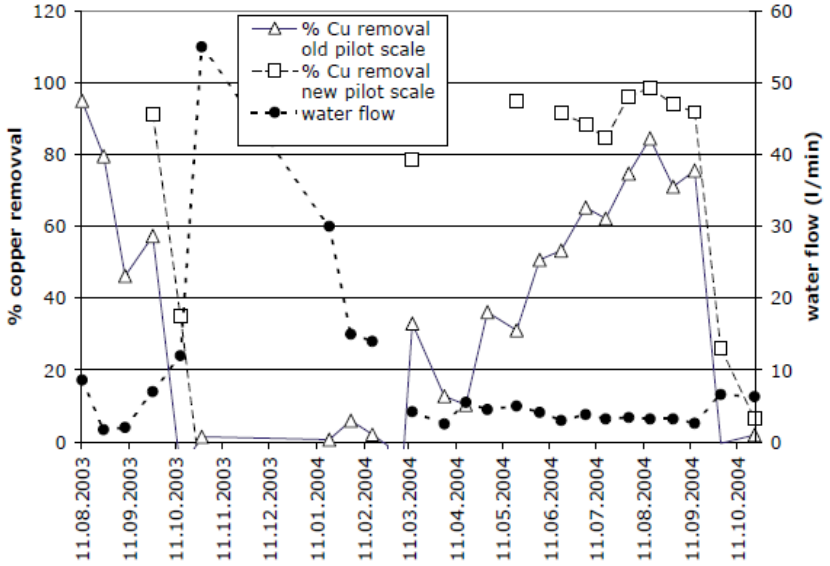

Figure 10: Copper removal (%) by pilot anaerobic reactors versus water flows (Ettner 2007, p.3)

Using a similar design, a pilot bioreactor system was built at the Folldal mine in 2006, with four 8 by 1.5 m basins filled with rotten hay, tree clippings, shell sand and gypsum to act as an extra sulfate source (Ettner 2007). The bioreactors were filled with water in the fall and left to rest for the winter with no flow. Unfortunately, no monitoring data were available from when system was restarted in the spring. However, the study indicated that cold winter temperatures did not prevent inoculation of the bioreactors by microorganisms and development of anaerobic conditions, low Eh and signs of sulfide precipitates were reported.

3.2.6. Bell Copper Mine, BC

At the Bell Copper mine in Smithers, BC, two experimental wetlands were constructed to determine the effectiveness of a year-round CW in a northern environment for treatment of Cu-contaminated water (Sobolewski et al, 1994). Two membrane lined ponds (300 m^2 and 75 m^2) were constructed, fertilized with manure and planted with peat mats dominated by sedges (*Carex aquatilis* and *Carex laeviculmis*). The ponds were also planted with cattails (*Typha latifolia*) and beaked sedges (*Carex rostrata*) and were fully vegetated within a year (Figure 11). For the first year, the wetlands were fed with low flows of mine drainage with low levels of Cu (0.3-1 ppm) at a pH of 6-8. They were 98% effective at removing Cu (Figure 12) throughout the winter months when the wetlands were covered in ice and even when the influent Cu concentrations occasionally spiked to 10 ppm (Sobolewski et. al., 1994). Mine drainage with high levels of Cu (35-50 ppm) at pH 3.5 was then introduced to the wetlands. For the first six weeks, they maintained removal efficiency, but then gradually started deteriorating reaching 40% efficiency for the large wetland and 80% for the small one. Both a decrease in pH and SRB population were observed concurrently with the reduction of Cu removal efficiency. The reduction of efficiency of the wetland was likely due to reduction in the activity and growth of SRB, which were not acclimated to the low water pH. Longer retention times and pretreatment to increase pH were suggested as means to address the shortcomings of these wetlands for treatment of highly contaminated mine drainage (Sobolewski et al, 1994).

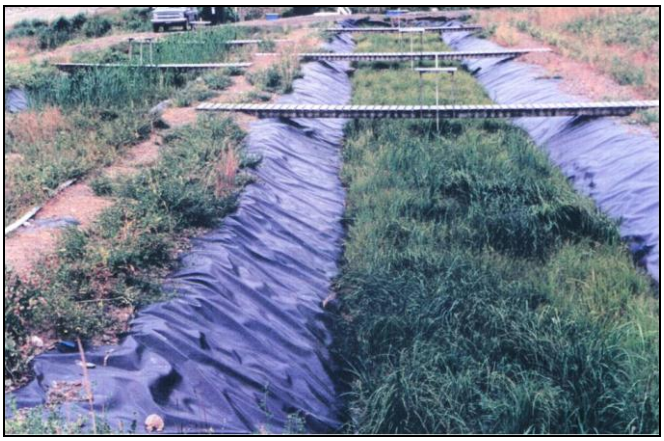

Figure 11: Pilot wetlands at the Bell Copper Mine (Sobolewski A., personal communications, November 12, 2014).

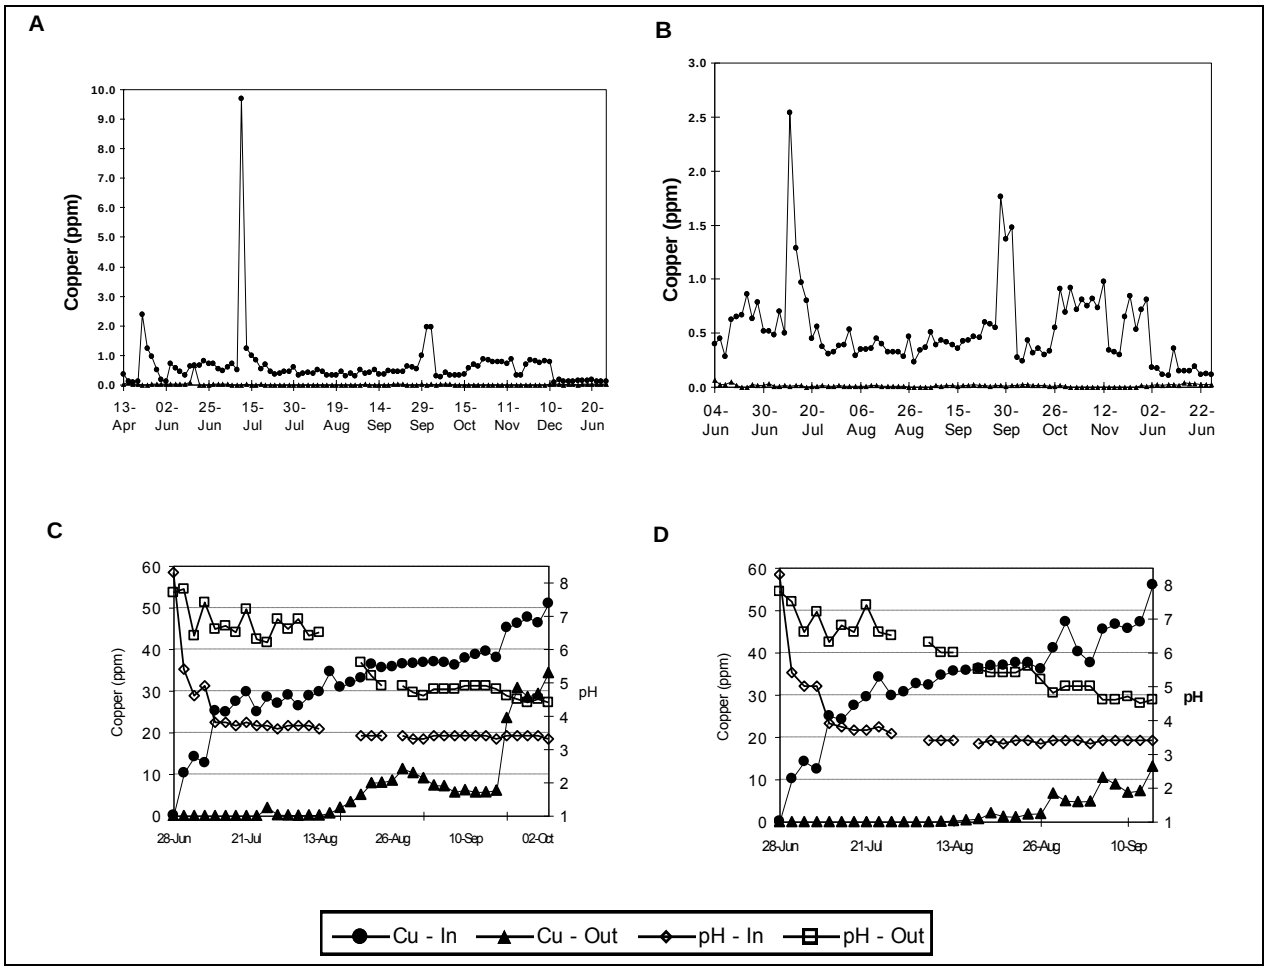

Figure 12: Copper concentrations and pH of influent and effluent for the large (A, C) and small pond (B, D) at low strength (A, B) and high strength feed (C, D) (April 1992 to Oct 1993, Sobolewski et al, 1994, p. 686). Note different scales used in A and B.

3.2.7. Lilly/Orphan Boy Mine, Montana

At the Lilly/Orphan Boy Mine in Montana, USA an in-situ bioreactor was constructed and operated between 1994 and 2005 to treat ARD at the abandoned mine (Canty, 2000; Nordwick et al, 2006; Bless et al, 2008). The bioreactor was built within an old mineshaft, approximately 9 m below the static water level. Organic matter, cow manure and straw were placed on a platform inside the shaft with mine water flowing upward through the organic substrate (Figure 13). This below-ground design offered protection from the cold winter temperatures (ambient temperature was 8 °C) and worked successfully for over 11 years. Removal efficiencies were between 98% and >99% for Al, Cd, Cu and Zn and 96% for As. However, the mineshaft bioreactor design also came with challenges, including metal leaching within the mine tunnel as water travelled out through the portal, creating effluent with, in some cases, higher contaminant concentrations (As and Fe) (Table 4). Additionally, this system was affected by snowmelt and spring run-off. Higher metal concentrations in the spring were attributed to greater metal leaching from the rocks by oxidation due to oxygenated surface water infiltrating into fractures in the rocks and tunnel walls (Nordwick et al, 2006). For most metals, metal removal had

seasonal variability with high removal efficiencies during the summer, but low removal efficiencies at all other times of the year (Figure 14). However, Mn and Zn were removed effectively year-round.

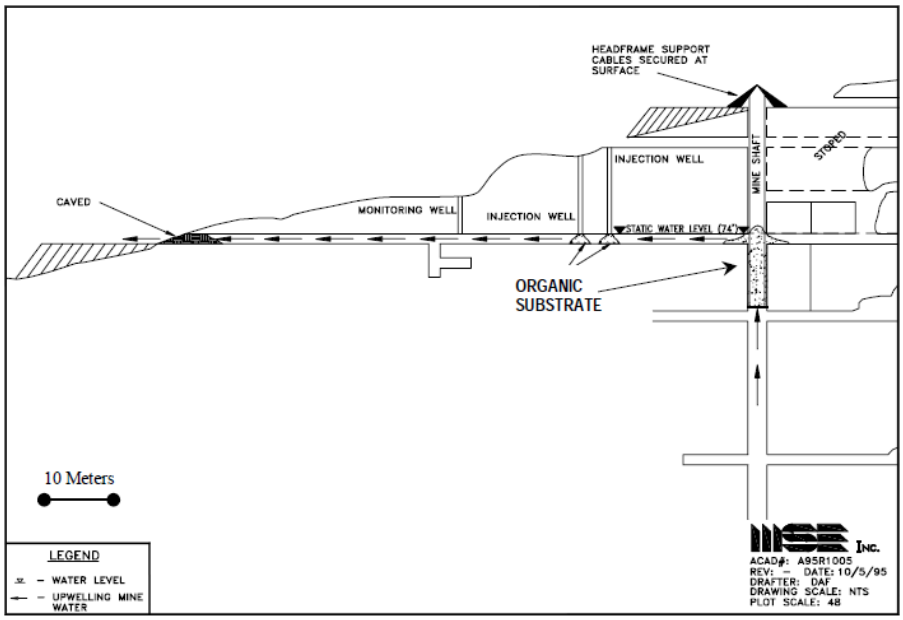

Figure 13: Underground bioreactor at Lilly/Orphan Boy Mine, Montana (Nordwick et al, 2006, p. 1412).

Table 4: Representative mine water chemistry at Lilly/Orphan passive treatment system (dissolved metals in mg/L) (Bless et al, 2008, p. 243).

Sample	Month	Fe	Zn	Al	Mn	As	Cd	Cu	SO_4	pH
Pretreatment shaft	Several	27.7	26.1	9.7	6.2	1.07	0.33	0.32	277	3.0
Pretreatment portal	Several	14.1	19.4	7.4	5.5	0.08	0.24	0.33	213	3.4
Treated tunnel water	March 2001	9.3	<0.01	<0.02	1.4	0.02	<0.005	0.022	59	7.4
	May 2001	13.2	0.06	<0.02	2.7	0.13	<0.005	<0.005	214	7.0
Treated portal effluent	March 2001	30.8	10.1	0.2	5.5	5.26	0.040	<0.002	161	6.1
	May 2001	11.2	28.8	11.2	6.4	0.05	0.301	0.686	394	3.4

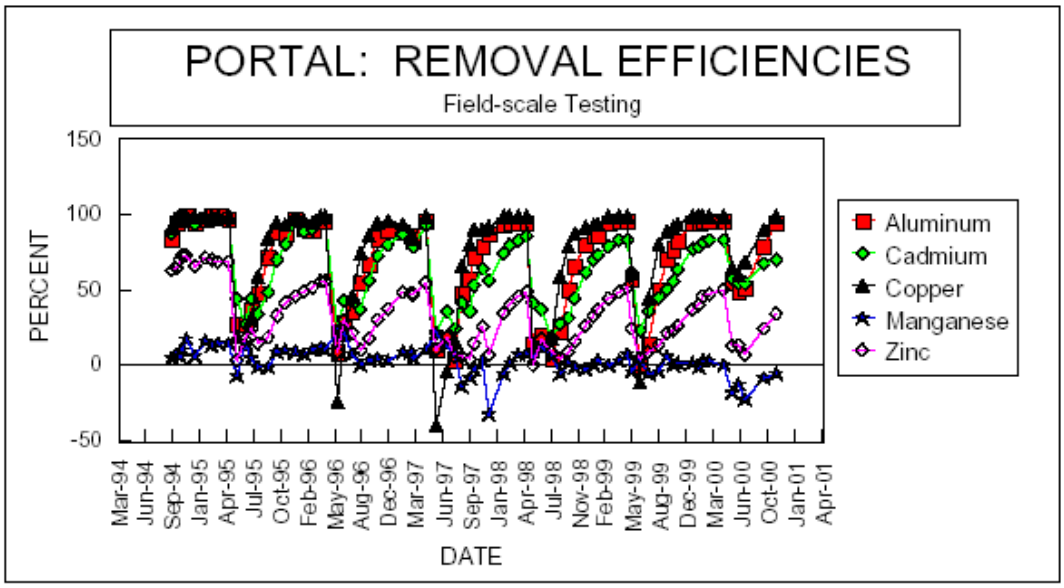

Figure 14: Metal removal in Lilly/Orphan Boy Mine (Canty, 2000, p. 3).

3.2.8. Calliope Mine, Montana

Pilot-scale bioreactors were built at the Calliope Mine in Montana to determine the effect of freezing on SRB (Nordwick et al, 2006; Wilmoth 2002). Two bioreactors were placed in trenches (21.8m and 18.6m long) and one was constructed aboveground (22.1m long) to investigate the impact of seasonal freezing and thawing on treatment performance (Figure 15). The trenches were filled with cow manure, straw, limestone and Terracell^{TM} to prevent organic matter settling, improve permeability and ensure uniform flow through the bioreactors (Figure 16). The systems were operated with a horizontal flow and 4.5 days residence time (+1 day pretreatment in the longer belowground system). Once the SRB populations were established, the mine water was introduced. Zinc, Cu, and Cd were removed as sulfides through bacterial activity while Fe, Mn, Al and As removal was affected by SRB only in an indirect manner by responding to increased pH caused by SRB activity. Zn, Cu and Cd were removed from the ARD to approximately 500 to 800 µg/L for Zn, 80 µg/L for Cu, and 5 µg/L for Cd in both the belowground and aboveground configurations, indicating that at Calliope site, the bioreactor efficiencies were not affected by freezing and thawing. Removal of Fe, Al and Cu was very effective (99%), whereas As was not removed at all and Mn were removed to a lesser extent (32%). Plugging by chemical precipitates affected the flow rate during operation. However it was observed after deconstruction of the aboveground bioreactor that less organic material would have been just as effective, which would have increased the permeability without compromising the efficiency. Overall, a uniform horizontal flow was successfully achieved in the bioreactors. The pilot project also demonstrated that SRB need time to establish, but once established and supplied with organic carbon, they can maintain an active population at temperatures ranging from 2°C to 16°C, without being affected by winter conditions (Figure 16). Additionally, a well-established population can withstand freezing in winter with little or no effect on their activity during the rest of the year.

3.2.9. Cadillac Molybdenite Mine, Quebec

At the decommissioned Cadillac Molybdenite Mine in Northern Quebec a 170 m^3 bioreactor was constructed to treat ARD with acidic pH ranging from 2.7-5.6 (Kuyucak et al, 2006). Passive treatment was chosen due to the lower cost and maintenance as compared to an active system and the remoteness and limited access for much of the year. The extreme cold for 6 months of the year (average -20°C) also presented a challenge in the design of the system. The treatment unit consisted of a collection ditch, an anaerobic cell filled with wood chips, limestone, hay and manure, followed by an oxidation pond and a limestone drain (Figure 17). The nutrient mixture was allowed to condition for 2 months prior to installation in the cell to allow the establishment of SRB before winter. In addition, an overflow drain was installed in the anaerobic cell and the collection ditch to allow excess mine drainage to bypass the SRB cell and help keep uniform flow in the bioreactor. The surface of the collection ditch and anaerobic cell were covered with 50 mm polystyrene sheets and 0.25 m of clay to prevent freezing (Figure 18). During the winter, the effluent temperature dropped to 3°C and the anaerobic cell was at 4°C. Since its implementation in 2004, removal to below regulated limits for Cu (0.3 mg/L), Ni (0.5 mg/L) and Zn (0.5 mg/L) has been successful (Table 5). Iron removal was not as successful during the winter, when settling of Fe precipitates in the oxidation pond was inhibited by freezing. Aluminum removal was also improved during the summer as SRB activity increased. Monitoring of the site continues and an expansion is planned to accommodate all of the effluent.

3.2.10. Marchand Mine, Pennsylvania

In a PTS treating coal mine drainage in Pennsylvania, Hedin (2013) found that seasonality did not significantly affect Fe removal efficiency over a six year monitoring period. The system is comprised of 6 connected ponds and a CW planted with a mix of aquatic species (Figure 19). Models predicted Fe oxidation rates would be 10 times slower in cold seasons than in warm seasons (-15°C to +35°C); however, that was not the case in this PTS; Fe removal was found to be temperature independent (Figure 20). An inverse relationship between pH and temperature offset the expected reduction in efficiency. CO_2 solubility increases as temperature decreases, so it was unexpected when CO_2 degassing increased at colder temperatures in the ponds. This was likely due to more thorough mixing at colder temperatures. Surface waters are continually cooled and sink due to density gradients resulting in deep water that is more saturated with CO_2 coming to the surface and degassing. The increased degassing causes an increase in pH, which in turn increases Fe oxidation rates. Although this process can account for the results observed in the ponds, the seasonal dynamics in the wetland cell were far more complex. While the temperature in the oxidation ponds never fell below 4°C, portions of the wetland froze during cold weather and it was largely covered with ice during cold periods. The ice cover reduced gas exchange processes during the winter and biological activity increased during the summer. As a whole, the PTS was effective year-round at reducing Fe levels to below permissible limits (Table 2) and Fe removal efficiency did not change seasonally. Additionally, the iron sludge precipitated in the ponds is recoverable and may be sold to offset the treatment costs (Hedin, 2013). This case study highlights the complex interactions that can occur between temperature-sensitive processes, complicating predictions of temperature effects on removal rates.

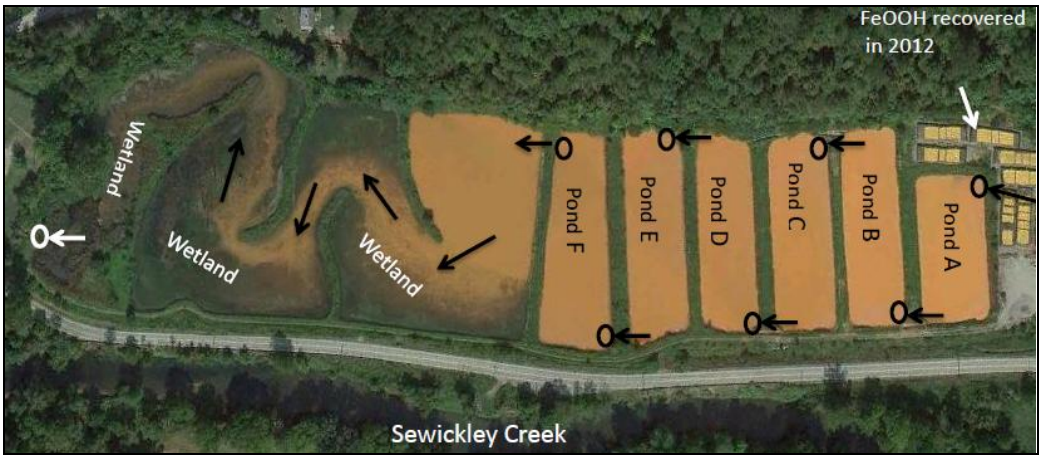

Figure 19: Aerial view of the Marchand mine bioreactor ponds, wetlands and recovered iron sludge (Hedin, 2013, p.9).

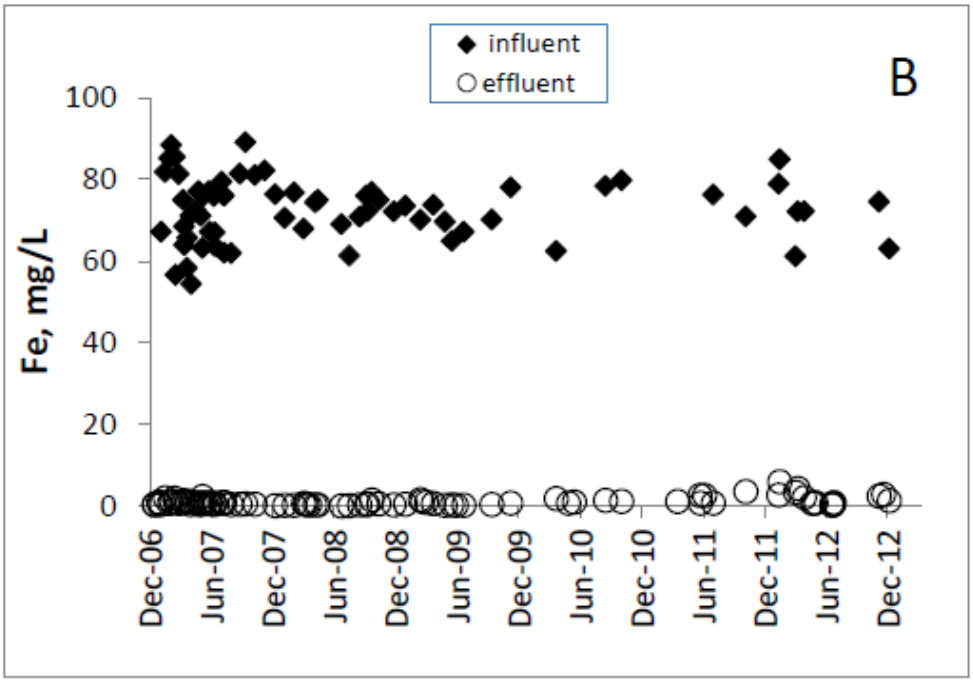

Figure 20: Total Fe concentration at influent and effluent of the Marchand mine treatment system, Pensylvania (Hedin, 2013, p.10).

3.2.11. Teck Smelter, Trail, BC

A PTS was constructed near Trail, BC to treat effluent containing very high concentrations of As, Zn and Cd from a Pb/Zn smelter (Table 6) (Duncan et al, 2002; Mattes et al, 2004). The first phase, constructed in 1997, consisted of three wetland cells (50 m^2 for 1st and 2nd cell and 300 m^2 for 3rd cell). The first cell was planted with *Brassica spp*. and *Helianthus annuus*, the second planted with *Calamagrostis canadensis* and other native grasses from the local area and the third cell was planted with *Typha latifolia* (Figure 21). The cells were initially watered with stream water to allow root growth to establish during the first year. In 1998, a vertical sub-surface flow bioreactor was built upstream with pulp mill biosolids, sand and cow manure. It was designed to allow 1 m of standing water to sit on top to protect it from winter freezing and to ensure it stayed anaerobic. Additionally, all pipes and control valves were buried below 0.9 m. Due to plugging in the first bioreactor and to increase Zn removal, another bioreactor cell was similarly constructed in 2000, upstream of the first (Figure 21), which was subsequently rebuilt. The second cell included limestone to increase the pH and thus improve Zn removal efficiency. The system was fully winterized for year-round operation, although was shut down due to a frozen pipe after a year of operation. After two years of operation (spread over a 5 year period), the system reached a net removal efficiency of 96% for As, Cd and Zn (Table 6), although As levels in the effluent were still not below stringent discharge limits. While seasonal efficiencies are not available, this system purportedly works efficiently year-round and successfully withstands freezing conditions.

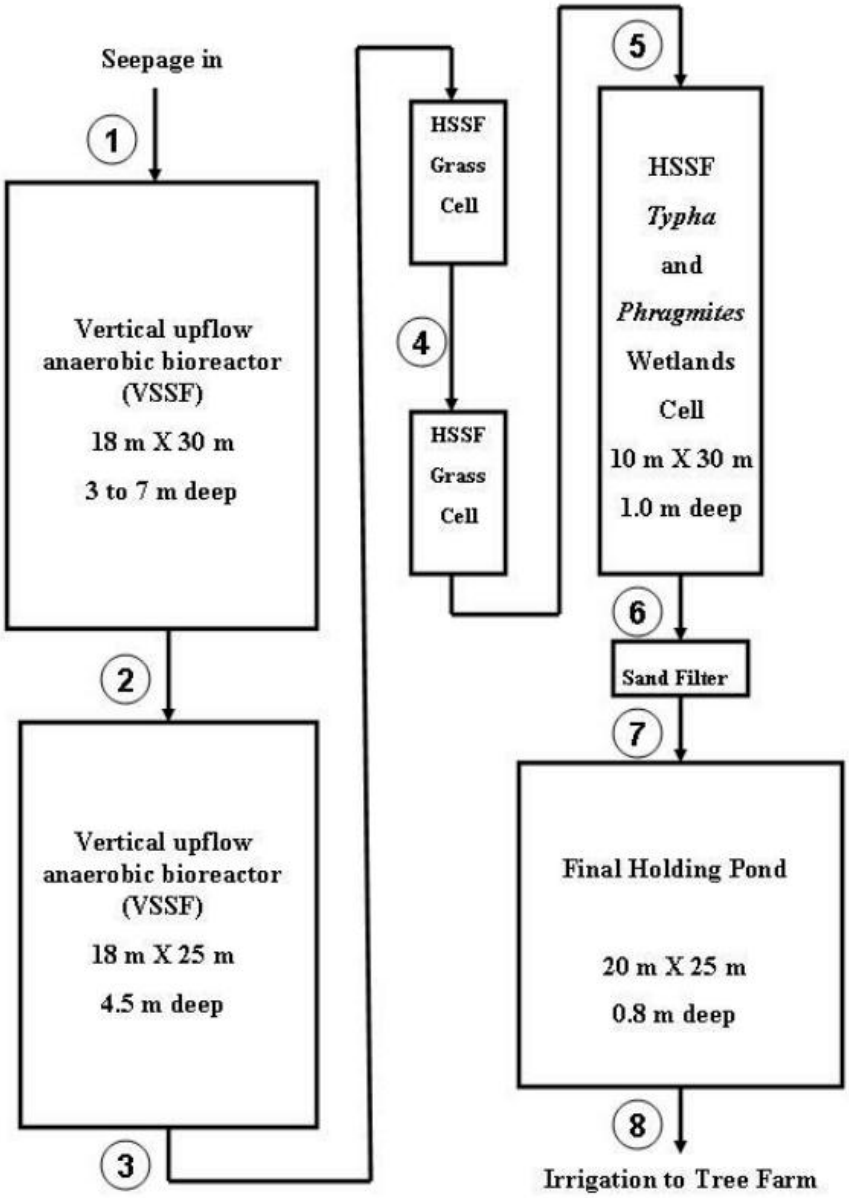

Figure 21: Diagram of the sequence of PT components at the Teck smelter, Trail, BC (Duncan, 2010, p. 40).

Table 6: Metal concentrations (ppm) and percentage removal during to operating periods (257 and 576 days) of the passive treatment system at Teck smelter, Trail, BC (Duncan et al, 2002, p.5).

Sample Point	As. Conc.	% Removed	Cd. Conc.	% Removed	Zn Conc.	% Removed
Input	69.5		5.1		355	
Anaerobic 1	18.7	73.1	2.1	58.8	177	50.0

Final Pond	1.3	13.3	0.03	25.0	15.1	23.7
Total %		98.1		99.4		95.7

3.2.12. Uranium mine, Curilo, Bulgaria

A four cell constructed wetland in Curilo, Bulgaria successfully treated acidic drainage (pH 2-4) from a uranium deposit over a 10 year period (Groudev et al, 2008). The wetland cells were lined with a mixture of soil, plant and spent mushroom compost, cow manure, crushed limestone, silt and sand. Several barriers of this mixture were placed perpendicularly to the water flow. The wetland was vegetated with *Typha latifolia*, *Typha angustifolia, Phragmites australis, Scirpus lacustris,* and some *Juncus, Eleocharis, Poa* and *Carex* species. The wetlands significantly reduced heavy metal concentrations year-round, operating with a flow-rate between 0.2 to 1.0 L/s and a residence time between 0.5 and 5 days (Table 7). While efficiency was strongly temperature dependent, the effluent metal concentrations during the winter months (when water temperatures were below 5°C) were still below permissible discharge concentrations. Microbial activity was lower in wintertime; however, the longer residence time (i.e. lower flow) helped to sustain satisfactory removal efficiency. High metal concentrations measured in dead biomass indicated that sorption processes by dead plants and clays played an important role in removing metals in during the winter (Groudev et al, 2008).

Table 7: Water quality data before and after treatment by constructed wetlands at Curilo, Bulgaria (Groudev et al, 2008, p.94).

Parameters	Before treatment	After treatment	Permissible levels for waters used in agriculture and industry
Temperature, °C	(+0.1)–(+25.1)	(+0.1)–(+28.0)	–

Cobalt, mg/l	0.23–6.20	<0.1–<0.5	0.5
Iron, mg/l	73–1072	<1–14	5
Manganese, mg/l	0.95–55	<0.5–6.4	0.8
Arsenic, mg/l	0.01–0.59	<0.01–<0.1	0.8

3.2.13. Wood Cadillac, QC

An anaerobic bioreactor was built at the historic Wood Cadillac mine site, in northwestern Quebec, to treat an As-rich effluent. The tailings at Wood Cadillac are sulphidic with an excess of buffering capacity, producing neutral mine drainage (Tasse et al, 2003). The 50 x 57 x 1 m bioreactor was filled with local yellow birch bark to create reducing conditions and fed with seepage at average flow rates of 7.3L/sec in 2000 and 5.0 L/sec. in 2002 (Germain and Cyr, 2003). The biofilter displayed high As removal efficiencies, even in November with a typical seasonal temperature decrease (Figure 22) and the concentrations of As were lowered to below 0.057 mg/L except in June 2001. Overall, this bioreactor fulfilled its objectives over the first three years when it was monitored. Later in 2004, after 5-years of operation and with no interventions, Libeiro (2007) studied the bioreactor again and reported that As removal was still achieved by the reactor, lowering the inlet concentration of 0.03-0.26 mg/L down to 0.002-0.05 mg/L at the bioreactor outlet.

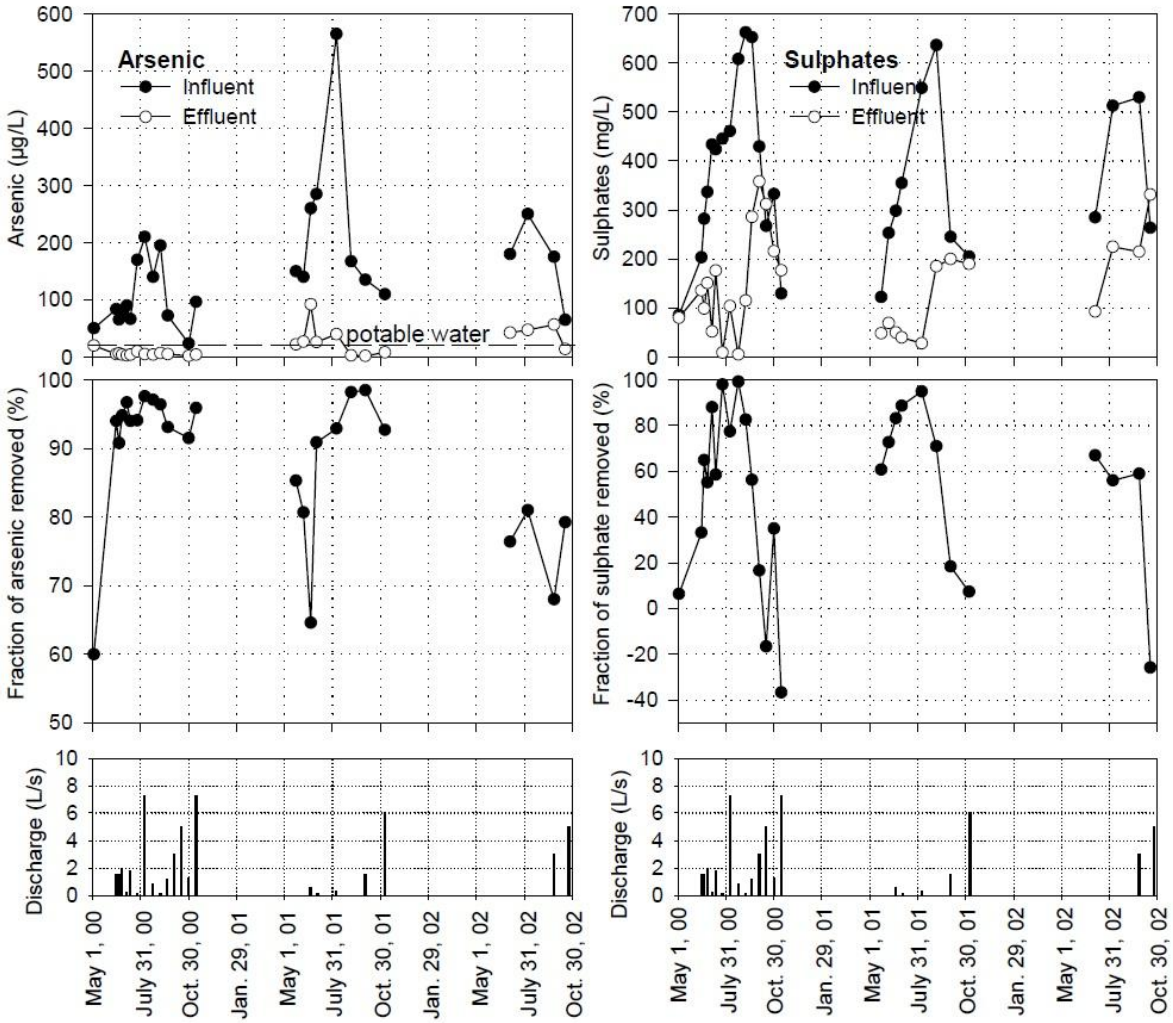

Figure 22: Arsenic and sulphates at the influent and effluent of the biofilter and their respective fraction removed from May 2000 to October 2002. Measured discharge rates are also shown (Germain and Cyr, 2003, p. 7).

3.3. Cold climate solutions

Several pilot scale and full scale PTSs have been built in cold climates and while the efficacy of these PTSs varies, many have successfully treated mine-impacted water (Sobolewski et al, 1994; Nordin, 2000; Duncan, 2002; Wilmoth, 2002; Kuyucak et al, 2006; Groudev et al, 2008; Sobolewski, 2010; Alexco, 2012; Hedin, 2013). It is clear, however, that cold climate adaptations are required for PTSs in these environments. While site-specific adaptations are often required, some basic principles are common to most cold climate PTSs, discussed below.

3.3.1. Burial and insulation

Freezing temperatures cause obvious problems where liquid water is concerned. Solutions are also relatively straightforward. Freezing of PTSs due to cold ambient winter temperatures can be avoided by underground burial or belowground operation. To avoid hydraulic failure caused by freezing, pipes should be buried below the frost line and/or heat-traced (Duncan, 2002; Alexco, 2012). Bioreactors may also be built in abandoned mineshafts to allow year-round operation in cold climates (Nordwick et al, 2006).

Insulating PTSs from freezing can also be achieved in various ways. Insulation may be in the form of burial under organic matter, vegetation or standing water, as in the case of horizontal sub-surface flow wetlands (Duncan et al, 2002); insulation with a layer of straw (Kadlec et al, 2003); polystyrene sheets (Kuyucak et al, 2006); air pockets (Giaever, 2003); or snow cover (Kadlec et al, 2003). For systems in the far north, the design must account for interactions with permafrost, both in the short-term (potential freezing from the sides and bottom of excavations) and in the long-term (subsidence induced by loss of permafrost). If precautions are taken then maintenance of above zero temperatures in bioreactors or CWs can be relatively easy, as decomposition and bacterial activity help to maintain temperatures.

3.3.2. Establishment of biotic communities

PTSs rely on biotic components for which seasons of high productivity are often short and also coincide with periods when construction takes place. Bacteria and vegetation in northern environments are adapted to survive and thrive in these conditions, however, in engineered systems the time needed to establish these communities can be overlooked. Due to extreme seasonal variation in cold climates, any PTS with components of vegetation or microorganisms must prepare for periods of low or no productivity. Construction should be planned such that vegetation is allowed to fully establish in wetlands before mine-impacted water is introduced (Goulet & Pick, 2001). Typically, excavation of beds and other earthworks will be done in the fall, while plant propagation and fertilization is done in early spring, allowing a full growing season to recover from transplantation shock and establishment of a sturdy root system.

Similarly, SRB populations need time to colonize substrates prior to introduction of contaminated waters and cold temperatures (Gusek, 2002; Kuyucak et al, 2006; Nordwick et al, 2006; Alexco, 2012). Starting passive systems in warm ambient temperatures at the beginning of the summer is often the best way to ensure the survival and establishment of SRB and macrophytic communities. Burial of the organic layer can also aid in the establishment of dense biotic communities (Kuyucak et al, 2006). More specifically, when a new PTS is commissioned in the fall, establishment of the microbial community and satisfactory removal efficiencies might require 3 to 12 months (Wilmoth, 2002; Hedin, 2013). Sufficient establishment of biotic communities can be a challenge in cold climates with short growing seasons, but is often crucial to the efficient functioning of PTSs.

3.3.3. Maintenance of constant flow

Constant, steady flow through a PTS is essential to maintain hydraulic retention times and to avoid freezing. Hydraulic failure due to freezing may occur if flow is decreased below a minimum rate. Additionally, increased flow during spring run-off can be detrimental to the efficiency of a PTS. Flow

through PTSs should be maintained at a constant rate through different seasons to reduce the potential of flushing out heavy metals (August et al, 2002; Nordwick, 2006). Flushing of metals may also occur as a result of system shutdowns or addition of new treatment cells (Duncan, 2010). To aid in maintaining constant flow, flow equalization ponds should be designed upstream of the treatment system. Overflows may also be necessary to accommodate spring run-off or surges in flow (Kuyucak et al, 2006). Bypasses may be necessary for components that may not function in winter. Parallel systems can also be used to accommodate increases in flows (Ettner, 2007). Recirculation of treated water at times of low flow volume may also be a solution for some PTSs. While maintaining constant flow is not an easy task in areas with extreme seasonal variation in flow rates, solutions do exist and further innovation will continue to improve this aspect of PTSs.

3.3.4. Liquid carbon sources

Bioreactors that rely on bacterial activity to treat mine-impacted water experience reductions in organic matter decomposition during the winter when cold temperatures cause limited productivity. To offset the reduction in organic matter decomposition, which feeds SRB, the addition of liquid carbon may be advantageous (Tsukamoto et al, 2004; USEPA, 2005; Sobolewski, 2010 Alexco, 2012; Gould et al, 2012). Often, the increased and year-round treatment performance more than offsets increased costs incurred by the need for reagent addition (Sobolewski, pers. Comm., October, 2014). Glucose, lactate/acetate, ethanol, methanol, ethylene glycol and other carbon sources have all been used to supplement bioreactors. Finding the optimal liquid carbon source and concentration required often relies on bench or lab-scale testing.

3.4. Knowledge gaps

Mining companies in the North attempting to implement PTSs face many challenges and despite the growing body of knowledge on their performance in cold climates, there are areas that require future research. As more cold climate PTSs are developed and implemented, our understanding of the factors affecting their efficiency and long term performance will continue to grow.

3.4.1. Seasonal variation in efficiency

While some studies have assessed seasonal variation in pilot-scale PTSs (Goulet & Pick, 2001; August et al, 2002; Gusek, 2002; Hedin, 2013; Panos et al, 2013), a greater understanding of the factors that affect efficiency losses would help PTS designers maximize the potential of their PTS. Understanding the metabolic activities of SRB and the entire scope of the microbial communities present in bioreactors and wetlands at permanently low temperatures is crucial (Robador et al, 2009). More importantly, studies are needed to determine if a relationship can be established between summer and winter metal removal rates and rates of sulfate reduction, carbon consumption, metal precipitation and sorption (Gammons et. al., 2000). Such seasonally-adjusted rates will support the development of seasonally-adjusted treatment performance and design criteria for PTSs that function year-round. Often, site-specific factors such as precipitation, temperature, pH, type of mine discharge and PTS design will interact in novel ways creating unique situations. However, with more PTS being built in cold climates, patterns about the behaviour of such systems are starting to emerge.

3.4.2. Abiotic factors in winter

A number of studies have highlighted the importance of abiotic factors in removing metals during winter months (e.g., Kwong and Whitley, 1993; MacGregor, 2002). Freeze/thaw cycles affect metal attenuation in sediments and can cause diffusion into permafrost which may lead to long-term storage (MacGregor, 2002). Sedimentation may also play an important role in CWs in the winter (Wittgren & Maehlum, 1997). These abiotic factors could be incorporated into the design of PTSs to improve winter treatment performance. As in Section 3.3.1, these factors may be unique in each setting; however as more cold climate PTSs are developed, the interplay between biotic and abiotic factors will be better understood.

3.4.3. Local species and feedstocks

Most of the research about wetland plants and organic substrates in PTSs has been done in temperate regions. As PTSs are introduced into new environments, native species and local feedstocks will have to be identified. Native plant species should be chosen to minimize the risk of introducing invasive species and to ensure that the plants are adapted to their environment. Identification of native plants that are metal tolerant and are low shoot accumulators (Stolz & Greger, 2002) requires lab, bench and pilot trials. Additionally, locally available substrates for SRB activity in bioreactors and CWs should be identified. Ideally these will be waste materials that are available on-site or nearby. While organic substrates like manure, peat, woodchips and sawdust might be easily obtained in more southern areas, these materials are often not as plentiful in remote, northern mine sites. Identification and characterization of potential feedstocks would allow PTS designers to choose the appropriate substrate for their system.

3.4.4. Expected lifetime of PTSs in cold climates

The design life of PTSs are generally not well-understood, especially in cold climates, although many natural wetlands seem to demonstrate the longevity sought after by PTS designers. Predicting the lifetime of a PTS is essential to planning its construction, as well as potential maintenance requirements. Characterization of potential organic substrates can help to optimize the long-term performance of bioreactors (Neculita et al, 2010). Research into organic substrates available in the north and their behaviour in PTSs would serve to better predict the potential lifespans of cold climate PTSs. Further research and monitoring of natural wetlands receiving mine drainage might also help elucidate the mechanisms and characteristics of long term treatment wetlands.

3.4.5. Optimal organic carbon source

Addition of a liquid carbon source to PTSs can be a useful approach to offset the loss of efficiency in cold temperatures. Reduced decomposition of organic matter can cause a reduction in microbial activity and populations. SRB and other microorganisms can be fed with a liquid carbon source to maintain their activity and population throughout the winter months. Studies have assessed various different organic carbon sources for supplementing bioreactors in cold climates (Tsukamoto et al, 2004; EPA, 2005; Gould et al, 2012; Sobolewski, 2010). Further research is required to assess the effect of carbon feed and the rate of carbon consumption in order to help predict the carbon amounts required to design efficient PTS in cold climate locations. Optimizing a carbon source for cold climate

bioreactors will enhance their performance; however, the engineering requirements and costs for systems that supply organic carbon sources should also be assessed.

4. CONCLUSION

With increasing industrial activity in northern Canada there is a need for research, development and implementation of cost effective systems that ensure long term environmental protection. Passive treatment of mine impacted water has become increasingly common over the last 30 years. Passive treatment systems (PTSs) often consist of constructed wetlands (CWs), bioreactors, or some combination and/or variation on both of these components. These PTSs are sustainable alternatives to active treatment systems and represent the next generation of mine water treatment.

Natural wetlands have been treating mine-impacted water in cold climates since mining activity began and provide important information about the processes that drive PTSs, as well as providing insight into the potential for the long-term performance of CWs. Numerous studies have found evidence of metal retention in natural wetlands from both natural and anthropogenic sources of contamination. Following observed natural attenuation processes and metal retention demonstrated in natural wetlands, engineered PTSs have been designed and implemented to treat contaminated water worldwide.

Mine sites in northern environments are often located in remote locations with limited access and power, short growing seasons and cold winter temperatures, conditions which can present challenges for PTS design. These challenges however, are also often reasons for choosing PTSs, which can be constructed to operate year-round with little maintenance and no power. PTSs should ideally be able to function for decades with no power and while most systems are not truly “walk-away” scenarios, they are generally much lower maintenance than active systems. Implementation of PTSs in cold climates has been less common to date; however, several pilot scale and full scale PTSs have been built in cold climates. While the efficacy of these PTSs varies, many have successfully treated mine-impacted water to meet or exceed water quality objectives.

While success in cold climates has been variable, many PTSs have been highly successful (Norway, Bulgaria, BC, Yukon, and Quebec). Often, site-specific factors such as precipitation, temperature, pH, mine discharge chemistry and PTS design will interact in novel ways creating unique situations. As PTSs are constructed in cold climate, remote environments, patterns regarding the behaviour of such systems are starting to emerge. It is clear from this review that PTSs can be successfully implemented in cold climates, provided extensive planning and research in regards to design and construction are taken into consideration to address challenges encountered in northern environments. Some of the challenges facing PTSs in cold climates include hydraulic failure due to freezing in winter, reduced microbial activity, and increased water flows during spring melt. Many adaptations have been developed to overcome these challenges such as burial and insulation of pipes to prevent freezing, allowing sufficient time for the biotic community to establish following construction, ensuring constant flow over the season and identifying appropriate feedstocks and carbon sources that promote SRB and other microorganisms. Due to not only the site-specific challenges associated with implementing PTSs, but the additional challenges in cold climates, laboratory, bench- and field- scale experiments are needed prior to full scale implementation. However, due to the many advantages PTSs provide over active systems, these systems should be strongly considered for use in the North.

EXECUTIVE SUMMARY

Casino Mining Corporation (CMC) is currently evaluating the Casino Copper-Gold Project, a proposed copper-gold-molybdenum mine located in the Dawson Range Mountains of the Klondike Plateau, approximately 300 km northwest of Whitehorse, Yukon Territory, Canada.

The deposit is hosted by the Casino Complex, a suite of igneous intrusive rocks with an intense hydrothermal alteration overprint. The project site is unique as the region was not glaciated during the Wisconsin Advance. The proposed mine calls for 120,000 tonnes per day (tpd) of ore production using open pit methods.

Knight Piésold Ltd. (KPL) has been retained to complete a Feasibility level geotechnical assessment and pit slope design for the proposed Casino open pit. Geotechnical site investigations were completed by KPL in 1994, 2010, and 2011, to collect geomechanical and hydrogeological data for open pit slope design. A preliminary pit slope geotechnical assessment was completed in 2008 based on a review of the 1994 geomechanical data and presented in the KPL report "Preliminary Open Pit Slope Design" (Ref. No. VA07-01637, January 2008). Additional site investigation data were collected by KPL during May to August of 2010 and CMC produced an updated pit shell model the following November. KPL completed a review of the new pit shell model using the 1994 and 2010 geomechanical data and presented the results in the report "Updated Open Pit Slope Design" (Ref. No. VA10-01460, February 2011). A supplementary geotechnical site investigation program was performed in 2011 to collect additional geotechnical data in support of a Feasibility level pit slope design. The findings of the site investigation are presented in the report "2011 Geomechanical Site Investigation Data Report – Open Pit" (Ref. No. VA101-325/8-6, April 2012).

A simplified geotechnical model was developed for pit slope design, which includes four geotechnical domains as follows:

- Overburden (silty SAND and GRAVEL with trace clay, residual soils and talus)
- Weathered Zone (largely within the Dawson Range Batholith unit)
- Prospector Mountain Suite (Late Cretaceous, Patton Porphyry, Explosion Breccia, Intrusion Breccia), and
- Dawson Range Batholith (Middle Cretaceous, Granodiorite and Diorite).

Overburden is present as a thin veneer across most of the deposit area, but is up to 30 m thick in localized areas near the northern edge of the proposed pit. Weathered Bedrock underlies the overburden and varies in depth from 30 to 200 m throughout the deposit area. The Dawson Range Batholith (DRB) domain occupies the majority of the deposit. The central and southwest portions of the deposit are exposed within the Prospector Mountain Suite (PMS) domain.

The proposed open pit includes two major mining zones, namely the Main Pit and West Pit, respectively. A total of eight design sectors were delineated for pit slope stability assessment based on the projected wall geology and wall orientations. Sub sectors were defined to differentiate the overburden and weathered zones from the fresh bedrock.

Kinematic stability analyses were performed for all design sectors using stereographic techniques to determine the failure modes that are kinematically possible in bench and/or multi-bench scale slopes. Multi-bench scale wedge failures are kinematically possible in the M-North and W-North Sectors. Multi-bench planar failures are kinematically possible in the M-South and W-North Sectors.

In addition, bench scale wedge, planar, and toppling features were identified in various design sectors. Bench face angles and inter-ramp slope angles have been selected to reduce the risk from structurally controlled wall failures.

Large-scale multi-bench rock mass slope stability was assessed through the use of limit equilibrium modelling methods. Limit equilibrium stability models were set up for overburden slopes, inter-ramp slopes within each geotechnical domain, and final M-North, M-Northeast, and W-West Walls, respectively. The analysis indicates that the following pit slope angles are achievable if low damage wall blasting practices and effective slope depressurization measures are implemented:

Design Sector	Slope Height	Wall Geology	Bench Face Angle	Bench Height	Bench Width	**Inter-ramp Angle**	Max Inter-ramp Slope Height	**Overall Slope Angle**
	M		°	m	m	**°**	m	**°**
M-North	30	Overburden	40	5	4	**27**	200	**39**
	600	DRB	60	15	8	**42**		
M-Northeast	30	Overburden	40	5	4	**27**	100[(1)]/200	**40**
	600	DRB	65	15	8	**45**		
M-South	540	PMS, DRB	65	15	8	**45**	200	**42**
Central	210	PMS	65	15	8	**45**	200	**N/A**
W-North	285	DRB	60	15	8	**42**	200	**39**
W-South	480	DRB	65	15	8	**45**	200	**42**
W-Southwest	345	PMS	65	15	8	**45**	200	**42**
W-West	210	DRB	65	15	8	**45**	200	**42**

NOTES:

1. A 100-m high inter-ramp slope is recommended for slopes developed in weathered bedrock. The maximum height for the inter-ramp slopes in fresh rock is 200 m.

A conceptual pit water management plan was also developed for costing purposes. It includes surface water diversion ditches, vertical pumping wells, horizontal drains, and pit dewatering systems. Groundwater seepage into the pit was estimated to be in the order of 190 L/sec for the final pit configuration. The pit dewatering systems were designed to remove pit water from a 1 in 10 year 24 hour storm event. It was determined that approximately 1390 L/sec would flow into the pit during the design storm event. Two pumps operating at a combined capacity of 320 L/sec would be required to dewater the pit over a six day period. Booster pump stations have been included at every 100 m rise in elevation.

Careful controlled blasting should be conducted to minimize the blasting damage to the pit walls. Catch benches should be cleaned as required to ensure effectiveness. Scaling loose material off of the walls is recommended to reduce the hazard of falling rock. It is recommended that horizontal drains and vertical pump wells be installed during mining operations to reduce pore water pressure in the middle and lower slopes.

An extensive geotechnical monitoring program is recommended to detect slope instabilities that may occur during operations. Geotechnical mapping of the pit walls and any tension cracks, installation and regular monitoring of surface prisms, and the implementation of automated pit wall deformation monitoring systems are recommended as part of the monitoring program.

It is recommended that additional geomechanical and hydrogeological data collection be collected during the early stages of pit operations. The data collection programs may include bench surface mapping, piezometer installation and monitoring. Additional information will be used to enhance the geotechnical database, update the rock mass structural model, and refine the hydrogeological model. The pit design should be optimized when additional geotechnical information becomes available. The final pit designs and pit dewatering plans should be reviewed by qualified geotechnical engineers.

1 – INTRODUCTION

1.1 PROJECT BACKGROUND

Casino Mining Corporation (CMC) is currently evaluating the Casino Copper-Gold Project, a proposed copper-gold-molybdenum mine, in the Yukon Territory. The project is located in the Dawson Range Mountains of the Klondike Plateau approximately 300 km northwest of Whitehorse, Yukon Territory, Canada, as shown on Figure 1.1. This area is unique as the region was not glaciated during the Wisconsin Advance.

The deposit is hosted by the Casino Complex, a suite of igneous intrusive rocks with an intense hydrothermal alteration overprint. The deposit will be mined using open pit methods with a nominal mill throughput of 120,000 tonnes per day (tpd) of ore. The general arrangement of the project site is shown on Figure 1.2.

1.2 PREVIOUS WORK

Knight Piésold Ltd. (KPL) has been involved in the Casino Project since the early 1990's. Previous work relating to the investigation and design of the Casino Open Pit included the following:

- **Preliminary Surficial Geotechnical Investigations** – Approximately 20 geotechnical trenches were excavated for visual description and preliminary characterization of surficial materials in 1993. Representative soil samples were collected for laboratory testing, including particle size analyses, natural moisture contents, Atterberg limits (plasticity), compaction tests and permeability tests. The results of the site investigations are included in KPL report "Report on Preliminary Surficial Geotechnical Investigations" (Ref. No. 1831/1, March 1994).
- **1994 Geotechnical and Hydrogeotechnical Investigations** – KPL drilled and logged 11 drillholes throughout the open pit area. Groundwater monitoring wells were installed in three drillholes, and thermistors were installed in three other holes. In situ packer, falling head permeability tests, and shut-in pressure tests were conducted within the drillholes, and representative rock core was collected for laboratory testing. Point load testing was conducted on site on select rock core samples. The results of the investigations are included in KPL report "Data Compilation Report on 1994 Geotechnical and Hydrogeotechnical Investigations" (Ref. No. 1832/2, February 1995).
- **Preliminary Open Pit Slope Design** – A preliminary open pit geotechnical assessment of the 1995 pit shell model was completed in 2008 utilizing the available relevant geotechnical data. Kinematic and limit equilibrium stability analyses were performed. Recommendations for bench geometry, inter-ramp slope and overall slope angles were provided in KPL Letter Report "Preliminary Open Pit Slope Design" (Ref. No. VA07-01637, January 2008).
- **2010 Geotechnical Site Investigation** – Three oriented geomechanical holes were completed in 2010. In situ permeability testing was conducted at regular intervals during drilling. A standpipe piezometer was installed in one drill hole and vibrating wire piezometers were installed (by AECOM) in the remaining two holes. Packer hydraulic conductivity (Lugeon) tests were conducted at selected intervals in all of the drillholes. The results of the investigations performed by KPL are included in KPL report "2010 Geotechnical Site Investigation Data Report" (Ref. No. VA101-325/3-4, November 2010).
- **Updated Open Pit Slope Design** – KPL completed an updated pit slope geotechnical design for the Pre-feasibility study. This updated geotechnical study was conducted to incorporate the 2010 Geotechnical Site Investigation data into the existing open pit pre-feasibility design. Recommendations for bench geometry, inter-ramp slope and overall slope angles were provided in KPL Letter Report "Updated Open Pit Slope Design" (Ref. No. VA10-01460, February 2011).
- **2011 Site Investigation** – Five oriented geomechanical holes were completed in the summer of 2011. In situ packer permeability testing was performed at regular intervals during drilling. Standpipe piezometers were installed in three of the drill holes. Borehole surveys were conducted in three holes using an acoustic televiewer. Overburden and rock core samples were collected for laboratory testing. The results of the investigation are included in KPL report "2011 Geomechanical Site Investigation Data Report" (Ref. No. VA101-325/8-6, 2012).

Additional work has been performed on site by AECOM in support of the feasibility study. AECOM has installed a total of 2 thermistors, 7 vibrating wire piezometers, and 10 (mini) piezometers in the open pit area between 2008 and 2010. The hydrogeological investigations by AECOM are

summarized in the report "Casino Project – Hydrogeological Technical Report – DRAFT" (Ref. No. 60146995-9, March 2011).

1.3 SCOPE OF WORK

KPL has been retained to conduct a feasibility level geotechnical design for the Casino open pit. The geomechanical and hydrogeological information collected from the previous field programs was utilized to develop a geotechnical database for the feasibility level pit slope design. The open pit geotechnical assessment included:

- Geotechnical characterization and geotechnical model development
- Slope stability analyses
- Conceptual pit water management plan, and
- Pit slope recommendations.

This report presents the major findings along with recommendations for the Casino pit slope development and pit water management.

2 – GENERAL SITE SETTING

2.1 PHYSIOGRAPHY

The Casino Porphyry Copper-Gold-Molybdenum Project is located in the west-central region of the Yukon Territory in an overlapping zone featuring the Yukon Cataclastic Terrane to the North, and the Yukon Crystalline Terrane to the South (M3, May 2011). The site lies within the Boreal Cordillera ecozone, which includes several mountain ranges such as the northwest trending Dawson's Range Mountains. The region is characterized by well-rounded ridges and rolling hills that reach a maximum elevation of 1675 masl. It also includes several extensive plateau regions. The hills are deeply cut by a series of dendritic drainages of the Yukon River watershed, with the primary drainage channels occurring below an elevation of 1000 masl (M3, May 2011).

The Dawson's Range exhibits unique surficial geology because the area did not experience continental glaciation during the Pleistocene. The effects of minor alpine glaciation such as cirques and terminal moraines are present in some areas (M3, May 2011).

2.2 REGIONAL GEOLOGY

The Casino Deposit is centered in an Upper-Cretaceous aged tonalite porphyry stock that is elongated in the east-west direction. The stock intrudes Mesozoic granitoids of the Dawson's Range Batholith as well as Paleozoic schists and gneisses of the Yukon Crystalline Complex (M3, May 2011).

The intrusion of the tonalite stock caused extensive brecciation of the country rocks, which is best developed at the eastern end of the stock where the fracture system extends up to 400 m wide in plan view (M3, May 2011). The fractures in the stock and country rocks have copper, gold, and molybdenum mineralization from hydrothermal fluids which flooded the brecciated rocks.

Outcrop exposure is rare as the overburden is extensive. Soils are found ranging from coarse talus of the immature horizons at higher elevations to more mature soil horizons and thick organic layers on the valley floors.

2.3 CLIMATE AND HYDROMETEOROLOGY

The climate of the west-central Yukon is considered sub-arctic, with widespread permafrost on north-facing slopes and discontinuous permafrost on south-facing slopes. It is characterized by long, cold, dry winters and short, warm, wet summers. Typical wind speeds in the region are relatively stable throughout the year at approximately 2.3 m/s from the southwest direction (KPL, June 2010).

The mean monthly temperatures range from approximately -18.1°C in January to 11.1°C in July (M3, May 2011) and are moderated by the effects of the Pacific Ocean. The daily maximum temperatures occur in July and are typically around 30°C (KPL, June 2010).

Precipitation is generally highest during the summer months of July and August and lowest during the winter months of February to April. The estimated mean annual precipitation is approximately 500 mm, falling as snow throughout the months of November to March, as rain from May to September, and as a mixture of the two in the remaining months. The highest humidity values are generally 70 to 80% and are experienced in the fall and early winter. The lowest humidity values are generally 50 to 60% and experienced in the spring and early summer (KPL, June 2010).

2.4 HYDROGEOLOGY

The Casino Project is situated on a small divide, with the North slopes draining into Canadian Creek and Britannia Creek, which are tributaries of the Yukon River. Slopes situated on the south side of the divide drain into Casino Creek and its subsidiary Dip Creek, which is a tributary of the Donjek and Yukon Rivers (M3, May 2011).

Flow patterns of Big Creek, the Indian River, and the Little South Klondike River were compared using data from 1983, 1985-1991, and 1993 in order to come up with a reasonable representation of expected flow patterns for the site area. These water bodies were used because they are contained within similar watersheds and occur over terrain similar to the Casino Project site (KPL, June 2010).

The analysis resulted in the production of similar bi-modal hydrographs with peak flows during the freshet, which most commonly occurs in May as a result of spring melting. Second, smaller peaks occur in late summer as a result of increased rainfall as well as melting of the active permafrost layer. Low flows occur during the winter when precipitation falls as snow and many of the smaller streams freeze solid. The approximate evapotranspiration value was determined to be 308 mm annually (KPL, June 2010).

2.5 SEISMICITY

The region of the southwest Yukon Territory and northwest British Columbia is one of the most seismically active areas in Canada. The seismic hazard in the region is also influenced by the seismically active region of southeast Alaska. The coastal region has experienced many large earthquakes, including events with magnitudes in the range of magnitude 7.0 to 8.0. In 1958 a magnitude 7.9 earthquake occurred along the Fairweather fault (the northern extension of the Queen Charlotte transform fault). The most significant inland zone of seismicity follows the Dalton and Duke River segments of the Denali fault zone through the southwest Yukon. Farther inland there is only minor seismicity between the Denali and Tintina fault systems, including the region of the Casino Project site.

Review of historical earthquake records and regional tectonics indicates that the Casino Project site is situated in a region of low seismic hazard. A probabilistic seismic hazard analysis has been carried out using the database of Natural Resources Canada. The results are summarized in Table 2.1 in terms of earthquake return period, probability of exceedance (for a 23 year design operating life) and median average maximum ground acceleration.

Table 2.1 Summary of Probabilistic Seismic Hazard Analysis

Return Period (Years)	Probability of Exceedance[1] (%)	Peak Ground Acceleration (PGA)	
		Median PGA[2,3] (g)	Estimated Mean PGA[3,4] (g)
100	21%	0.04	0.05
475	5%	0.07	0.08
1000	2%	0.08	0.10
2500	1%	0.11	0.14

NOTES:

1. PROBABILITY OF EXCEEDANCE CALCULATED FOR A DESIGN LIFE OF 23 YEARS.
   $q = 1^{-(-L/T)}$
   WHERE: q = PROBABILITY OF EXCEEDANCE
   L = DESIGN LIFE IN YEARS
   T = RETURN PERIOD IN YEARS
2. PEAK GROUND ACCELERATIONS OBTAINED FROM THE SEISMIC HAZARD DATABASE OF NATURAL RESOURCES CANADA.
3. PEAK GROUND ACCELERATIONS ARE FOR "VERY DENSE/SOFT ROCK" (SITE CLASS C), AS DEFINED BY THE NATIONAL BUILDING CODE OF CANADA (2005).
4. MEAN PGA VALUES ESTIMATED AS 1.2 X MEDIAN VALUES.

The corresponding maximum acceleration is 0.07g for a return period of 475 years, confirming a low seismic hazard for the site.

3 – FUNDAMENTALS OF PIT SLOPE DESIGN

3.1 GENERAL

The objective of the pit slope design is to determine the steepest, practical slope angles for the open pit mine to maximize the extraction of the identified ore resource. This must be balanced against the fact that over-steepened slopes may lead to the development of large instabilities that could ultimately impact worker safety, productivity and mine profitability. The pit slope design approach is based on achieving an acceptable level of risk and incorporating this into the stability analyses as a Factor of Safety (FOS) and/or Probability of Failure (POF).

This section briefly introduces pit slope terminology that is used throughout this report and some of the key geotechnical and mining factors that can impact slope design. In addition, a summary of the analysis techniques utilized during this study and the adopted risk management approach are discussed.

3.2 PIT SLOPE CONFIGURATIONS

The inter-relationships between bench geometry, inter-ramp slope angle and the overall slope angle are illustrated on Figure 3.1. The primary components of a pit design are as follows:

- **Bench Geometry** – The heights of benches are typically determined by the size of the shovel chosen for the mining operation. The bench face angle is typically selected in such a way as to reduce the amount of material that may detach and fall from the face or crest. The bench width is sized to prevent small wedges and blocks from the bench faces falling down the slope and potentially impacting personnel and equipment. The resulting bench geometry will dictate the inter-ramp slope angle. Double or triple benches can be used in certain circumstances to steepen inter-ramp slopes.
- **Inter-ramp Slope** – The maximum inter-ramp slope angle is typically dictated by the bench geometry. However, it is also necessary to evaluate the potential for multiple bench scale instabilities due to large-scale structural features such as faults, shear zones, bedding planes, foliation, etc. In some cases, these persistent features may completely control the achievable inter-ramp angles and the slope may have to be flattened to account for their presence.
- **Overall Slope** – The overall slope angle that is achieved in a pit is typically flatter than the maximum inter-ramp angle due to the inclusion of haulage ramps. Other factors that may reduce the overall slope angles are things such as, rock mass strength, groundwater pressures, blasting vibration, stress conditions and mine equipment requirements.

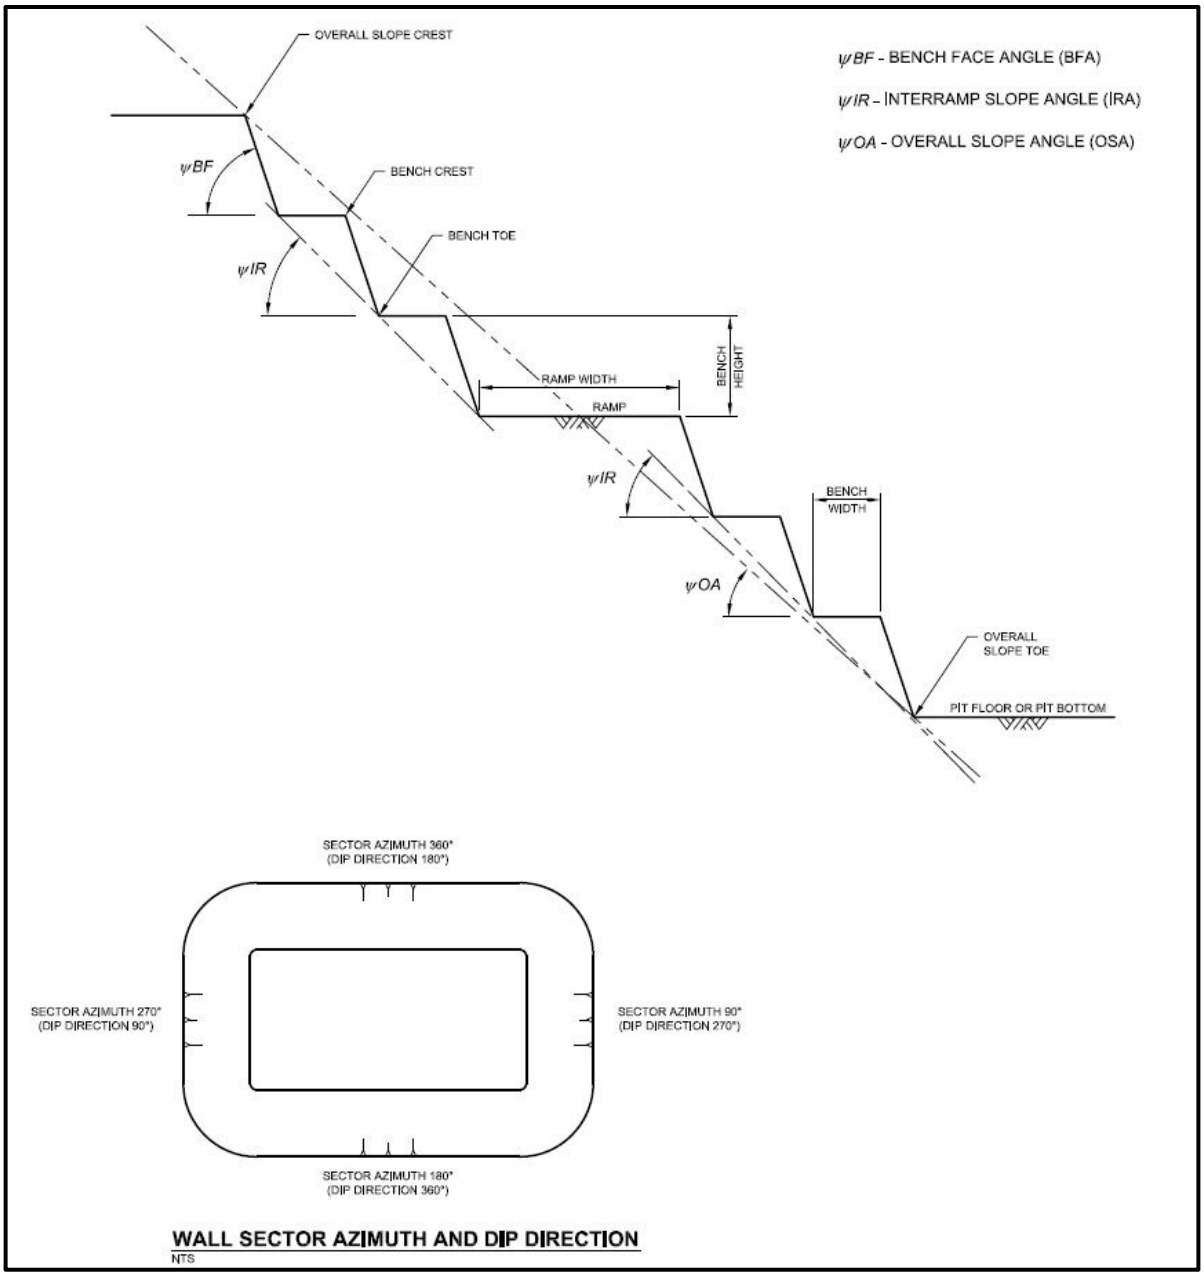

Figure 3.1 Typical Open Pit Slope Configurations

3.3 KEY CONSIDERATIONS FOR PIT SLOPE STABILITY

The stability of open pit slopes in rock is typically controlled by the following key geotechnical and mining factors:

- **Lithology and Alteration** – The rock types intersected by the final pit walls and level of alteration are main factors that impact eventual stability of the pit. Geotechnical domains are created by grouping rock masses with similar geomechanical characteristics.

- **Structural Geology** – Large-scale structural features such as the orientation and strength of major, continuous geological features such as faults, shear planes, weak bedding planes, structural fabric, and/or persistent planar joints will strongly influence the overall stability of the pit walls.
- **Rock Mass Structure** – Small-scale rock mass structural features such as the orientation, strength, and persistence of smaller scale structural features such as joints will control the stability of individual benches and may ultimately restrict the inter-ramp slope angles.
- **Rock Mass Quality and Strength** – Rock mass quality is characterized by using Rock Mass Rating (RMR_{89}), a classification system developed by Bieniawski (1989). Rock mass strength is typically estimated via intact rock strength. Lower rock mass strength may reduce the overall slope angles.
- **Groundwater Conditions –** High groundwater pressures and water pressure in tension cracks will reduce the rock mass shear strength and may adversely impact slope stability. Slope depressurization programs can reduce water pressure behind the pit walls and allow steeper pit slopes to be developed.
- **Blasting Practices** – Production blasting can cause considerable damage to the rock mass along interim and final pit walls. This increased disturbance can be accounted for during design by incorporating a reduction in the effective strength of the rock mass. Controlled blasting programs near the final wall can be implemented to reduce blasting induced disturbances and allow steeper slopes.
- **Stress Conditions –** Mining induces stress changes due to lateral unloading within the vicinity of the pit. Strain due to stress release can lead to reductions in the quality of the rock mass and increases in slope displacements. Localized changes in pit wall geometry, which result in 'noses', can cause a decrease in the stress regime. This decrease can result in an increased incidence of ravelling type instability in these areas. Modifying the geometry and mining sequence can sometimes manage these stress changes to enhance the integrity of the final pit walls.

3.4 METHODOLOGY FOR PIT SLOPE STABILITY

The pit stability assessment was completed by defining representative geotechnical domains with similar geology, structure, rock mass quality and strength characteristics. A series of pit design sectors were then defined by incorporating the mine geometry into the geotechnical domains and a number of different types of stability analyses were undertaken to determine appropriate slope angles for a given open pit slope. Slope stability analyses undertaken in this study included:

- **Kinematic Stability Analyses** – Stereographic analyses were conducted using the structural data to identify the kinematically possible failure modes of the pit walls. Appropriate bench face angles and/or inter-ramp slope angles were assigned in such a way as to reduce the potential for discontinuities to form unstable wedges or planes. Typically, it is not cost-effective to eliminate all potentially unstable blocks and a certain percentage of bench face instability is acceptable. Most of the smaller unstable features will be removed by the scaling process.
- **Rock Mass Stability Analyses** – Limit equilibrium analyses of the rock slopes were performed to estimate the FOS against large-scale, multiple-bench slope failures. Inter-ramp slopes and select overall pit slopes were modelled as part of these analyses.

3.5 ACCEPTANCE CRITERIA FOR PIT SLOPE DESIGN

The recommended pit slope configurations are developed using data interpreted from a simplified geotechnical model, the rock mass characteristics and groundwater conditions. As this data may be limited or variably distributed and/or of uncertain quality the target level of confidence during a feasibility level pit slope study is typically around 50% to 70%. A general guidance to pit slope design acceptance criteria is summarized below in Table 3.1 (after Read and Stacey, 2009); suggested FOS targets for open pit design at Casino are highlighted in **Bold**.

Table 3.1 Summary of Pit Slope Design Acceptance Criteria

Slope Scale	Consequences of Failure	Acceptance Criteria		
		FOS (min) (Static)	FOS (min) (Dynamic)	POF (max) P[FOS≤1]
Bench	Low to High	1.1	N/A	25% - 50%
Inter-ramp	Low	1.15 - 1.2	1.0	25%
	Medium	**1.2**	**1.0**	**20%**
	High	1.2 – 1.3	1.1	10%
Overall	Low	1.2 – 1.3	1.0	15% - 20%
	Medium	**1.3**	**1.05**	**5% - 10%**
	High	1.3 – 1.5	1.1	≤5%

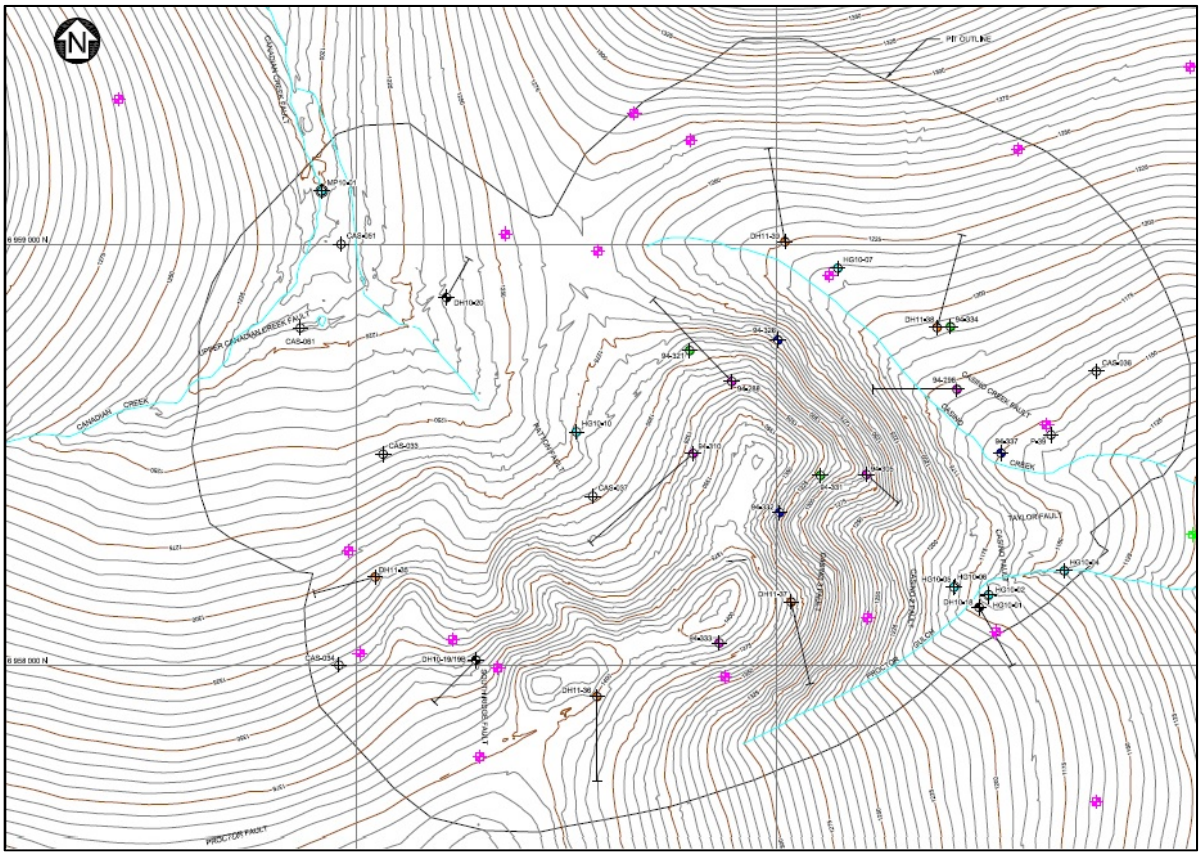
It is noted that there are few recorded instances in which earthquakes have been shown to produce significant slope instability in hard rock open pits. In most cases earthquakes have produced small shallow slides and rock falls in rock slopes, but none on a scale sufficient to disrupt mining operations (Read and Stacey, 2009). Therefore, given the nature of the low seismic hazard at the site, slope stability under seismic (earthquake) conditions is not a significant consideration for the pit slope design for the Casino Project.

4 – GEOTECHNICAL CHARACTERIZATION

4.1 GENERAL

The feasibility study for the open pit utilized information collected during the 1994, 2012, and 2011 geotechnical site investigation programs. The field programs included diamond drilling and logging of oriented core, in situ permeability testing and piezometer installation.

The characterization of the open pit geotechnical conditions was based on all relevant geological, geomechanical, and hydrogeological information from both geotechnical and exploration drill holes, including descriptive geological and geotechnical logging, in situ tests, field testwork and laboratory results.



4.2 DATA SOURCES

The information presented comes from a variety of sources and has been compiled to present the basis for establishing a simplified geotechnical model for pit slope design. The compiled data addresses the four main areas of information required for the pit slope design: geology, structure, rock mass and hydrogeology.

The sources of information that contributed to the development of the geotechnical model for open pit design include:

- 1994 Geotechnical/Hydrogeotechnical Investigations (KPL, February 1995)
- 1994 Exploration and Geotechnical Drilling Program (Pacific Sentinel Gold Corp., 1995)
- 2010 Geotechnical Site Investigation (KPL, November 2010)
- 2010 Hydrometeorology Report (KPL, June 2010)
- 2011 Geotechnical Site Investigation (KPL, April 2012)

Figure 4.1 shows the locations of the geotechnical drill holes and test pits completed within the open pit area during the 1994, 2010 and 2011 site investigation programs. A summary of all geotechnical drill holes completed during these programs is included in Table 4.1. Detailed results for overburden and rock laboratory testing, rock mass quality and rock mass structure characterization are presented in the Data Compilation Report on 1994 Geotechnical/Hydrogeotechnical Investigations (Ref. No. 1832/2, February 1995), 2010 Geotechnical Site Investigation Data Report (Ref. No. VA101-325/3-4, November 2010) and 2011 Geomechanical Site Investigation Data Report (Ref. No. VA101-325/8-6, April 2012).

4.3 GEOLOGY

4.3.1 Overburden

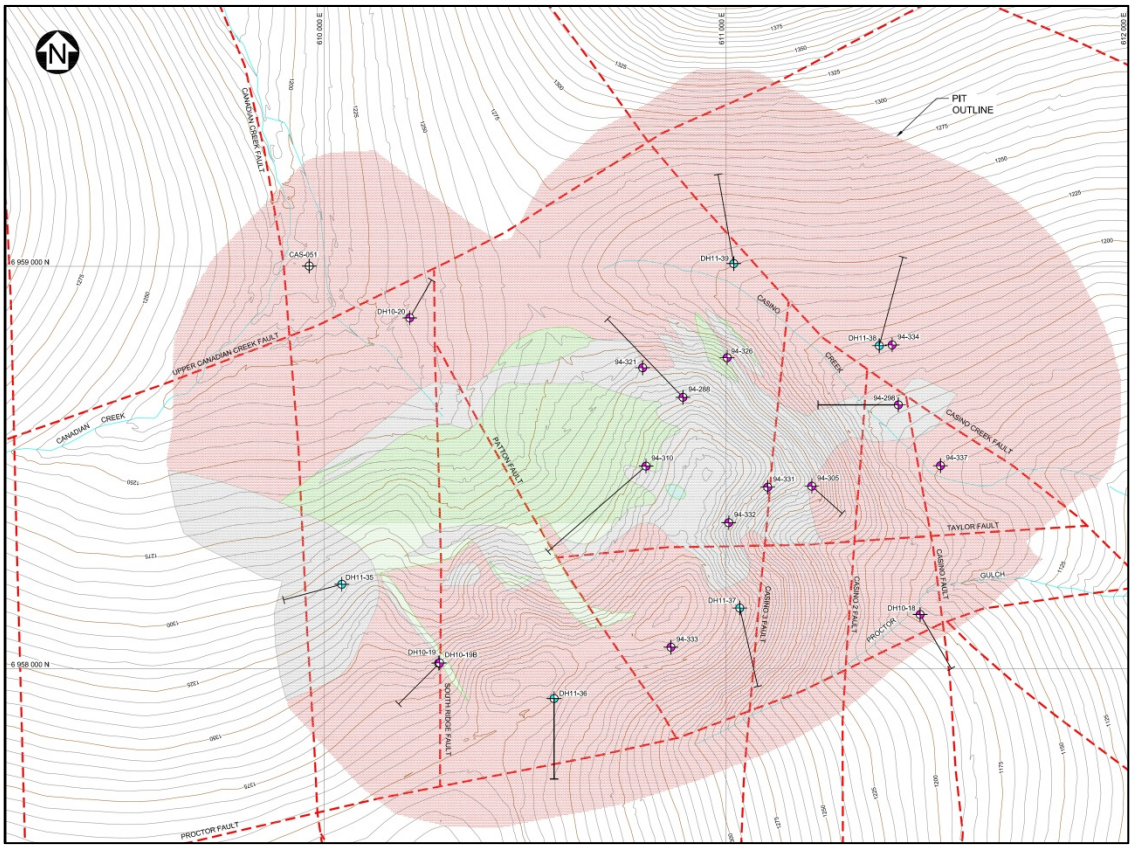
Mechanical weathering has played a dominant role in the production of overburden. Frost action and weathering processes have broken down the top of the bedrock into angular cobble to silt sized particles, referred to as “residual soils” by the project team. The relatively high silt content for residual soils indicated enrichment with windblown loess.

Colluvial deposits have formed along slopes, with the windblown loess and residual soils mixing during transportation downslope. The mixing process causes the colluvium to be locally organic rich. Blocky talus or scree is common at the base of slopes in the deposit area.

The typical composition of the overburden is SAND to GRAVEL with some cobbles and trace clay. The overburden is typically loose to medium dense. The thickness of overburden varies considerably throughout the open pit area due to preferential weathering of bedrock along shear, alteration and fault zones. Drill logs indicate that overburden is negligible in the south side of the deposit, but as thick at 30 m along the north side of the main deposit.

4.3.2 Bedrock

The Casino deposit is centred in a complex of quartz monzonites, intrusion breccias, shallow porphyritic intrusions, and a central breccia to microbreccia body. The major lithology units in the deposit area (from Pacific Sentinel Corp., 1995) are summarized below:



- Patton Porphyry (Late Cretaceous) – The main body of the Patton Porphyry is a relatively small stock approximately 300 by 800 m and is surrounded by an altered intrusive breccia in contact with rocks of the Dawson Range. The Patton Porphyry also forms discontinuous dykes ranging from less than one to tens of meters wide, intersecting both the Patton Porphyry plug and the Dawson Range Batholith.
- Intrusive/Contact Breccia (Late Cretaceous) – The intrusive/contact breccia surrounding the main Patton Porphyry body consists of granodiorite, diorite, and metamorphic fragments in a fine-grained Patton Porphyry matrix.
- Explosive Breccia – Abundant fragments of the Patton Porphyry and its intrusive breccia are present in a late explosive breccia pipe. The unit indicates multiple episodes of brecciation as it contains 5 to 50% ragged fragments of altered intrusive breccia and host rock, with lesser fragments of quartz-phyric Patton Porphyry.
- Dawson Range Batholith (Middle Cretaceous) – The Dawson Range Batholith (DRB) is the main country rock of the deposit, and is characterized by hornblende-biotite-quartz diorite, hornblende-biotite diorite, and biotite-hornblende granodiorite.

Minor lithological units that have been encountered in the open pit area include Yukon Metamorphic rocks (comprised of metasediments, metavolcanics, gneiss and quartzite) and several mafic dykes.

A sub-surficial bedrock geology map is shown on Figure 4.2.

Potassic alteration is centered on and related to the microbreccia that forms the core of Patton Hill. It produced fine grained aggregates of K-feldspar and disseminations of magnetite and biotite. Phyllic alteration typically forms texture destructive quartz-sericite envelopes to quartz-pyrite veinlets (Pacific Sentinel Corp., 1995).

Weathered bedrock is present through the deposit area, varying in thickness from several tens of metres to 200 m thick. The weathered bedrock was identified during the 2010 and 2011 site investigations as part of the geotechnical logging of the drill core. Bedrock was classified as “weathered” if weathering processes have considerably weakened the rock and penetrative discoloration has occurred.

4.4 STRUCTURE

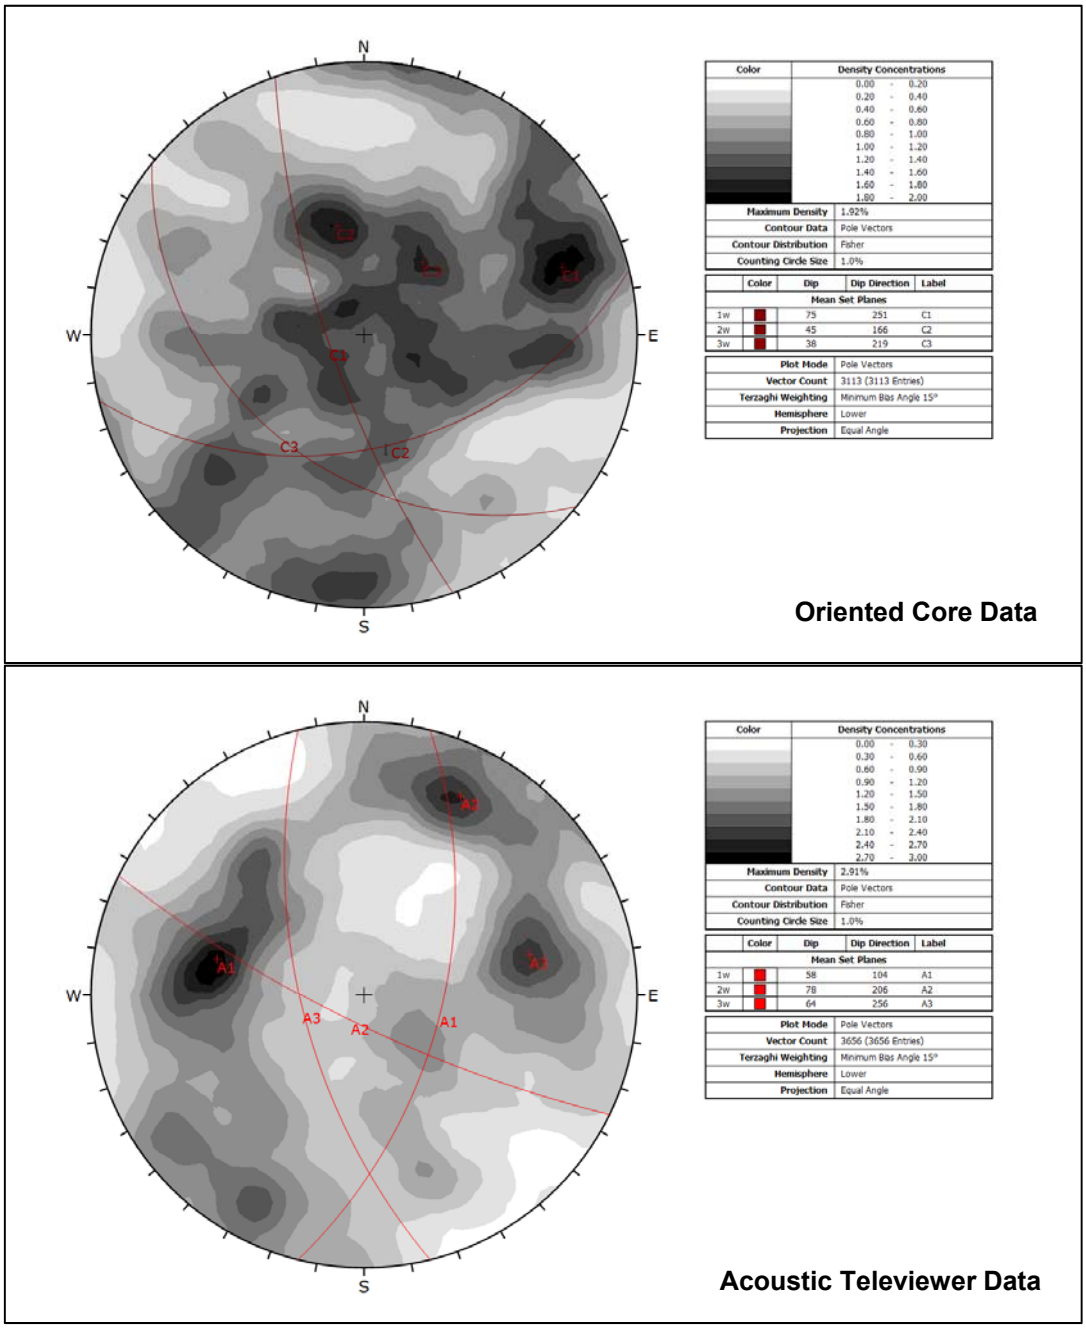
4.4.1 Data Collection Methods

The structure of the bedrock within the open pit area was identified from data collected during the 1994, 2010 and 2011 site investigation programs. Oriented core logs and data from bore hole televiewer surveys were used to create a structural database.

Twelve oriented drill holes have been completed within the open pit area. Four holes were completed in 1994 (DH94-288, DH94-298, DH94-305 and DH94-310), three in 2010 (DH10-18 to 20), and five holes in 2011 (DH11-35 to 39). Drill core during the 2010 and 2011 geotechnical investigations was oriented using the Reflex ACT I and ACT II RD (respectively) core orientation systems.

Borehole televiewer surveys were completed in three drill holes (CAS-051, DH11-35 and DH11-36). The boreholes were scanned using an acoustic televiewer (ATV) probe by the COLOG Division of Layne Christiensen Company (COLOG) and the dip/dip direction of each fracture was calculated from the resulting images. The fractures were also ranked based on the apparent aperture of the feature; from 0 for sealed structures to 5 for major fractures with large openings or breakouts.

Large scale structural features, such as faults, were delineated by the Casino geologists. The surface traces of identified faults are illustrated on Figure 4.2. Fault traces plotted onto the pit shell model indicate that the faults are sub-vertical.



4.4.2 Data Quality Control

Overall pit structure was plotted on stereonets using the Rocscience Inc. DIPS software (DIPS). The data was sorted by source type (oriented core and ATV) and plotted on individual stereonets. All oriented core data and ATV data was corrected for orientation bias using borehole traverse information. Survey Data from the ATV and a Reflex EZ-Shot survey tool was used to compile the borehole traverses.

4.4.3 Structural Orientations

Stereographic plots of the oriented core data and ATV data are shown on Figure 4.3. Eastward and westward trending discontinuity sets are present in both data sets. The oriented core data indicates that these discontinuity sets are typically moderately dipping. The ATV data shows that the east/west dipping discontinuity sets are steeply dipping.

The steeply dipping discontinuity sets presented in the ATV data can be seen as minor pole concentrations within the oriented core data. The discrepancy between the oriented core and ATV data sets is due to the size of each data base and the location of the drill holes in which the ATV surveys were completed. Approximately 8000 discontinuities were measured in the oriented core drilled throughout the open pit area, whereas the ATV survey was conducted within the western end of the open pit and only 250 discontinuities (after filtering out rank 0 and 1 rated features) were recorded.

2. ORIENTED CORE DATA PROVIDED BY KNIGHT PIÉSOLD LTD. DURING THE 2010 AND 2011 GEOTECHNICAL SITE INVESTIGATIONS PROGRAMS.

Figure 4.3 Overall Rock Mass Structure

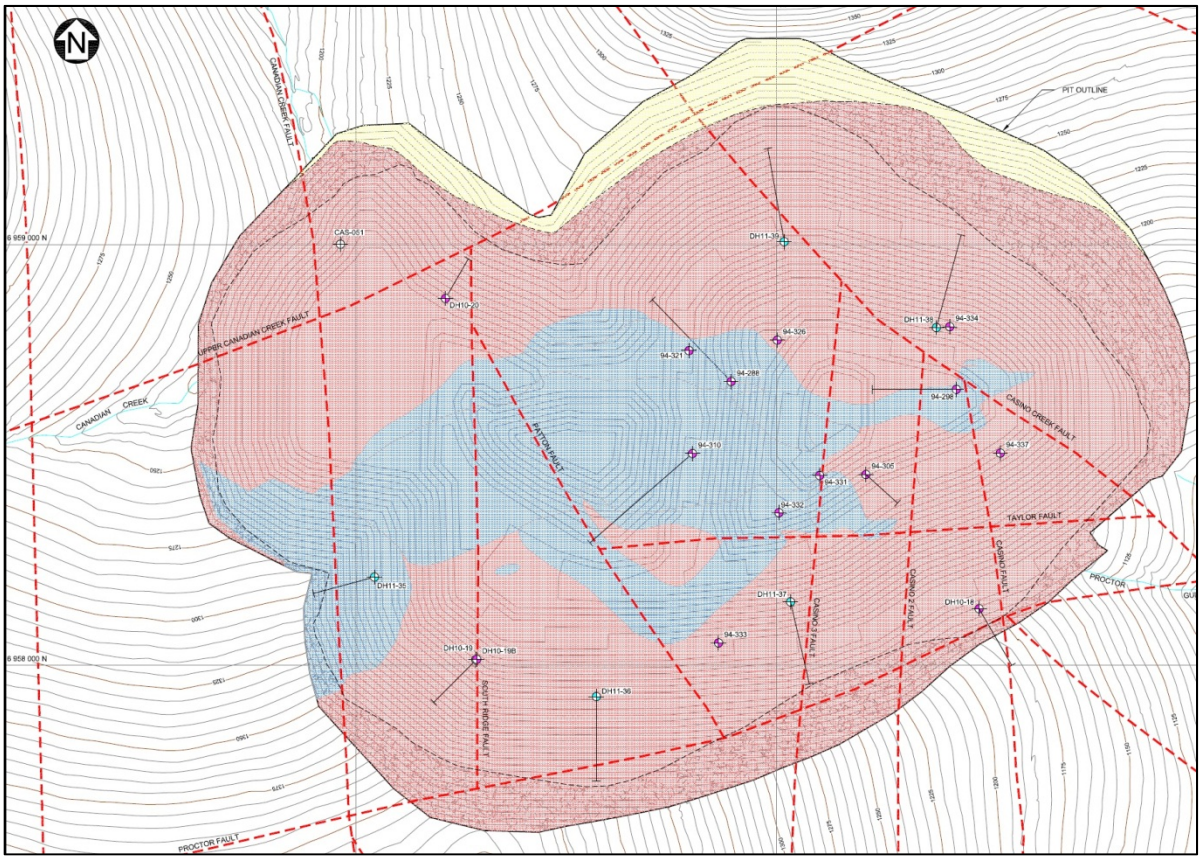
Several faults are present within the Casino deposit area. The largest fault affecting the deposit area on the property is the Casino Creek Fault, a broadly curved steeply dipping, strike-slip fault trending at 310°. Numerous small faults are present on the east side of the Casino Creek Fault, as indicated by the 1994 drill holes. Most of these faults have sub-horizontal slickensides and chlorite-hematite alteration. The Patton Fault also runs through the deposit area, and is sub-vertical with an approximate 310° trend. This fault heads south from Canadian Creek and ends near Patton Hill. A number of other faults have also been identified in the deposit area, and are typically sub-vertical to vertical.

4.5 ROCK MASS

4.5.1 Geotechnical Domains

The geological units that are present on site were grouped into four geotechnical domains for the purpose of geotechnical characterization and stability analysis. The geotechnical domains are as follows:

- Overburden – The overburden is classified as loose to medium dense sand and gravel with some cobbles and trace clay. Overburden is typically found along the northeast rim of the pit with a maximum thickness of 30 m.
- Weathered Zone – The weathered diorite/granodiorite rock vary in thickness from tens to 200 m within the deposit.
- Prospector Mountain Suite (PMS) – The late Cretaceous Patton Porphyry, intrusion breccia and explosive breccia rocks comprise the PMS domain.
- Dawson Range Batholith (DRB) – The middle Cretaceous diorite and granodiorite that comprise the DRB domain.



A preliminary pit shell was utilized to project the final wall geology for the Casino open pit. The projected wall geology is presented on Figure 4.4 along with the fault traces.

4.5.2 Intact Rock Strength

Field estimates of intact rock strength were collected for each drill run. A number of core samples were selected for laboratory point load and Unconfined Compressive Strength (UCS) testing. The test results were compiled and grouped by geotechnical domain.

A summary of the laboratory rock strength values and the average rock strength by geotechnical domain can be seen on Table 4.2. Results of the laboratory rock strength testing indicates that the PMS and DRB domains are considered “Hard” rock with average UCS values of 51 and 55 MPa respectively.

No samples from the Weathered Zone were selected for laboratory strength testing. The intact rock strength of the weathered bedrock in each geotechnical domain was assumed to be equal to one standard deviation below the average rock mass UCS. The strength of the weathered PMS and DRB domains are 31 and 39 MPa, respectively, and are considered “Average” strength rock.

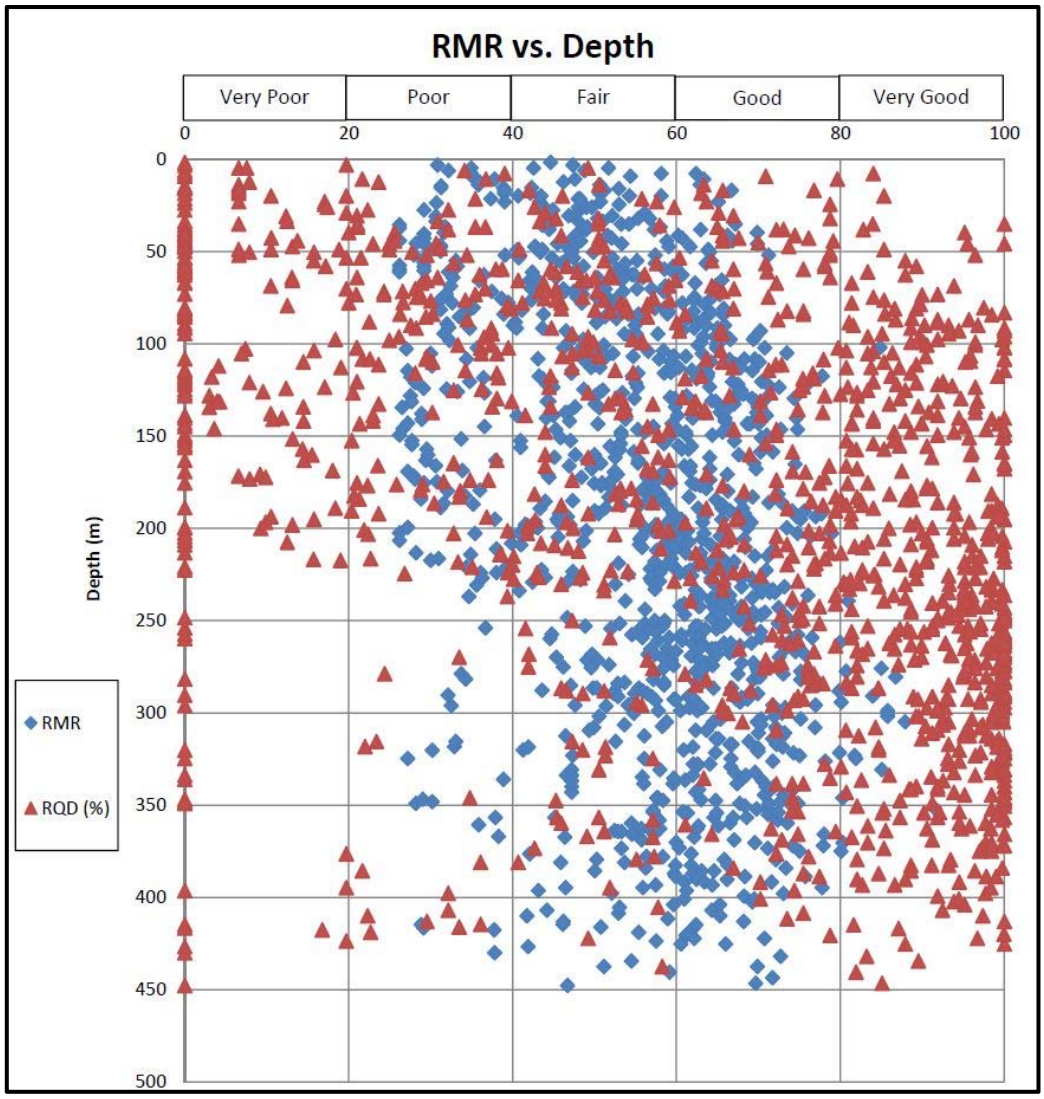
	Rock Mass Quality Description	FAIR	FAIR	FAIR	FAIR	FAIR	FAIR
Hydraulic Conductivity (m/sec)		6.E-08					

4.5.3 Rock Mass Quality

RMR_{89} values were calculated for each drill run during the 2010 and 2011 site investigations, and the data was compiled and organized by geotechnical domain. The drill hole RQD and RMR vs. depth for the two rock geotechnical domains are illustrated on Figure 4.5 and Figure 4.6. It is noted that while RQD shows trends of increasing with depth, the average RMR typically remains constant.

A summary of the RMR_{89} values and resulting average rock mass quality by geotechnical domain can be seen on Table 4.2. The PMS and DRB domains are considered “FAIR” quality rock with average RMR_{89} values of 61 for fresh bedrock. The RMR_{89} values for weathered bedrock are 47 and 41 for the PMS and DRB domains, as logged during the 2010 and 2011 site investigations.

NOTES:



1. "DEPTHS" ARE INCLINED DRILL HOLE DEPTHS.

Figure 4.5 RQD and RMR vs. Depth for Prospector Mountain Suite Domain

4.5.4 Overburden Strength Parameters

Samples of overburden were collected within the open pit area during the 2011 site investigation and sent to the Knight Piésold Soil Laboratory in Denver for soil index testing and classification. No in situ density tests of the overburden were performed; however, field logs indicate that the overburden is typically loose to medium dense. A unit weight of 18.7 kN/m^3 was assumed for the overburden material as a typical value for medium dense soils.

The overburden is assumed to be a cohesionless material. A base friction angle (phi) of 30° was assumed for the material as shown in Table 4.3.

NOTES:

1. "DEPTHS" ARE INCLINED DRILL HOLE DEPTHS.

Figure 4.6 RQD and RMR vs. Depth for Dawson Range Batholith Domain

4.5.5 Rock Mass Strength Parameters

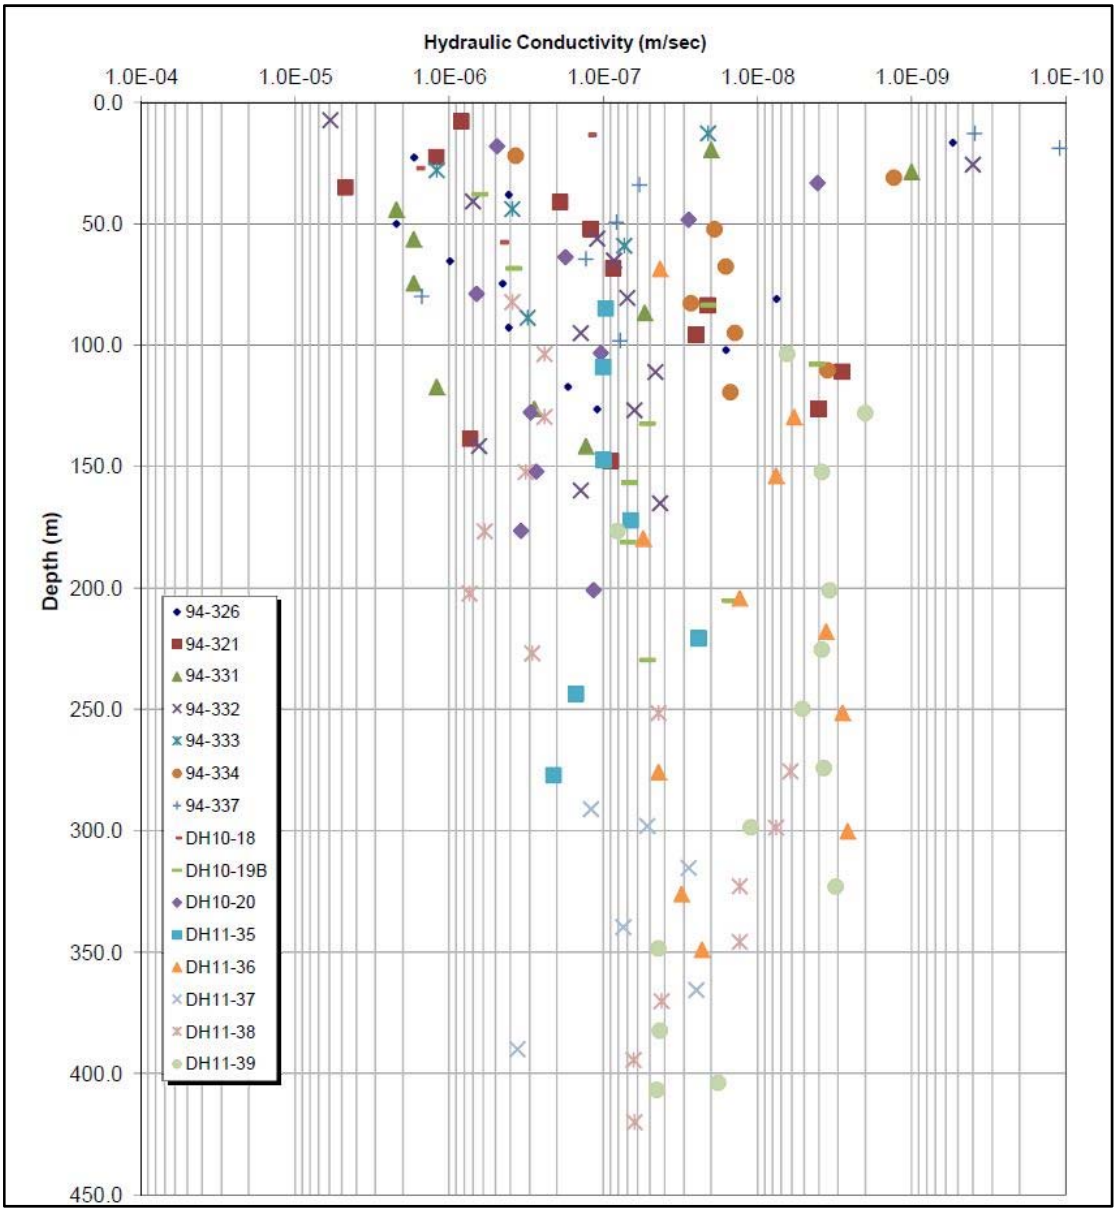
The overall rock mass strength parameters were derived using the Hoek-Brown criterion (2002 edition). The characteristics of the rock mass are described by lithology, intact rock strength and rock mass quality. The strength properties can be adjusted to account of the expected level of rock disturbance. Rock mass disturbance is typically caused by blasting damage and from strains resulting from stress changes in the pit walls due to unloading during mining. The design values of the rock mass strength parameters are summarized in Table 4.3.

Table 4.3 Summary of Design Parameters of Soil and Rock

Material		Unit Weight (kN/m^3)	UCS[1] (MPa)	GSI[2]	Friction Angle (°)	Confining Stress (kPa)	m_i[5]
Overburden		18.7			30[3]	-	-
Dawson Range Batholith	Weathered	26.2	39	36	See Note 4	1500	25
	Fresh		55	54			
Prospector Mountain Suite	Weathered	26.2	31	42	See Note 4	1500	19
	Fresh		51	54			

NOTES:

1. UCS VALUES FROM LAB TESTING OF ROCK SAMPLES. TEST RESULTS WERE AVERAGED TO PROVIDE UCS VALUE.
2. GSI = RMR -5. RMR VALUES FROM BORE HOLE LOGS WERE AVERAGED FOR EACH GEOTECHNICAL DOMAIN AND STATE OF WEATHERING.
3. A SENSITIVITY ANALYSIS WAS PERFORMED ON OVERBURDEN USING ASSUMED FRICTION ANGLES FO 25° TO 35°.
4. FRICTION ANGLE DETERMINED USING SHEAR STRENGTH FUNCTION CALCULATED USING UCS, mi AND GSI.
5. INTACT ROCK CONSTANT, mi, ASSUMED AS TYPICAL VALUES FOR ROCK TYPE (HOEK-BROWN, 2007).



The UCS values of each geotechnical domain were determined from laboratory rock strength testing results. The lithological factor (m_i) has been estimated for each domain according to the general rock types. The m_i values are 19 for the PMS domain (representative of breccia) and 25 for the DRB domain (representative of diorite).

The Geological Strength Index (GSI) was estimated based on the RMR values. GSI was introduced by Hoek et. Al. (1995) to overcome issues with the RMR values for very poor quality rock masses. For better quality rock masses (GSI > 25), the value of GSI can be estimated from Bieniawski's RMR (1989) as GSI = RMR - 5. Therefore, as the RMR values are greater than 25, the GSI values are assumed to be mathematically equivalent to the equation above.

4.6 HYDROGEOLOGY

The groundwater level in the deposit area typically varies from 3 m below surface to 30 m. A groundwater depth of 100 m was observed in the southwest region of the deposit (Hole DH10-19B).

In situ hydrogeological testing performed during the 1994, 2010 and 2011 site investigations indicate that the hydraulic conductivity of the rock mass varies between $1x10^{-5}$ m/sec to $1x10^{-9}$ m/sec within the upper 150 m of bedrock. The permeability of the rock reduces moderately with depth, with tested hydraulic conductivities of $1x10^{-7}$ to $1x10^{-9}$ m/sec observed. A summary of hydraulic conductivity vs. depth is shown on Figure 4.7. The average hydraulic conductivity of the rock mass, taken as the geometric mean of the tested permeability results, is $6x10^{-8}$ m/sec.

NOTES:

1. HYDRAULIC CONDUCTIVITIES PLOTTED AGAINST INCLINED DEPTH OF DRILLHOLE.

Figure 4.7 Summary of Rock Mass Hydraulic Conductivities

5 – PIT SLOPE STABILITY ASSESSMENT

5.1 GENERAL

The proposed Casino open pit will extend to a maximum depth of approximately 590 m. The feasibility pit slope design considered site specific data collected during site investigations throughout 1994 to 2011. A series of design sectors were delineated for pit slope assessment. Both kinematic and soil/rock mass slope stability analyses were performed to determine appropriate slope configurations for each design sector.

5.2 PIT DESIGN SECTORS

CMC developed a pit shell model in September 2011, which contains two distinct mining zones, the Main Pit and the West Pit, which will be developed concurrently during operations. A total of eight pit design sectors were delineated primarily based on the nominal pit wall orientations with a secondary consideration to pit wall geology.

Figure 5.1 shows the projected pit wall geology along with the proposed design sectors. The thickness of the weathered bedrock within each design sector was estimated by the RQD and RMR profiles of the geotechnical holes. The RQD and RMR vs. Inclined Depth plots of the 1994, 2010 and 2011 drill holes are presented in Appendix A with respect to each pit design sector. The depth to fresh bedrock was indicated on the 2010 and 2011 drillhole plots and estimated based on a comparison of RQD values in the 1994 drillholes. The estimated extent of the weathered bedrock within the final pit walls is also illustrated on Figure 5.1. A brief description of the design sectors is shown in Table 5.1.

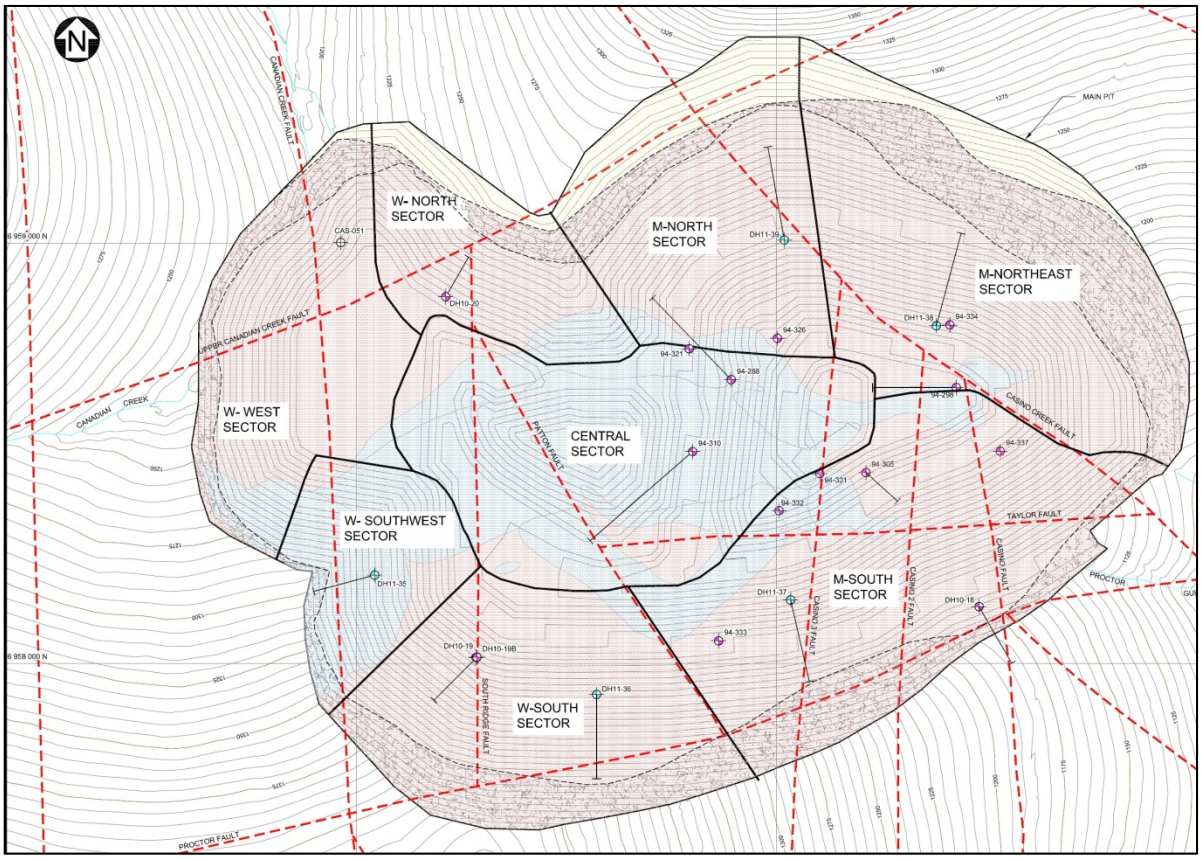
5.3 KINEMATIC SLOPE STABILITY ANALYSES

5.3.1 General

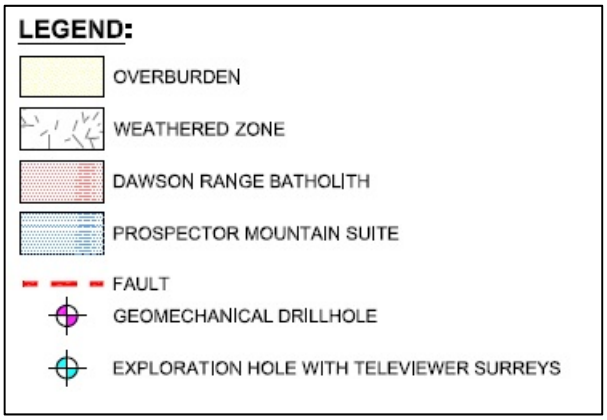
The purpose of these analyses was to identify the kinematically possible failure modes within each design sector using the stereographic technique. Bench geometry was selected to reduce the potential for small-scale discontinuities to form bench-scale instabilities. Inter-ramp angles were determined to reduce the potential of multiple bench failure to an acceptable level.

5.3.2 Modes of Failure

Kinematically possible failure modes in rock slopes typically include planar, wedge and toppling failures. These failure modes will occur if discontinuities are pervasive at bench scale or greater, if weak infilling is present along the discontinuities, or if the geometry of the discontinuities is conducive to failure. Stereographic analyses of peak pole concentrations of the discontinuity data can be used to identify potential modes of failure. A brief introduction on each mode of failure is provided below:



- **Planar Failure** – This failure mode is kinematically possible where a discontinuity plane sits at a shallower inclination than the slope face (daylights) and at an angle steeper than the friction angle.
- **Wedge Failure** – This failure mode is kinematically possible where the plunge of the intersection of two planes (sliding vector) is inclined less than the slope face (daylights) and at an angle



greater than the combined friction angle which is determined from the characteristics of each plane that forms the wedge. Where kinematics are the controlling factor, the recommended pit slope angles have been adjusted to reduce the potential for large-scale, multiple bench wedge failures.

- **Toppling Failure** – This failure mode is kinematically possible due to interlayer slip along discontinuity surfaces where sub-vertical jointing dips into the slope at a steep angle β. The condition for toppling to occur is when $\beta > (\phi j + (90 - \Psi))$, where Ψ is the slope face angle and ϕj is the friction angle (Goodman, 1989).

Table 5.1 Summary of Design Sectors

Sector	Maximum Slope Height (m)	Wall Orientations (°)	Geotechnical Domains	Overburden Thickness (m)	Weathered Bedrock Thickness (m)
M-North	630	135, 170	DRB	30	60
M-Northeast	630	195, 220, 240, 270	DRB	30	250

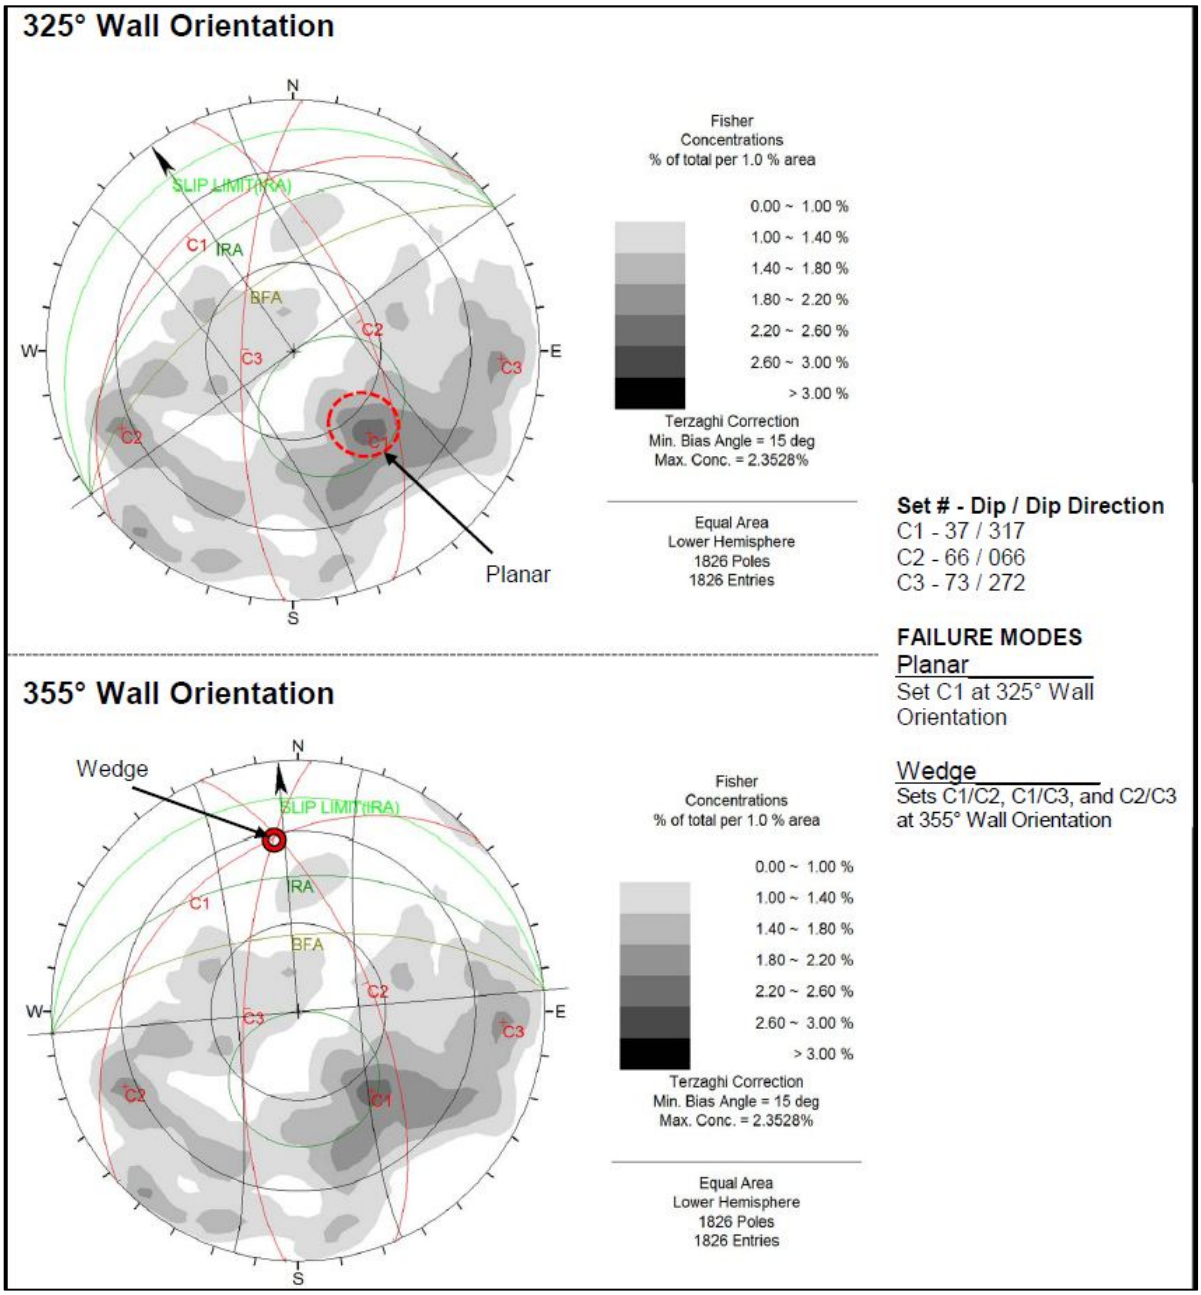
Figure 5.1 Open Pit Design Sectors

5.3.3 Stereographic Analysis

Stereographic analyses have been carried out for each design sector using the DIPS program (Rocscience Inc., 2001). The analysis assumes that failures will occur as the results of sliding blocks or wedges along the defects of rock mass. This type of analysis does not consider slope failure within the rock mass. Stereographic plots for individual oriented core hole and televiewer survey hole are presented in Appendix B. The drillhole rock mass structural data were grouped by design sectors for further kinematic stability analyses.



Pit wall orientations were measured from a preliminary pit shell model provided by CMC in 2010. Where the pit walls contain a pronounced curve, multiple analyses were conducted to account for the changing pit wall dip direction within the sector.

A joint friction angle of 29° was used for all discontinuities. This value is based on the results of direct shear testing performed on samples collected during the 2011 site investigation.

Multiple stereographic plots were created for each design sector in order to account for the variation of pit wall orientations within each sector. The results of the kinematic stability analyses are summarized on Table 5.2. A brief discussion for each design sector is provided below:

- **M-North Sector** – This sector was comprised of a curved section of pit wall with pit wall dip directions of 135° to 170°. Multi-bench wedge failure is kinematically possible within this sector. Variation and scatter within the discontinuity sets may result in bench scale planar and wedge failures to develop. Slightly flatter bench face and inter-ramp angles are recommended for this sector.
- **M-Northeast Sector** – This sector encompasses the majority of the east side of the Main Pit and includes a pronounced curve (pit wall dip direction varies from 195° to 270°). Bench scale wedge failures are kinematically possible.
- **M-South Sector** – This sector is comprised of a shallowly curved wall with pit wall dip directions of 325° to 355°. Multi-bench planar and wedge failures are kinematically possible. Slightly flatter bench face and inter-ramp angles are recommended for this sector.
- **Central Sector** – This sector is comprised of central bottom section of the pit, with major wall orientations of 030°, 100°, and 180°. Multi-bench wedge failure modes are identified for the south facing walls in the Central Sector.
- **W-North Sector** – The W-North Sector is a moderately curved wall that ranges in pit wall dip direction from 180° to 240°. Multi-bench planar and wedge failures are kinematically possible. Therefore, slightly flatter bench face and inter-ramp angles are recommended for this sector.
- **W-South Sector** – The W-South Sector is moderately curved with pit wall dip directions ranging from 000° to 040°. Toppling failure is kinematically possible at both the inter-ramp and bench scales.
- **W-Southwest Sector** – The W-South Sector contains a sharply curved wall with nominal pit wall dip directions ranging of 010° and 090°. The potential for kinematically controlled failures is less significant in this sector.
- **W-West Sector** – This sector encompasses the west side of the West Pit and is moderately curved with pit wall dip directions ranging from 090° to 135°. Bench scale planar and wedge failures are kinematically possible.

A typical stereographic analysis is illustrated on Figure 5.2. Detailed results of the kinematic stability analyses are shown in Appendix B.

5.3.1 Bench Face Angle Analysis

Further bench face angle analyses were conducted using the SWEDGE limit equilibrium program (Rocscience Inc.) for the M-North, M-Northeast, and W-North Sectors. Wedge failures are kinematically possible in these areas. Cumulative bench scale wedge and planar failures were

estimated based on the structural discontinuity sets identified within each design sector in comparison to the relevant bench geometry. The bench height was 15 m, the bench widths were 8 m, and the targeted bench reliability was 70%. The results of the bench face angle analyses are shown in Appendix B.

5.3.2 Implications of Kinematic Analysis Results

The bench face angles have been reduced to 60° to offset the risk of planar and wedge failures occurring within the M-North and W-North Sectors. The inter-ramp slopes, which are dictated by bench geometry, will be 42° within these sectors to lower the risk of multi-bench planar/wedge failures.

5.4 OVERBURDEN AND ROCK MASS SLOPE STABILITY ANALYSES

5.4.1 General

The maximum achievable overall slope angle in large open pit mines may be controlled by the overburden/rock mass strength. Limit equilibrium stability analyses were performed using the SLOPE/W computer program (GEO-SLOPE International Ltd., 2007). The limit equilibrium analyses were completed to evaluate the overall slope stability of the jointed rock mass and overburden. A minimum FOS of 1.2 has been targeted for inter-ramp slopes, and 1.3 for the overall pit slopes (Read & Stacey, 2009).

The overburden model utilizes soil unit weight and friction angle as the primary material parameters. Intact rock strength, the Hoek-Brown constant for rock mass (mi), GSI, unit weight, and blast disturbance factors are the primary material parameters used in the bedrock slope models.

5.4.2 Rock Mass Disturbance

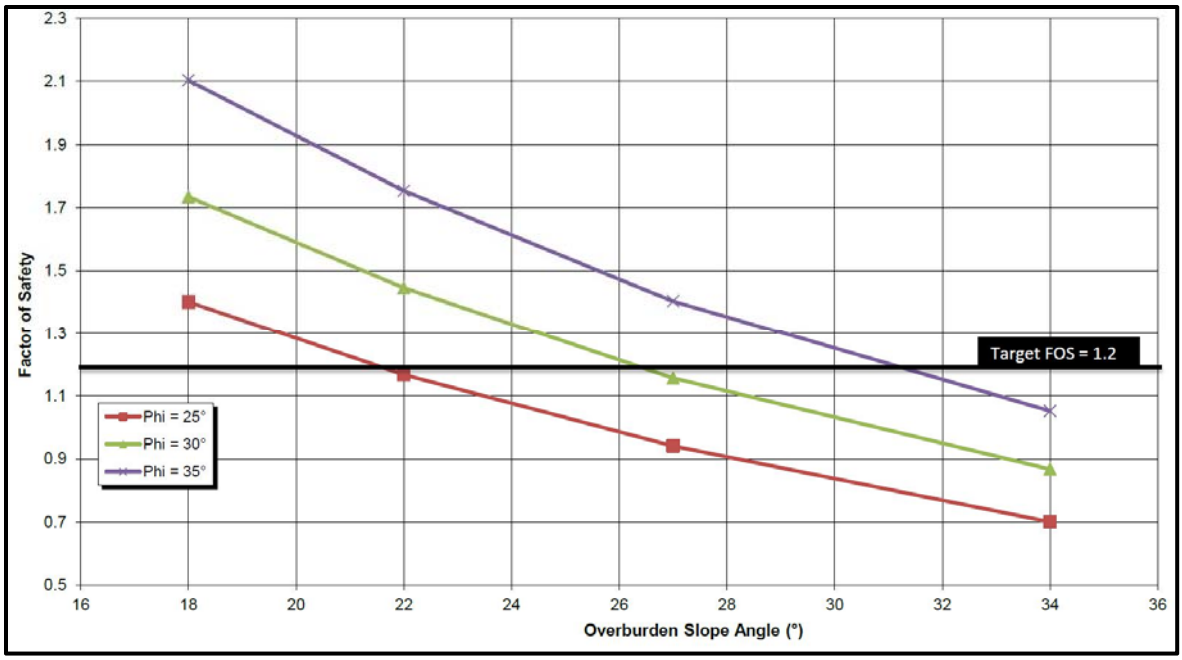
The overall rock mass strength parameters were derived using the Hoek-Brown failure criterion (2002 edition). The characteristics of the rock mass are described by lithology, intact rock strength and rock mass quality. The strength properties can be adjusted to account for the expected level of rock disturbance. Rock mass disturbance is typically caused by blast damage and from strains resulting from stress relaxation in the pit walls due to unloading during mining.

Hoek et al., 2002 recommends that the utilized rock mass strengths be downgraded to disturbed values to account for rock mass disturbance associated with heavy production blasting and stress relief. He indicates that a disturbance factor of 0.7 would be appropriate for a mechanical excavation where no blasting damage is expected. KPL experience indicates that a disturbance factor approaching a value of 0.85 may be achievable for moderate height slopes with the application of controlled production blasting practices (buffer blasting). A value of 1.0 is assumed for conventional production blasting. Disturbance values of 0.85 and 1.0 were selected for the limit equilibrium analyses to demonstrate the impact of blasting damage.

Faults were not modelled explicitly as part of the limit equilibrium analysis. The faults within the pit are sub-vertical, and are expected to account for some localized areas of instability, but are not considered to be controlling factors for the stability of the ultimate slopes.

5.4.3 Overburden Slope Stability Analyses

Overburden is typically negligible throughout much of the open pit deposit area; except in the northern area of the Main Pit where it is upwards of 30 m deep.



Five overall slope angles (18°, 22°, 27°, and 34°) were modelled for a 30-m high overburden slope, to represent the 3H:1V to 1H:1V slopes, assuming both partially saturated and fully drained (dry) conditions. The pore water pressure within the partially saturated slopes was modelled as 20% of the overburden stress (i.e., with a coefficient of pore water pressure, Ru, of 0.2). The purpose of running multiple scenarios was to show the impact of steepening the overburden slope angle on the FOS.

The friction angle of the overburden material was estimated based on experience with similar soil materials as no laboratory testing data is available for the overburden within the open pit area. A base case friction angle of 30° was adopted in these analyses. Further sensitivity analyses were conducted to account for a range of potential soil friction angles. A range of friction angles from 25° to 35° was used with the assumed base case of 30° for the sensitivity analyses.

The results of the base case analyses are summarized in Table 5.3 and Figure 5.3 shows the computed FOS with respect to various slope angles. A 2H:1V (approximately 27°) overburden slope may be achieved if the slope is completely drained and the friction angle of the overburden material is at least 30°.

Table 5.3 Summary of Overburden Analyses

Geotechnical Unit	Overall Slope Angle (°)	Groundwater Condition	Factor of Safety
Overburden	34 (1.5H:1V)	Partially Saturated	0.6
		Fully Drained	0.9
	27 (2H:1V)	Partially Saturated	0.9
		Fully Drained	1.2
	22 (2.5H:1V)	Partially Saturated	1.1
		Fully Drained	1.5
	18 (3H:1V)	Partially Saturated	1.4
		Fully Drained	1.7

Figure 5.3 Overburden Slope Stability Analysis Results FOS vs. Slope Angle

5.4.4 Rock Mass Inter-Ramp Slope Stability Analyses

Inter-ramp slope models were created to determine the stability of the disturbed rock mass during mining operations in both fresh bedrock and weathered bedrock. These simplified models utilized a single geotechnical domain with disturbed rock mass parameters (the entire model has a disturbance factor applied).

Read and Stacey, 2009, indicate that 200 m is typically the highest practical inter-ramp slope height that should be utilized for open pit slope design. Therefore, haulage ramps and/or step-outs should be included as appropriate to limit the inter-ramp slope height. Models were created for slope heights of 100 m, to show the FOS achievable under moderate slopes heights, and 200 m to show the effect on the FOS of the inter-ramp slope at the maximum height. An inter-ramp slope angle of 45° was utilized in the analyses for both fresh and weathered bedrock. Disturbance factors of 0.85 and 1 were applied to the models to demonstrate the impact of blasting practices.

Groundwater was modelled using a piezometric line to represent the phreatic surface of the water. It was assumed that hydrostatic conditions exist below the piezometric line. Two groundwater cases were modelled; a fully saturated slope and the other with the phreatic surface set 30 m back horizontally from the pit face.

Table 5.4 summarizes the results of the rock mass slope stability analyses for both geotechnical domains, in both weathered and fresh bedrock, at an inter-ramp scale. A blasting disturbance factor (D) of 1 was considered for the base case as it is assumed that conventional production blasting will be utilized during interim pit wall development.

Slope laybacks or widened haul ramps should be constructed every 100 m in weathered bedrock slopes. Fresh bedrock inter-ramp slopes can be built up to 200 m in height before slope laybacks will be required. Groundwater depressurization measures are required in both weathered and fresh bedrock slopes. Detailed modelling setup and results are shown in Appendix C.

Table 5.4 Summary of Inter-ramp Slope Stability Analyses

Geotechnical Unit (1)	Inter-Ramp Slope Angle	Slope Height	Blast Disturbance D	Groundwater Depressurization (2)	Factor of Safety

5.4.5 Overall Slope Stability Analyses

The M-North, M-Northeast, M-South, and W-Southwest pit walls were analysed using limit equilibrium techniques. These sectors contain the tallest slopes in the pit within each of the geotechnical domains. Overall slopes angles of 40° were utilized in the analyses, based on the pit shell model provided by CMC (November, 2010).

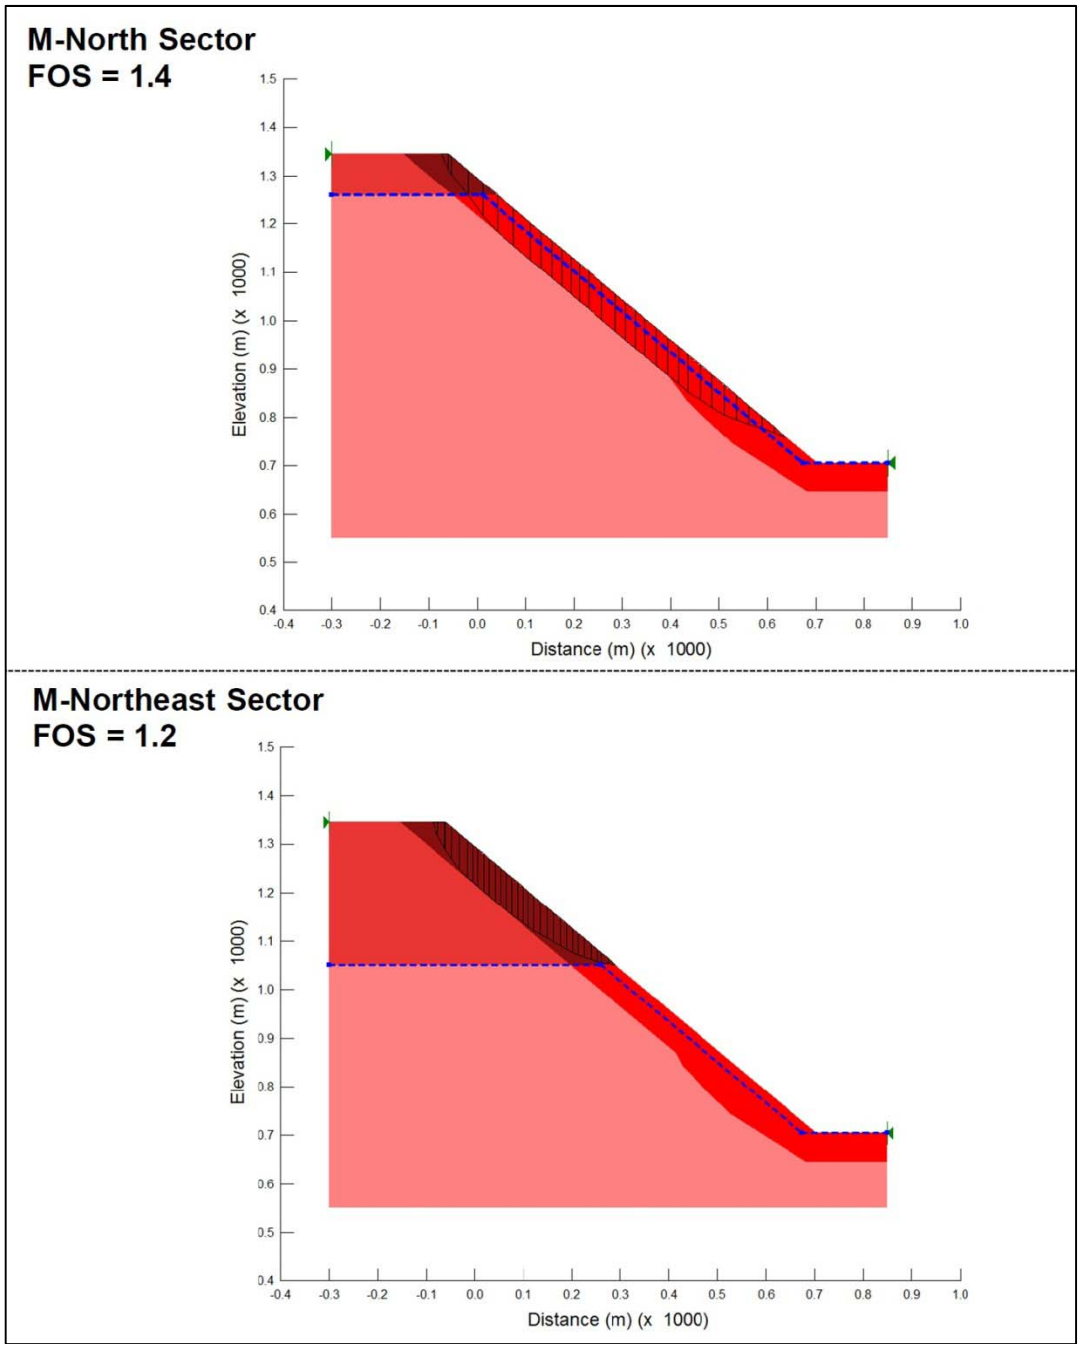
Disturbance factors (D) of 0.85 and 1 were applied to the face of each modelled slope. The disturbed section was projected 60 m horizontally into the pit walls to simulate blasting damage from production blasting (Hoek 2012). The disturbed zone was expanded near the base of the slope to reflect increased stress caused by the relaxation and rebound of the rock mass as the pit is excavated. The extent of the induced stress zone was established using a simplified 2D stress

model analyzed in Examine2D (Rocscience Inc.). A disturbance factor of zero was applied to the rock mass beyond the disturbed zone as assigning a disturbance factor to the entire overall slope will result in overly conservative model results (Hoek, 2012). The multiple disturbance factors were utilized to show the effect of production blasting vs. controlled production blasting on the overall stability of the open pit. The base case scenario assumes a disturbance factor of D = 1 for the final pit walls considering additional stress-induced disturbance in very high pit slopes.

A piezometric line was utilized to establish groundwater pressure in the slope. Three groundwater conditions were modelled to simulate a fully saturated slope, a slope where the weathered bedrock allows drainage (is dry) but is saturated below, and a slope with drained weathered bedrock and a phreatic surface simulating horizontal drains within the pit walls. It is conservatively assumed that hydrostatic pressures exist below the phreatic surface. The base case stability analysis assumes the weathered bedrock is drained and 30 m of horizontal depressurization in all pit walls.

Table 5.5 summarizes the results for the overall slope stability analyses of the M-North, M-Northeast, M-South and W-West pit walls and their calculated FOS. The results of the overall slope stability analyses are shown on Figure 5.4 and Figure 5.5. Detailed modelling results are shown in Appendix C.

The weathered bedrock within the M-Northeast Sector is upwards of 250 m thick. A FOS of 1.2 is the maximum achievable FOS within this sector. It is noted that the failure slip surface occurs entirely within the weathered bedrock. As such, the stability of this slope will be governed by the inter-ramp scale stability of the weathered bedrock. The M-Northeast Sector was not considered as a base case scenario for overall slope stability.



The results of the base case stability analyses show that a FOS of 1.3 is achievable in the final pit slopes of the M-North, M-South, and W-Southwest Sectors at overall slopes angles of 40°. The predicted failure surface runs through the blast disturbed rock. Slope depressurization by use of horizontal drains and drainage of the weathered bedrock is required for slope stabilization. Vertical pumping may be required if the weathered bedrock does not drain naturally and if cold winter conditions preclude the effectiveness of the horizontal drains. This should be assessed during the early stages of mining operations and adjusted as necessary to facilitate slope depressurization.

Table 5.5 Summary of Overall Slope Stability Analyses

Pit Design Sector	Geotechnical Units [1]	Total Slope Height	Overall Slope Angle	Depth to Fresh Bedrock	Disturbance Factor	Groundwater Depressurization		Factor of Safety
						Vertical	Horizontal Groundwater Depressurization[2]	
		(m)	(°)	(m)	(D)	(m)	(m from pit wall)	
M-North	DRB	630	40	85	1	85 (Assume drainage of weathered bedrock)	30	1.4
M-Northeast	DRB	630	40	250	1	250 (Assume drainage of weathered bedrock)	30	1.2

6 – PIT WATER MANAGEMENT PLAN

6.1 GENERAL

The development of the open pit will have a significant impact on the local hydrogeologic regime, as the pit will become a groundwater discharge area. The existing groundwater table is near surface and will gradually be lowered during pit development. Pit inflows are likely to come primarily from the North and West edges of the pit, where topography slopes towards the final pit rim.

The pit water management systems will comprise a combination of techniques including surface water diversion ditches, vertical pumping wells, horizontal wall drains and water collection systems. These measures will be implemented as a staged observational approach during pit development and will involve the installation of depressurization measures and associated monitoring of groundwater pressures. This will enable an assessment of the pit slope drainage capability and the requirements for additional installations.

A conceptual level pit water management plan has been developed for groundwater depressurization and for the controlled removal of both groundwater inflows and precipitation runoff from within the pit. The pit water management systems should include allowances for:

- Diversion ditches to collect surface runoff, snowmelt and seepage along the pit crest and the base of the Weathered Bedrock materials.
- Horizontal drains installed in both interim and final pit walls
- A series of pumps and collection systems which transfer water from the pit excavation to a surface sump located near the primary crusher for recycle to the milling process, and
- Modifications to the depressurization systems to account for the extreme cold during winter months and the high inflows during the freshet period.

These depressurization/dewatering features are discussed in more along with the estimates of pit inflows. The pit shell model provided by CMC (November, 2010) was utilized for the pit water management assessment.

6.2 SURFACE WATER DIVERSION

Diversion ditches along the north and west pit crest are required to divert the surface runoff away from the pit during operations. These surface runoff ditches will capture and divert the majority of all runoff, snowmelt and infiltration before the water flows into the pit and will reduce power requirements for pumping from the deeper levels of the pit. Ditches will need to be modified for different stages of pit development. It may be appropriate to include low permeability glacial till or synthetic liner materials along sections of these ditches in order to reduce ditch leakage.

6.3 SLOPE DEPRESSURIZATION SYSTEM

Pit slope depressurization reduces pore water pressure within the overburden and rock mass, which in turn minimizes the potential of slope failures developing. Vertical wells and pumps can be used in conjunction with horizontal drains to depressurize the slopes. Diversion ditches and pumps can be utilized to divert surface water and seepage out and away from the pit.

6.3.1 Vertical Pumping Wells

An allowance for deep vertical pumping should be included in the feasibility study. It was assumed for the purposes of the overall slope stability analyses that the weathered bedrock present at the surface of the deposit will drain freely. However, the weathered bedrock varies in thickness throughout the pit area and the permeability of weathered rock mass may vary throughout the pit. Vertical wells may be required along the North Walls of the pit to reduce pore water pressures and the flow of groundwater into the pit.

Several faults intersect the deposit area and may act as preferential flow paths for groundwater inflow into the pit. The installation of wells into the faults may be required to reduce groundwater inflow. An allowance of 20 vertical depressurization wells should be included for Feasibility costing purposes. The typical depth of the wells is assumed to be in the order of 300 m.

Well pumping rates were estimated by determining the steady state radial flow to a well in the presence of constant recharge. A 300 m deep well pumping at 2 L/sec is estimated to provide sufficient drawdown for slope stabilization.

6.3.2 Horizontal Drains

Horizontal drains provide an efficient and cost effective mechanism for the control of groundwater inflows and for depressurization of open pit slopes. The effectiveness of horizontal drain installations is dependent upon the permeability of the rock mass along with the length and spacing of the drains. It is impossible to accurately predict the exact location or spacing of the horizontal drains that will be required during operations and it is essential that the dewatering program be continuously modified throughout operations as additional information becomes available on the hydrogeologic conditions in the open pit.

Drain holes will be drilled sub-horizontally, at approximately 3° to 5° above horizontal. It is recommended that the horizontal drains be drilled 50 to 100 m into the middle and lower pit slopes. Experience has shown that 100 m is a reasonable, practical and economic target length for horizontal drain installations.

The spacing of the horizontal drains must be determined such that adequate effective drainage is achieved at a point midway between adjacent installations. This spacing will be determined during open pit development and through observation and monitoring of piezometric conditions within the pit slopes. It is recognized that the actual drain spacing will likely vary across different areas of the open pit. The M-North, M-Northeast, M-South, and W-North Sectors may require a greater density of horizontal drains to reduce the risk of wedge failures developing.

For design purposes, the following average horizontal drain spacings have been estimated based on experience from other open pit operations. Centre to centre drain spacing for horizontal drains installed within interim pit slopes has been estimated at 150 m on average. Interim pit slopes are defined as those slopes that will remain for a period of at least 2 years. The spacing for drains installed within final pit slopes has been estimated at 60 m on average.

It is anticipated that the horizontal drains will freeze during the winter season. KPL experience on other projects in Canada has shown that the freezing of the rock mass and drains may have an

impact on slope behaviour. Additional depressurization from vertical pumping wells may be necessary, particularly during the winter months to maintain slope depressurization.

6.4 PIT DEWATERING SYSTEM

6.4.1 General

The estimates for water inflow volumes into the pit were developed based on meteorological and hydrogeological data collected from the project area in conjunction with groundwater monitoring and permeability testing conducted during the 1994, 2010, and 2011 geotechnical investigations.

Potential sources of pit inflows include:

- Dewatering of fissures and fractures into the rock mass
- Infiltration of precipitation into the groundwater system
- Surface runoff, and
- Direct precipitation into the pit.

Pit inflows were calculated using the Mass Balance Approach coupled with a simplified Dupuit approximation equation for steady radial flow (Freeze and Cherry, 1979). The Mass Balance Approach for estimating pit inflows has been proposed by Brown (1988). With this approach, a rough approximation of pit inflows was estimated by assuming a percent infiltration of precipitation into the groundwater system. The pit inflows were calculated for the final stage of pit development for the mean annual precipitation, ten year wet year precipitation, and storm event precipitation occurring over a 24 hour period.

Removal of water from the pit should be performed using a sump and pump system. Sumps should be installed in the lowest point of the pit as excavation progresses. Booster pumps should be placed every 100 m of elevation change or less. Additional sumps may be required during operations to adequately collect all pit seepage water.

6.4.2 Inflows from Average Annual Precipitation

Values for the mean annual precipitation and runoff coefficients were taken from the 2010 Casino Hydrometeorology Report (KP Ref. No. VA101-329/5-3). Twenty-four hour rainfall events were calculated based on more recent hydrometeorology data.

The Casino open pit area has a mean annual precipitation of 500 mm. It is assumed that all surface water will be diverted away from the pit through the use of diversion channels, so the average pit inflows from precipitation will come from direct precipitation onto the pit and groundwater infiltration.

It is assumed that 66% of the surface water will infiltrate the groundwater system before collecting in the pit sumps, and as such a runoff coefficient of 0.44 was applied. The calculated inflows from the average annual precipitation are listed on Table 6.1. An annual pit inflow, averaged over the course of the year, is estimated to be 49 L/sec for the final pit.

This approach does not account for groundwater inflows from underground aquifers and meteoric water that has infiltrated the groundwater regime.

Table 6.1 Open Pit Inflows and Pump Design

	Pit Stage	Estimate of Seepage Inflow		Inflow from Average Annual Precipitation	Total Average Annual Pumping Requirement	Inflow from 1 in 10 yr. 24 Hour Storm Event	Dewatering Period	Design Pump Flow

NOTES:

1. ESTIMATED PIT SEEPAGE INFLOWS ARE CALCULATED USING THE DUPUIT APPROXIMATION EQUATION FOR STEADY RADIAL FLOW IN AN UNCONFINED AQUIFER.
2. PIT SURFACE AND PLAN AREAS ARE CALCULATED ASSUMING THE PIT IS CONICAL WITH A CONSTANT RADIUS AT THE CREST ELEVATION AND PIT BOTTOM. PIT RADII ARE APPROXIMATE MEASUREMENTS FROM THE STAGED PIT SHELL MODELS.
3. THE CAPACITY OF THE PIT PUMPING SYSTEM SHOULD COVER THE SUM OF GROUNDWATER SEEPAGE AND DIRECT PRECIPITATIONS. GROUNDWATER LEVEL IS ASSUMED TO BE NEAR THE SURFACE FOR THE PURPOSE OF INFLOW CALCULATIONS.
4. DESIGN PUMP FLOW BASED ON 120% BASE PUMPING + 24 HOUR STORM RUNOFF REMOVED OVER THE SPECIFIED DEWATERING PERIOD.
5. MAIN PIT AND WEST PIT EXCAVATED INTO SEPARATE PIT BOTTOMS STARTING IN STAGE 4. TWO PUMPS WITH A COMBINED CAPACITY OF ~320 L/SEC ARE RECOMMENDED TO DEWATER THE PIT DURING THE 1 IN 10 YEAR STORM EVENT.

6.4.3 Groundwater Inflow Estimates

A simplified estimate of groundwater inflow into an open pit can be made using the Dupuit approximation equation for steady radial flow in an unconfined aquifer. This approach assumes that flow is horizontal and the hydraulic gradient is equal to the slope of the groundwater table at the

seepage face and does not vary with depth. Groundwater inflow estimates using this approach are reported to be in good agreement with more detailed analytical methods when the gradient is low and the depth of the unconfined flow is shallow. The radial inflow (Q) to the pit can be calculated as follows:

$$Q = \frac{\pi k H^2}{\ln(R/r)}$$

Where:

- *k* is the average hydraulic conductivity of the rock mass. A k value of $6x10^{-8}$ m/sec has been assumed for the open pit, which is based on the geometric mean of test results from the 1994, 2010, and 2011 geotechnical site investigations.
- *H* is the head drop in the pit, and the maximum drop of 535 m has been assumed for the final pit by estimating an average slope height of 535 m and an average groundwater level of 0 m (i.e. ground surface).
- *r* is the equivalent radius of pit excavation and is calculated as the square root of the total pit surface area divided by π.
- *R* is the radius of influence and it is estimated as the equivalent radius of excavation plus 500m.

The maximum seepage inflow into the final pit has been estimated as 140 l/s (2220 gpm) by using the Dupuit Approximation equation. By including the inflows from direct precipitation of 49 l/s (based on the long term average annual precipitation for the site of 500 mm), a total pit average annual dewatering rate of 189 l/s (3000 gpm) has been estimated for the final pit configuration.

6.4.4 Storm Event Inflows

The dewatering system for the open pit will be required to handle the water flow resulting from a 24 hour storm period. A 1 in 10 year return period for the storm event was assumed for these calculations, based on experience with other open pit mines in the Yukon. This return period has a typical rainfall amount of 39 mm. The maximum operating capacity of the dewatering system was designed to remove storm event inflows over a period of four to six days, depending on the size of the pit at each development stage.

The open pit, once fully excavated, will take on approximately 1390 L/sec of water during a 24 hour rainfall event, in addition to the 189 L/sec from regular average annual inflows. The dewatering period will be adjusted by pit stage to reduce pumping requirements to approximately 300 L/sec for any given stage of mining. A design factor of 120% was applied for the pump design flow. The final pit dewatering system will require six days at a flow rate of 320 L/sec to dewater the pit. Table 6.1 shows the calculated inflows to the pit during the five main development stages and required pumping rate. It is assumed that a single pump operating at 160 L/sec will be sufficient to dewater the pit during stages one through three, as only one pit will be developed during these stages. The Main and West pits become distinct pit with separate pit bottoms during the development of Stage 4. It is recommended that another 160 L/sec capacity pump be installed to handle pit flows for a combined pumping capacity of 320 L/sec.

7 – PIT SLOPE DESIGN AND IMPLEMENTATION

7.1 GENERAL

The proposed Casino pit slopes will extend to a maximum depth of 630 m, making this pit one of the largest in the world. This feasibility pit slope design has considered site-specific geotechnical and hydrogeological information collected from site investigations from 1994 to 2011. Operational considerations related to the recommended slope angles are included in this section as well as a discussion of the experience encountered at other large open pit operations in Canada.

7.2 RECOMMENDED PIT SLOPE ANGLES

7.2.1 General

Recommended bench geometries and pit slope angles are summarized in Table 7.1. These recommendations are based on the results of the kinematic and rock mass stability analyses. Recommended slope angles are discussed below.

7.2.2 Bench Geometries

Bench geometries were selected to reduce the potential of small-scale discontinuities from forming unstable wedges and blocks etc. that can affect bench face integrity and reduce the effectiveness of rock all containment. The bench face angles derived from the kinematic analyses are as steep as can reasonably be achieved given the characteristics of the rock masses. Small bench-scale toppling and revelling type failures are expected due to the fractured nature of the bedrock; however, these failures can be removed during initial excavation or controlled through a normal bench maintenance program.

The pit benches are design to be 8 m wide with a 15 m high single bench configuration. The kinematic stability analyses undertaken in this study indicate that a bench face angle of 65° is expected to be achievable in the majority of pit walls throughout the pit. The exceptions to this design are the M-North and W-North Sectors, which have exhibited the potential for multi-bench planar and wedge failures. A bench face angle of 60° is recommended for these sectors, based on the results of the bench face angle analyses.

7.2.3 Inter-ramp Slopes

The inter-ramp slope angle is typically dictated by the bench geometry and controlled by large-scale structural features. A 15 m high single-bench configuration is recommended within all sectors. An inter-ramp angle of 45° can be used for most of design sectors. The inter-ramp angles in the M-North and W-North Sectors are recommended to be 42°, to reduce the risk of multi-bench wedge failures occurring.

Overburden should be cleared from the edges of the pit at a 2H:1V slope. A wider catcher bench should be developed along the bedrock contact to provide additional capacity for debris containment and seepage control.

Table 7.1 Recommended Open Pit Slope Angles

Design Sector	Max. Slope Height	Wall Geology	Bench Face Angle	Bench Height	Bench Width	Inter-ramp Angle	Max. Inter-ramp Slope Height	Max. Overall Slope Angle	Comments
	m		°	m	m	°	m	°	
M-North	630	Overburden	**40**	**5**	**4**	**27**	**200**	**39**	Reduction of inter-ramp angle to 42° will reduce the risk of multi-bench wedge failure in bedrock.
		DRB	**60**	**15**	**8**	**42**			
M-Northeast	630	Overburden	**40**	**5**	**4**	**27**	**100 (in Weathered Zone) 200 (in Fresh Bedrock)**	**40**	Weathered Zone down to 250 m deep, additional stepouts / ramps should be incorporated into the Weathered Zone slopes.
		DRB	**65**	**15**	**8**	**45**			
M-South	540	DRB, PMS	**65**	**15**	**8**	**45**	**200**	**42**	Potential planar and wedge failures are kinematically possible, but at the limit of the defect friction angle.
Central	210	PMS	**65**	**15**	**8**	**45**	**200**	**N/A**	Central lower pit walls with various orientations. The south facing maybe subject to potential wedge failure.
W-North	285	DRB	**60**	**15**	**8**	**42**	**200**	**39**	Reduction of the inter-ramp slope to 42° will reduce the risk of multi-bench planar and wedge failures.
W-South	480	DRB	**65**	**15**	**8**	**45**	**200**	**42**	Potential bench scale toppling failure is expected.
W-Southwest	345	PMS	**65**	**15**	**8**	**45**	**200**	**42**	
W-West	225	DRB	**65**	**15**	**8**	**45**	**200**	**42**	Potential bench scale planar failure is expected.

NOTES:
1. MAXIMUM SLOPE HEIGHT REPRESENTS THE HIGHEST WALL IN EACH DESIGN SECTOR.
2. RECOMMENDED SLOPE ANGLES DETERMINED BY THE KINEMATIC AND ROCK MASS STABILITY ANALYSES.
3. OVERBURDEN IS NEGLIGIBLE IN THE WESTERN AND SOUTHERN PIT WALLS.
4. THE OVERALL SLOPE ANGLES INCLUDED 1 TO 3 STEPOUTS OR HAUL RAMPS IN THE FINAL PIT WALLS.

7.2.4 Overall Slopes

The overall slope angle is determined by slope height, rock mass strength, groundwater pressure, blasting disturbance, and is typically restricted by inter-ramp angles. The overall slopes will be

flattened by incorporating haul ramps and cleanout benches into the pit wall design. It is recommended that the overall slope angles within the pit not be greater than 40° for the Main Pit and 42° in the West Pit.

7.3 OPERATIONAL CONSIDERATIONS

7.3.1 Controlled Blasting

Blasting disturbance is one of the controlling factors for rock mass strength and for overall stability. Slope instabilities are often triggered by the progressive deterioration (ravelling) of the wall face and this process often initiates with the detachment of small rock blocks bounded by the rock mass discontinuities. The preservation of rock mass integrity during mining is critical to prevent these progressive failures and is required to achieve the steepest bench face angles possible.

Pit slope angles are less critical in the early stages since the stripping ratio is typically controlled by the final overall pit slopes. Conventional production blasting can be used for the interim pit wall development. The initial pit can be developed with variable slopes and blast patterns to develop the optimal blast design for the final pit walls. Careful controlled production blasting practices are recommended for the final pit walls in order to reduce face damage and achieve steep slopes, particularly for the slopes situated in weathered bedrock and the M-North and M-Northeast sector walls. It is important that blast hole lengths be staggered so the bottom of the hole does not intercept the crest of the bench below. Trial blasts are also recommended wherever there is a substantial change in rock mass characteristics in order to evaluate and optimize blast performance.

7.3.2 Excavation and Scaling

It is important that the benches be kept clear and that the bench faces be maintained regularly so that they remain functional during mining operations. Scaling will be an important part of the bench maintenance program and may be conducted after blasting in areas where access is still available. Routine scaling may allow the bench widths to be minimized due to a reduction in the volume of material to be controlled.

7.3.3 Slope Depressurization

Groundwater is another key consideration for the overall pit slope stability. High water pressure can be expected within the pit walls and the slope depressurization measures include construction of surface ditches, perimeter pumping wells and horizontal drains are recommended for slope stabilization. The proposed slope depressurization program has been previously discussed in Section 6.3.

7.3.4 Slope Monitoring

Pro-active geotechnical monitoring is recommended for all stages of pit development. The monitoring program should be implemented as a staged approach and include detailed geotechnical and tension crack mapping, as well as a suitable combination of surface displacement monitoring (surface prisms and wireline extensometers) and piezometers. Sufficient staffing resources should be allocated to collect, process and interpret the geotechnical monitoring data on a weekly basis or as frequently as required. The timely identification of accelerated movements from surface

displacement monitoring and tension cracks will be critical. Up-to-date reports on the status of highwall stability should be compiled and discussed regularly with operation personnel. These reports will also assist mine engineering staff in their efforts to optimize final pit slopes and improve the effectiveness of the controlled blasting program. All seeps and springs should be inspected, mapped and photographed. Large-scale structures should be characterized and monitored as they have the potential to develop into tension cracks.

A typical geotechnical monitoring schedule is presented in Table 7.2. Detailed monitoring requirements are as follows:

- **Geotechnical Mapping** – Detailed geotechnical mapping should be carried out along all newly formed benches along the pit highwalls. Information to be noted should include the orientation of the main fracture sets, the type, thickness, extent (persistence) and frequency of any infilling (clay, gouge, chlorite, sericite, etc.), the distribution of joint spacings, the nature of the fracture surfaces (smooth, planar, polished, slickensided etc.) and any observations of seepage. Detailed maps for each bench face and a complete database should be compiled to include all of the recorded geotechnical data. All relevant (and particularly adverse) geotechnical information should be updated on weekly mine plans to ensure that mine planners and operations personnel are aware of the current geotechnical conditions. The geotechnical mapping will also provide the quantitative and qualitative information needed to conduct ongoing highwall stability assessments during mining activities.
- **Tension Crack Mapping** – Detailed tension crack mapping should be carried out along all newly formed benches. Information to be noted should include the surveyed location, orientation, aperture and both vertical and lateral extents of all tension cracks. The development of all tension cracks should be very carefully observed. The frequency of mapping and observations should be commensurate with the rate of development of individual tension cracks. Initial mapping and inspections should be carried out on a weekly basis. Simple extensometers should be installed across any significant tension cracks to confirm the rate and overall extent of movement. A detailed map and database should be compiled to include all the recorded data. The occurrence of tension cracks should be highlighted and presented on mine plans on a weekly basis so that mine planners and operations personnel are aware of the current ground conditions along the pit highwalls. Areas of slope movement that are associated with the development of tension cracks should also be monitored with surface displacement prisms as discussed below.
- **Surface Prism Monitoring** – Surface displacement monitoring survey prisms should be established along the highwalls to detect the onset of any possible movement/sliding at various locations within the vertical sequence of mining development of the open pit. An initial series of surface displacement monitoring prisms should be established along the crest of the highwalls as early in the mine-sequence as possible so that baseline information can be obtained. A subsequent series of surface displacement monitoring prisms should be established along all newly exposed benches. Prism surveying should be undertaken at regular intervals to develop a comprehensive record of highwall deformation. Data should be evaluated on an ongoing basis to enable the early detection of instability and allow for safe mining operations.
- **Piezometer Installation** - Enhanced depressurization will be required in order to provide an adequate factor of safety for the highwalls. As such, the extent to which the groundwater pore pressure decreases is important to assess. It is recommended that piezometers be installed to

allow long-term monitoring of groundwater depressurization over the life of the mine. These piezometers will be progressively installed during operations and locations for new piezometers should be reviewed on an annual basis.

- **Automated Monitoring Systems** – New advances in technologies allow for detailed monitoring of pit slopes. A number of systems are available that can be implemented to provide varying levels of monitoring detail. Slope Stability Radar utilizes a mobile radar station to continually scan selected slope areas. This method is not affected by dust, smoke or rain, and can provide near-real time monitoring of slope movement. Total stations can be set up as automated systems to scan surface prisms at regular intervals. These systems are typically packaged with operating software that allows users to specify monitoring frequency, scanning detail and scope, as well as set alarms to be triggered if specified movement thresholds are exceeded.

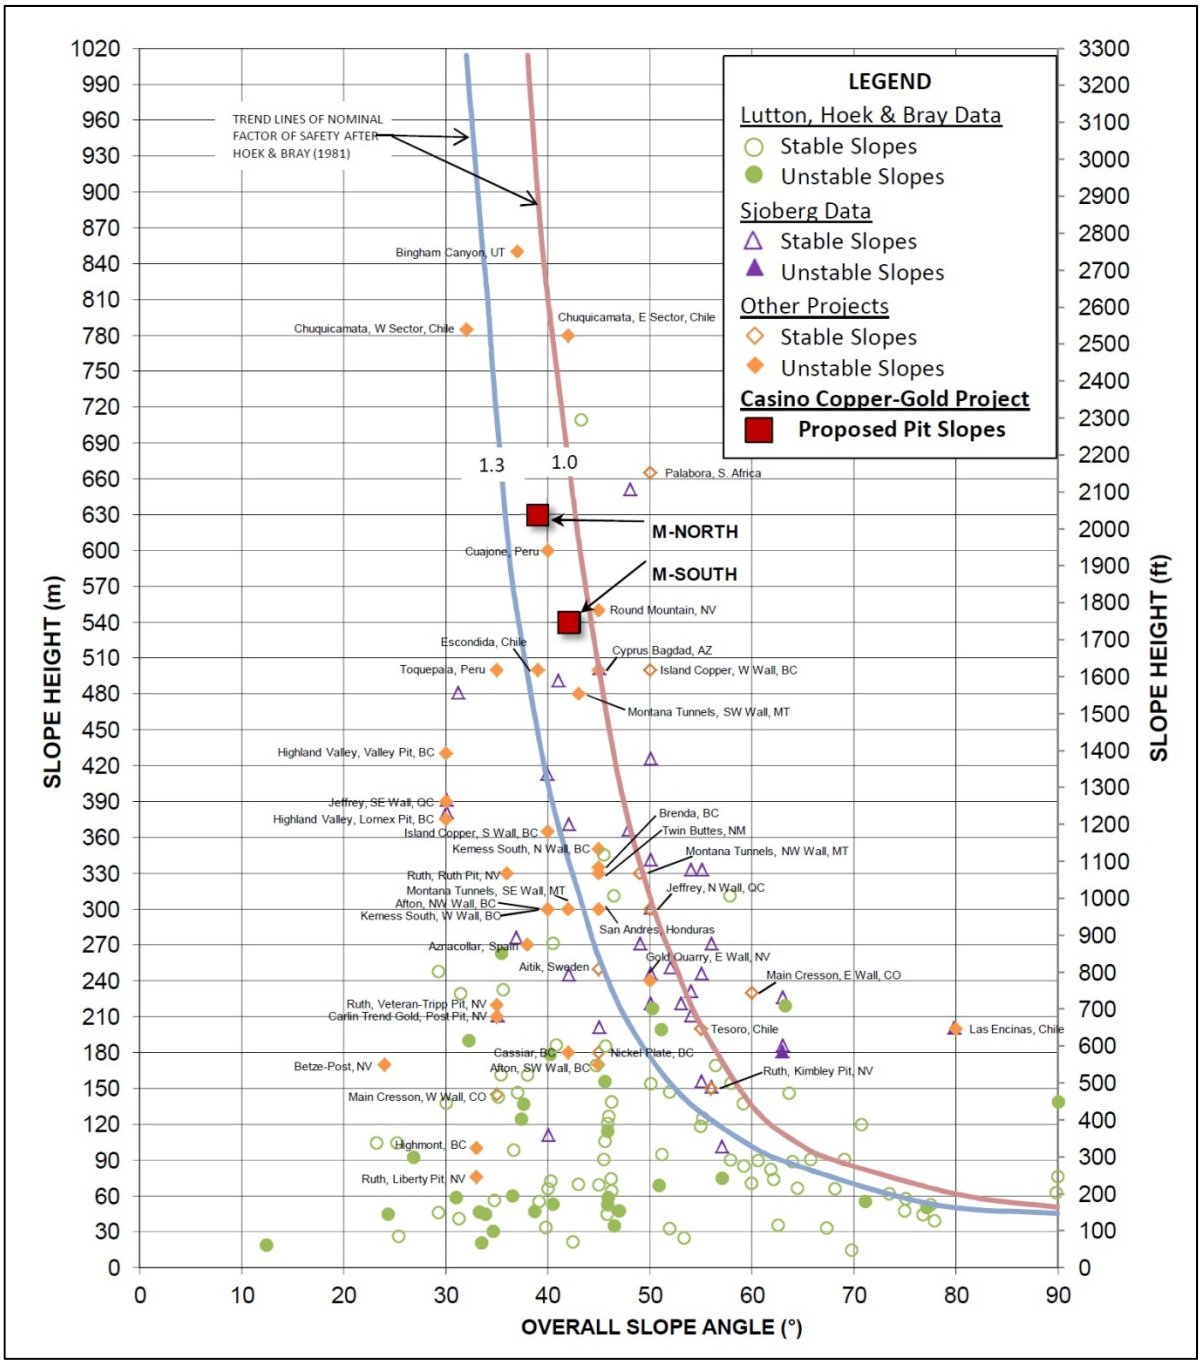
Table 7.2 Recommended Open Pit Geotechnical Monitoring Practices

Monitoring Items	Estimated Quantity	Suggested Monitoring Schedule	
		Active Mining Area	Inactive Mining Area
General Visual Inspection	N/A	Daily	Weekly
Geotechnical Mapping	All new bench faces	Monthly	Twice monthly
Tension Crack Mapping	As required	Weekly	Twice monthly
Surface Prism Monitoring	As required	Bi-weekly to Daily - Depends on the rate of displacement and location	Weekly
Time Domain Reflector System	As required, intersecting major slip planes.	As required, monitoring frequency should increase with rate of slip plane movement	As required, monitoring frequency should increase with rate of slip plane movement
Piezometer Monitoring	As required	Twice monthly	Monthly

NOTES:

1. VISUAL INSPECTIONS OF ALL FACES MAY BE REQUIRED AT THE BEGINNING OF EACH SHIFT AND WEEKLY INSPECTIONS OF THE HIGHWALL SHOULD BE COMPLETED."
2. ADDITIONAL CRACK MAPPING AND PRISM SURVEY MONITORING SHOULD BE CONDUCTED FOLLOWING SIGNIFICANT RAINFALL OR HEAVY BLASTING IN THE AREA."
3. SENSITIVE FACILITIES, WHERE SMALL DISPLACEMENTS WOULD RESULT IN DAMAGE TO THE FACILITY MAY REQUIRE MORE PRECISE MONITORING METHODS AND MORE FREQUENT MEASUREMENTS."

7.4 PRECEDENT PRACTICE



Pit slope stability depends on a variety of site-specific factors (geological structure, alteration rock strength, groundwater conditions, discontinuity characteristics and orientation, pit geometry, blasting practices, stress conditions, climatic conditions, and time) which make it difficult to provide direct comparisons with other operations. However, it is still quite useful to review the successes and problems encountered at other open pit operations in order to recognize opportunities and potential

constraints for the proposed open pit development. A summary plot of pit depth vs. slope angles achieved in various operations around the world is illustrated on Figure 7.1.

At an ultimate depth of up to 600 m, the pit slopes within the Casino open pit are significantly higher than most operating mines in Canada. The precedent for such large open pits is very limited, but the ultimate depths projected for some of these currently active open pits suggest that the proposed overall slope angles for the Casino open pit will be achievable provided that the recommended operational measures are implemented.

It is important to note that almost all of these large open pit operations, including porphyry copper mines, have encountered slope stability problems in some area of the mine. The experiences at most of the large open pits suggest that there is a significant likelihood that some area(s) of the pit slope will require flattening during operations in response to slope movement. Therefore, the mine plans should remain flexible so that extra stepouts/buttresses can be maintained in critical areas of the pit until the end of the mine life at which point lower factors of safety can be tolerated.

This comparison also highlights the importance of developing and maintaining good controlled blasting practices, effective groundwater depressurization measures and geotechnical data collection. It is also noted in these case studies, that adverse structural conditions have had a major impact on pit slope stability.

NOTES:

1. ORIGINAL DATA POINTS AFTER LUTTON 1970, HOEK AND BRAY 1981, AND SJOBERG 1996.
2. ADDITIONAL DATA FROM KNIGHT PIESOLD PROJECTS AND OTHERS.

Figure 7.1 Slope Height versus Slope Angle – Precedent for Hard Rock Surfaces

8 – SUMMARY AND RECOMMENDATIONS

The fundamental consideration for the geotechnical design of the Casino Open Pit at the feasibility stage is related to determining allowable inter-ramp and overall slope angles. These angles will affect the stripping ratio and the amount of ore that can be economically removed from the mineralized zone. The stability analyses confirm that the recommended pit slope angles presented in Table 7.1 are reasonable and appropriate. However, these slope designs have a number of operational constraints including careful controlled blasting and effective slope depressurization. An extensive geotechnical monitoring program should also be implemented throughout the pit operations.

It is recommended that additional geomechanical and hydrogeological data collection be conducted during the early stages of pit operations. The data collection programs may include bench surface mapping, piezometer installation and monitoring. Additional information will be used to fill the data gaps, enhance the geotechnical database, update the rock mass structural model, and refine the hydrogeological model. The pit design should be optimized when additional geotechnical information becomes available. The final pit designs and pit dewatering plans should be reviewed by qualified geotechnical engineers.

1. EXECUTIVE SUMMARY

The SO_2/Air cyanide destruction process and the Peroxide process were successful in reducing the residual CN_{WAD} (weak acid dissociable cyanide) to below 0.20 mg/L targets put in place by Western Copper Corporation. In general a good effluent quality was achieved for both process treatments used. The levels of base metals removal also showed good improvement for both process treatments used.

The solution was effectively treated using a single stage operating with approximately 60 minutes of retention and an SO_2 dosage of 5.0 g/g CN_{WAD}. A pH of 9.50 was found to be suitable for effective cyanide removal with minimal need of lime for pH control.

The need of copper sulphate ($CuSO_4$) addition was not required for effective removal of cyanide. The copper present in the feed solution was enough for the process to be catalytic during this test program. At the actual treatment facility, copper sulphate addition will be dependent upon the relative concentration of copper in the feed.

The Peroxide process test work did show good results but did require the addition of acid to keep the pH at set point of 9.5. Please note that during normal plant conditions it is not expected that acid would be required due to higher than normal pH found in the feed solution of 12.1. The solution was effectively treated using a single stage operating with approximately 60 minutes of retention and an H_2O_2 dosage of 6:1 molar ratio to CN_{WAD} was required to meet the 0.20 mg/L CN_{WAD}. A pH of 9.50 was found to be sufficient for effective cyanide removal metal precipitation.

Due to cost of the peroxide it is suggested that based on comparison of both the SO_2/Air and Peroxide process that peroxide is not cost effective process to be used at the Casino project.

2. SCOPE OF WORK

The present test work program was undertaken at the request of Western Copper Corporation on solutions produced after test work evaluation performed on the heap leach process for recovery of metals. The work included investigations of SO_2/AIR process and Peroxide process. The laboratory program was conducted at the Barrick Technology Centre in Vancouver, British Columbia. The detailed scope of work was according to the agreement between Western Copper Corporation and R&C Environmental Consulting Services Inc. of Ontario, Canada, and included the following:

- The objectives were to test the SO_2/Air and Peroxide process for effective removal of cyanide from feeds collected after the heap leach process under normal operating conditions.
- A target of less 1.0 mg/L CN_{WAD} had been set out by Western Copper Corporation as the objective to meet the present cyanide permits required under Canadian code agreement.
- Continuous cyanide destruction by the SO_2/AIR process to determine the effectiveness of the process solution effluents.
- Continuous cyanide destruction by Peroxide process to determine the effectiveness of the process solution effluents.
- Chemical characterization (cyanide speciation, dissolved metals, pH) of all process feed and residual streams when possible by site or off site laboratories.
- Final report summarizing results of the test work program and providing operating cost estimates for the various test options as well as conclusions and recommendations for process selection.

2.1 Feed Samples

A 20 liter sample was provided from the previous test work performed on the heap leach process. Western Copper personnel identified the sample as initial preg solution from Metcon Research's leach column Cl-01, taken in December 2009. Each day the feed solution was sampled and tested for cyanide weak acid dissociable using the picric acid method. Also samples of the feed solution were tested for metal's using the ICP method. Based on the results conditions of the test were established.

3. PROCESS DESCRIPTIONS

3.1 SO_2/AIR

The SO_2/AIR process can be applied to the treatment of both cyanide solutions and pulps, however, it is in the area of slurry treatment (CIP/CIL pulps or re-pulped filter cakes from a Merrill-Crowe circuit) where the process has enjoyed a recognized worldwide reputation. Main advantages of the process are the removal of the total cyanide to levels of about 1 mg/l, in a single-stage continuous reactor and low operating costs.

The technology uses sulfur dioxide (SO_2), in various reagent forms, (sodium sulfite, sodium metabisulfite, ammonium bisulfite, liquid SO_2, and SO_2 containing roaster gas or SO_2 from burning elemental sulfur) in combination with air (or pure oxygen). Stoichiometrically, the process requires a ratio of approximately 2.5 g of SO_2/g of CN_{WAD}. The oxidation of cyanide is in accordance with one of the following overall reactions:

$$CN^- + Na_2SO_3 + O_2 \rightarrow OCN^- + Na_2SO_4$$

Or:

$$CN^- + ½\ Na_2S_2O_5 + O_2 + ½\ H_2O \rightarrow OCN^- + ½\ Na_2SO_4 + ½\ H_2SO_4$$

Or:

$$CN^- + SO_2 + O_2 + H_2O \rightarrow OCN^- + H_2SO_4$$

As shown above, the oxidation of cyanide produces cyanate (OCN^-) and, depending on the SO_2 reagent, produces sulfuric acid (H_2SO_4) as an intermediate. At the prevailing pH of the process, however, the sulfuric acid is continuously neutralized with lime producing calcium sulfate dihydrate (gypsum), as follows:

$$H_2SO_4 + Ca(OH)_2 \rightarrow CaSO_4 \bullet 2H_2O$$

The process will oxidize free cyanide and all cyanide complexes with copper, nickel, zinc, silver, and cadmium. The oxidation is catalyzed by soluble copper (Cu^{2+}), which, if required, can be supplemented by addition of copper sulfate solution. As cyanide is oxidized, metals are liberated and precipitated out of solution as hydroxides by the following reactions:

$$Me^+ + OH^- \rightarrow MeOH$$

Or:

$$Me^{2+} + 2OH^- \rightarrow Me(OH)_2$$

Cyanide present in the form of a strong complex, bound with either iron, cobalt, or gold, and is not oxidized by the process. Gold cyanide, of course, should not be a concern for a destruction unit, as it is recovered by carbon within the plant. Removal of the iron and cobalt cyanide complexes is achieved by precipitation with copper or zinc, according to the following reactions:

$$Me^{2+} + Fe(CN)_6^{4-} \rightarrow Me_2Fe(CN)_6$$

Or:

$$Me^{2+} + Co(CN)_6^{4-} \rightarrow Me_2Co(CN)_6$$

Generally, the SO_2/AIR process works best in the pH range of 8 to 9 and optimum operating pH is determined during the test work program. Optimization of both pH operating range and reagent consumption has proven to be site-specific for all ore types tested to date.

Cyanate produced by oxidation of cyanide slowly hydrolyzes to carbonate and ammonium as follows:

$$OCN^- + 2H^+ + H_2O \rightarrow CO_2 + NH_4^+$$

Or:

$$OCN^- + OH^- + H_2O \rightarrow CO_3^{2-} + NH_3$$

Depending on pH.

3.2 Hydrogen Peroxide and Caro's Acid

Hydrogen peroxide (H_2O_2) has a well-established reputation as the process of choice for treating clear cyanide solutions. The primary benefit of hydrogen peroxide is that it is a "clean" chemical in the sense that the reaction product of the H_2O_2 itself is simply water. In a peroxide treatment system there will be no appreciable increase in the dissolved solids concentration; scaling and undesirable salting conditions are avoided. This is an important factor in any flow sheet scenario incorporating a filtration stage.

The oxidation of cyanide with peroxide produces cyanate and water as shown in the following equation:

$$CN^- + H_2O_2 \rightarrow OCN^- + H_2O$$

The cyanate subsequently hydrolyzes slowly to produce ammonium and carbonate ions:

$$OCN^- + 2H^+ + H_2O \rightarrow CO_2 + NH_4^+$$

or:

$$OCN^- + OH^- + H_2O \rightarrow CO_3^{2-} + NH_3$$

depending on the pH.

Although ammonia (NH_3) is toxic to fish at low levels, it is almost entirely available in the far less toxic cationic form (NH_4^+) at the natural pH of open waterways.

If excess hydrogen peroxide is present in the treated wastewater, it rapidly decomposes to water and oxygen, presenting no environmental threat:

$$2H_2O_2 \rightarrow 2H_2O + O_2$$

Hydrogen peroxide is capable of oxidizing both "free" cyanide (CN_f) and complexes (titratable cyanide):

$$CN^-, HCN, NaCN, KCN, Ca(CN)_2, Cd(CN)_4^{2-}, Zn(CN)_4^{2-}$$

and "weak acid dissociable" cyanide (CN_{WAD}) complexes, which include the above mentioned titratable cyanide species as well as the following metal cyanide species:

$$Cu(CN)_2^-,\ Cu(CN)_3^{2-},\ Cu(CN)_4^{3-},\ Ag(CN)_2^-,\ Ni(CN)_4^{2-}$$

In contrast, the following metal cyanide complexes cannot be oxidized by hydrogen peroxide. These compounds, along with CN_{WAD} complexes, are measured as "total" cyanide (CN_{tot}):

$$Au(CN)^{2-},\ Fe(CN)_6^{3-},\ Fe(CN)_6^{4-},\ Co(CN)_6^{4-}$$

However, it is still possible to achieve CN_{tot} limits by precipitating the $Fe(CN)_6^{4-}$ with, for example, copper ions:

$$Fe(CN)_6^{4-} + 2Cu^{2+} \rightarrow Cu_2Fe(CN)_6 \text{ (solid)}$$

This can normally be accomplished by lowering the pH to 8 to 9 in the presence of copper hydroxide. Occasionally, more copper must be added in the form of copper sulfate to achieve the desired CN_{tot} level.

The cyanide destruction reaction using peroxide is relatively fast in most wastewater samples. The presence of transition metals, especially copper, helps to accelerate the reaction. However, effluents that contain little or no metals may require a catalyst in order to accommodate a treatment circuit with limited effluent retention capabilities. Copper sulfate pentahydrate additions are ideal for this purpose.

Low effluent temperatures will significantly slow down the reaction time. Therefore, cyanide destruction circuits must be designed with sufficient retention time to allow the reaction to go to completion at the lowest possible effluent temperature experienced at a particular site. If shorter retention times are desired, more copper catalyst can be added to reduce the cyanide destruction reaction time.

Hydrogen peroxide can be shipped safely at high concentrations (up to 70% by weight H_2O_2) and stored for long periods of time without appreciable loss of activity, which makes H_2O_2 an ideal choice for remote locations. H_2O_2 has proven invaluable for emergency detoxification programs, where low capital costs and quick start-up are essential requirements.

4. Analytical Procedures

Two to three reactor displacements were carried out before representative samples of treated effluent were taken. The effluents were filtered and immediately prepared for the spectrophotometric determination of cyanide (CN_p) using the buffered picric acid method.

Filtrates were also analyzed for copper (Cu), and iron (Fe) using atomic absorption. The base metals samples were analyzed by site facility or independent laboratories. Also feed and final solutions were submitted to an independent laboratory for an ICP scan and cyanide.

Note: The cyanide concentration determined by the picric acid method (CN_p) includes all the cyanide except that complexed with iron in solution. Therefore, CN_p is greater than or equal to CN_{WAD} (weak acid dissociable cyanide) and is reported as CN_{WAD} in this report. The total cyanide (CN_T) can be accurately estimated using the formula: $CN_T = CN_{WAD} + 2.795 \times Fe$ (mg/L).

5. TEST RESULTS

5.1 Test Procedures

The SO_2/AIR process was carried out in continuous mode in a properly aerated and agitated reactor, as would be the case in typical plant operations for either slurry or barren solution. Reagents (sodium metabisulfite and copper sulfate if required) were added in continuous mode and the pH was controlled by automatic addition of a lime suspension. Tests were carried out at room temperature. Samples of feed and treated effluent were taken at regular intervals for process monitoring and final samples taken at steady state conditions.

The Peroxide process was also carried out in continuous mode in an agitated reactor, unlike the SO_2/Air process the peroxide process does not require air addition due oxygen being produced by the peroxide as it decomposes. The pH was controlled by automatic addition of acid (H_2SO_4). Tests were carried out at room temperature. Samples of feed and treated effluent were taken at regular intervals for process monitoring and final samples taken at steady state conditions.

5.2 Treatment Objectives

The treatment objectives were to meet less than 1.0 mg/L CNwad in all cases. The 1.0 mg/L CN_{WAD} objective corresponds to the desired effluent quality at point of entry to the tailings pond. Please note that the treated solution would be recycled to the heap until the heap leach pad is totally rinsed and free of cyanide before any of the waters would be pumped the final tailings pond. This procedure would limit the amount of solution required to rinse out the heap.

5.3 Solution Treatment

5.3.1 SO_2/AIR

The test work was carried out in continuous mode using SMBS and air addition, and provided the overall results.

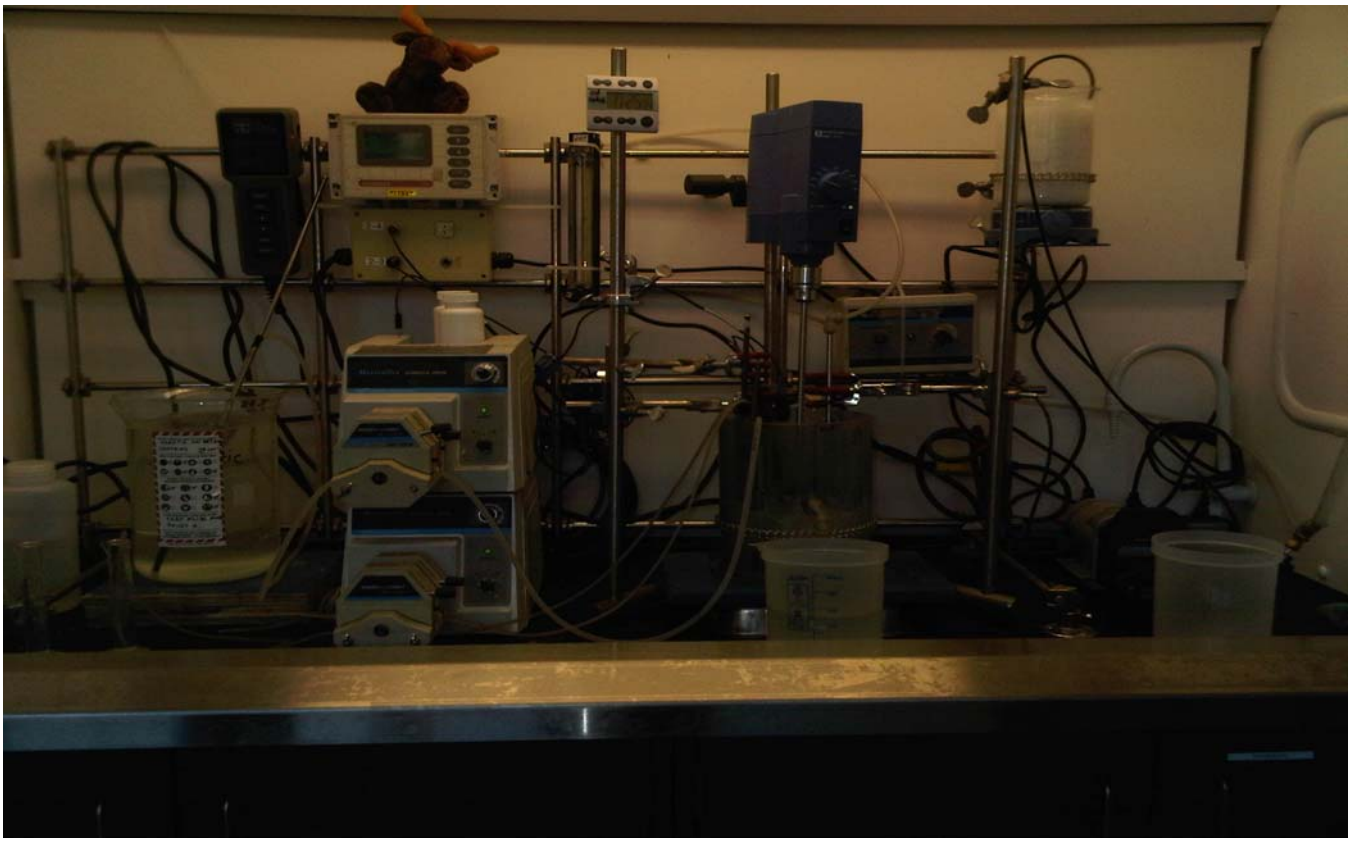
6. DISCUSSION of RESULTS



The present discussion deals with the relative effectiveness of the various treatments process options for the Casino Project.

6.1 Solution Treatment

Any discussion on the relative merits of the effectiveness of the processes (SO_2/Air, Peroxide) must center on the choice of the best result per process and the cost tonne of solution treated.

In the case of the Peroxide and SO_2/Air processes, the best result was that result that achieved the limit with the lowest reagent addition rates. The highest reasonable or typical reagent addition was chosen as the best value.

7. Typical Laboratory Set-up

8. Typical Reagent Consumptions

CASINO - PROJECT
OPERATING COST ESTIMATES:

SO_2/AIR PROCESS-USING Sodium Metabisulphite
BASIS: 1,000 m3 / day and 210 mg/L CNwad
ITEM CONSUMPTION UNIT COST OPERATING
DAILY COST: (CAD$)

SMBS 1,404 kgs/day @ 750 $/t = $379,080/year.
$Ca(OH)_2$ 210 kgs/day @ 210 $/t =$16,200/year.
TOTAL COST PER YEAR $395,280

Peroxide PROCESS-USING 70% H_20_2
BASIS: 1,000 m3 / day and 210 mg/L CNwad
ITEM CONSUMPTION UNIT COST OPERATING
DAILY COST: (CAD$)

H_2O_2 1,824 kgs/day @ 860 $/t = $564,710
H_2SO_4 0 t/yr @ 240 $/t = $157,593
TOTAL $722,303

Please Note that the above figures do not include capital and electrical cost involved in operating each of the process.

9. CONCLUSIONS AND RECOMMENDATIONS

Based on the test work, both SO_2/AIR and Peroxide effectively detoxify the effluents of the solutions tested, meeting or achieving lower than the 1.0 ppm CN_{WAD} target.

For economic reasons, the SO_2/AIR process is recommended over the peroxide process because of the advantages in operating and capital cost compared to the peroxide process. A Sulphur system configured to include a sulphur burner offers substantial operating cost savings. The additional capital for a sulphur burner would have a short payback period (based on present operating costs). Process selection for the Casino project will be highly driven by reagent pricing and capital cost. The SO2/Air process equipment can also be utilized for both solution and slurry treatment if required in the second phase of the project. On the basis of the present reagent price portfolio, the SO2/Air process is favored by a relatively inexpensive meta cost and the peroxide being penalized by quite expensive H_2O_2, reagent and capital cost.

EXECUTIVE SUMMARY

Constructed wetlands (CWs) have been employed as passive treatment systems for metal contaminated mine drainage in Canada. However, relatively few CWs have been documented in northern environments and further studies are needed to understand the metal removal mechanisms in wetlands operating under cold climates, with short growing seasons. The goal of this study was to evaluate the performance of laboratory-scale CWs for the removal of Cd, Cu, Se and Zn, as well as, to evaluate Cu and Se uptake in two northern plant species (*Carex aquatilis* and *Juncus balticus*). Eight laboratory-scale wetlands were constructed using local materials, including locally harvested plant species and microorganisms and operated under northern summer conditions for 10 weeks. The CWs were fed continuously with synthetic influent containing Cd, Cu, Fe, Se and Zn at concentrations predicted at mine closure. Average removal efficiencies of 96%, 99%, 79% and 97% were observed for Cd, Cu, Se and Zn respectively. There were no significant differences in plant establishment or growth between our CW treatments, or any evidence of increasing Cu uptake with increasing contaminant availability in either northern plant species. Increased belowground uptake of Se was observed at the higher influent concentration in the Pit treatment. However, overall our study suggests that uptake of contaminants by these two northern species is very minor (<0.06% Cu and <0.11% Se, except for *C. aquatilis* in one treatment <0.2% Cu and <0.4 % Se) and likely does not pose a risk to the surrounding environment. We conclude that CWs could operate as successful passive treatment solutions in a northern environment, at least during the summer months, pending further studies on winter treatment. Further studies are required to examine seasonal metal removal rates in relation to rates of sulfate reduction, carbon consumption, metal precipitation and sorption. In addition, potential contaminant uptake and the influence of functional plant characteristics on metal removal in a suite of northern plant species would further assist in the development of large-scale long-term northern CWs.

ACKNOWLEDGEMENTS

This research was funded by a NSERC Applied Research and Development grant held with Casino Mining Corporation. We would like to thank Andre Sobolewski of Clear Coast Consulting for his expertise and contribution to the project. Michel Duteau, Isobel Ness and Hiromi Moriya contributed to the project through field, greenhouse and laboratory assistance.

There were no significant differences in root and shoot length or biomass between the CW treatments for either species (ANOVA, p>0.05 for all comparisons). 18

Table 3 Distribution of total Copper and Selenium partitioned by water, plants and substrate for each constructed wetland (CW) treatment and plant species (*Carex aquatilis* (Carex) and *Juncus balticus* (Juncus)) after 10 weeks of treatment with synthetic contaminated waters. Values are given in mg Cu or Se and values in parentheses are percentile amounts of total mass of Cu or Se in the CWs. 24

1. BACKGROUND

Constructed wetlands (CWs) are biogeochemical systems where an effluent flows through a plant-soil matrix and natural processes reduce pollutant levels to a given discharge limit (Bathia and Goyal 2014). CWs have been applied for treatment of municipal, agricultural and industrial effluents with complex physical, chemical and/or biological mechanisms (Kaldec and Knight 1996, Kaldec and Wallace 2008). Once established, CWs can become self-sustaining ecosystems with the plants providing yearly renewal of carbon to fuel microbial activity (Contango Strategies 2014). CWs have been proposed as a sustainable and long-term solution for water treatment at mine closure in Canada due to their low maintenance and operational cost requirements and high removal capacity (Eger and Kairies Beatty 2013; Sheoran and Sheoran 2006). However, relatively few wetlands have been used in northern environments and further studies are needed to design systems that will best fit the remediation objectives and environmental constraints (Kaldec and Reddy 2001).

The processes involved in metals removal from mine-impacted water include, but are not limited to, reduction/oxidation, precipitation, bio-sorption, bioaccumulation and volatilization (Sobolewski 1999, Guittonny-Philippe et al 2014). Microbial sulfate reduction processes and metal precipitation as sulfide salts in the anaerobic zone of the substrate is considered a major mechanism for metal sequestration in CWs (Arroyo et al 2013). While wetland sediments are known to act as a sink for heavy metals (Sheoran and Sheoran 2006, Baldwin and Hodaly 2003, August et al 2002), bioaccumulation in plants is also considered to some extent a metal removal pathway. Metal uptake by plants growing in wetlands treating mine-impacted waters has been sparsely studied with records of metal uptake by *Carex aquatilis* and *C. rostrata* (August et al 2002, Stoltz and Greger 2002, Nyquist and Greger 2009), *Juncus maritimus* and *J. effuses* (Conesa et al 2011, Rahman et al 2011), *Typha latifolia* and *T. domingensis* (Mitsh and Wise 1998, Taylor and Crowder 1983, Maine et al 2006), *Phragmites australis* (Batty and Younger 2004, Stoltz and Greger 2002, Nyquist and Greger 2009) *Eichhornia crassipes* (Maine et al 2006) and *Salix Sp*. (Stoltz and Greger 2002). In most of these cases heavy metals were reported to be largely found in plant roots with minimal or no uptake into shoots. Metal uptake potential in aboveground shoots should be well characterized in CWs that are used for mine closure, as it could pose a risk by exposing foraging wildlife to contaminants. Uptake by wetlands plants can be strongly affected by the water chemistry, the plant species (Deng et al 2004, Sheoran 2006), as well as, the redox conditions and geochemistry in the wetland substrate (Sobolewski 2010).

Implementation of two large CWs has been proposed as part of the billion-ton Copper-Gold Casino deposit project, located in the Yukon, 300 km northwest of Whitehorse. CWs have been proposed as a passive option for remediation to mitigate the risk of metals discharge into the downstream environment. One 10 ha CW has been proposed to treat discharge from the 3.14 km^2 open pit, which then flows into the proposed 1,120 ha Tailings Management Facilities (TMF). A second 6 ha CW has been proposed down-gradient of the TMF for final water treatment before release into the Casino Creek watershed (Casino Mining Corp 2014). This plan was submitted earlier this year for revision under the Yukon Socio-Economic and Environmental Assessment Act, one of the regulations framing environmental permitting in Yukon Territory. However, very few data on northern wetlands

with northern plants are available in the literature and a deeper understanding of northern wetland systems and plant uptake capacity is required for assessment and development of passive water treatment in the North.

The three objectives of this study were to: 1) Assess the short term efficiency of laboratory-scale CWs for mine effluents containing Cd, Cu, Fe, Se and Zn, 2) assess the potential uptake of Cu and Se by two northern wetlands plants, and 3) examine the influence of a methanol-amendment on metals removal by the laboratory-scale CWs.

2. MATERIAL AND METHODS

2.1. Laboratory-scale wetland setup

Eight laboratory-scale CWs were established in late June 2014 in the Yukon Research Centre greenhouse (Fig. 1). Each wetland consisted of a 47 L tote filled with 35 L soil substrate (13 cm height) made up of a homogeneous mixture of 5% (v/v) peat (Premier®, PremierTech Horticulture, Rivière-du-Loup, Quebec), 55% (v/v) washed sand (GE Cement plant, Whitehorse) and 40% (v/v) washed pea gravel (GE Cement plant, Whitehorse) (Fig. 2). Hydraulic conductivity tests were conducted to achieve the appropriate ratio of peat, sand and pea gravel to allow for a 5 ml/min flow rate with a hydraulic residence time of approximately 5 days (Fig. 3). *Carex aquatilis* and *Juncus balticus*, two plant species common in northern natural wetlands with different root oxygen exchange rates, were collected from a natural wetland located on McIntyre Creek in Whitehorse, YT (60°44'48.6"N 135°06'17.5"W) (Fig. 4). Eight plugs of either species containing rhizomes, roots and approximately 250 ml of natural wetland substrate were transplanted from the natural wetland into each laboratory-scale CW. Each wetland contained only one species; therefore, 4 wetlands contained *C. aquatilis* and 4 contained *J. balticus*. Two days after transplant, fertilizer was added (Alaska® Fish Fertilizer 5-1-1, Lilly Miller, dosage of 20 ml/m^2). The CWs were then saturated with tap water up to the level of the substrate surface and left undisturbed (no flow) for 2 weeks to allow the rhizomes to establish and the microorganisms within the transplanted substrate to incubate. Tap water was then circulated for another 2 weeks through the CWs. After 4 weeks of incubation with tap water, the aboveground biomass was removed at a height of 2 cm, leaving no shoots. Synthetic influents containing metals were then circulated through the CWs for 10 weeks and new shoot growth was monitored.

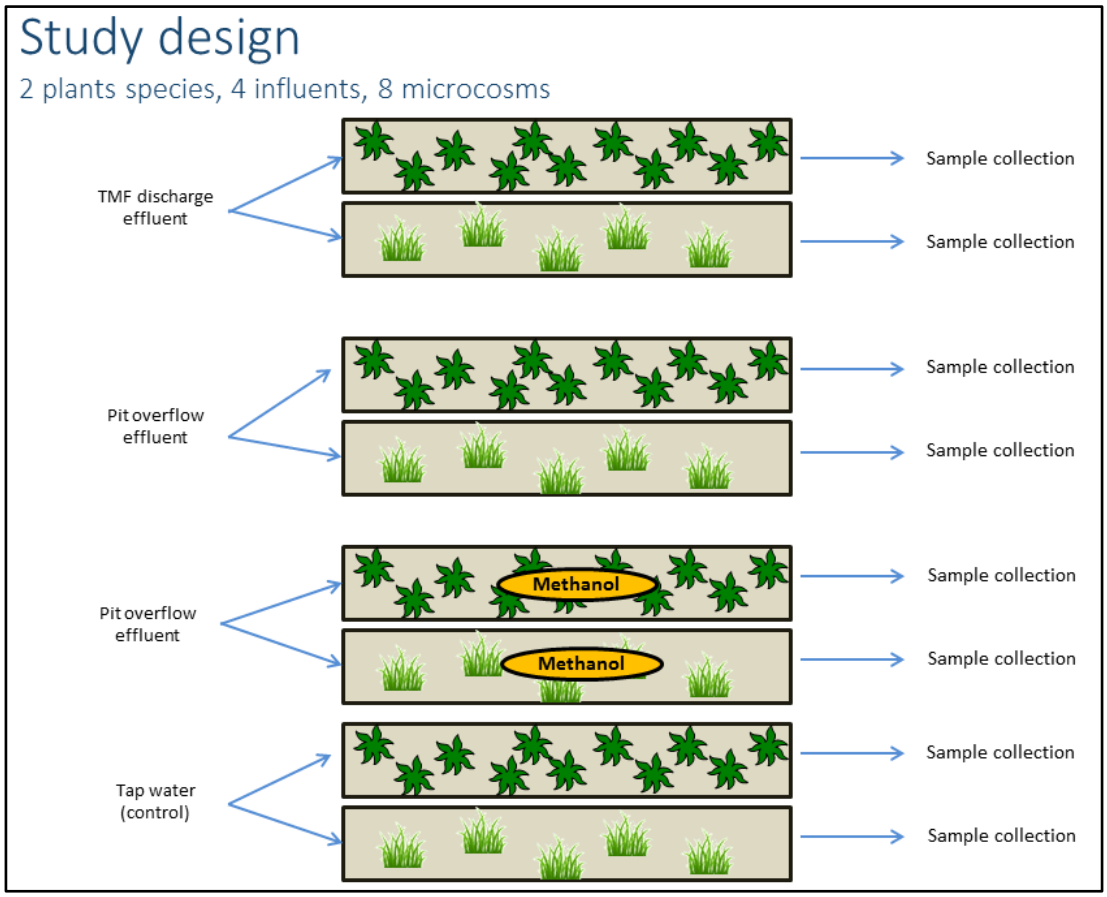

Figure 1 **Constructed Wetland (CW) study design using two plant species (*Carex aquatailis* and *Juncus balticus*) and 4 different synthetic influents (TMF, Pit, Pit(MeOH) and Control) for a total of 8 laboratory-scale CWs.**

Figure 4 Hydraulic conductivity testing to determine the appropriate ratio of peat, sand and pea gravel to achieve a 5 ml/min flow rate with a hydraulic residence time of approximately 5 days.

2.2. Synthetic influent preparation

Synthetic influents were prepared weekly by dissolving $CdSO_4*8/3H_2O$ (Acros Organics, ACS Reagent), $CuSO_4*5H_2O$ (Fisher Scientific, Fisher Bioreagents), $FeSO_4*7H_2O$ (Fisher Scientific, Reagent Grade), SeO_2 (anhydrous; Acros Organics, 99.8%) $ZnSO_4*7H_2O$ (Acros Organics, ACS Reagent) and Na_2SO_4 (anhydrous; Fisher scientific; Lab Grade) in DI water. Four CWs each had different water treatments (4 water treatments x 2 species for a total of 8 CWs):

i) TMF with metal concentrations that reflected the concentrations predicted at closure in the Tailings Management Facility,

ii) Pit with metal concentrations predicted at closure in the open pit,

iii) Pit(MeOH) with Pit metal concentrations and the addition of 1% MeOH (Fisher Scientific) added weekly and

iv) City of Whitehorse tap water that was considered a Control treatment (Fig. 1).

pH was similar in all influents while Cd, Cu and Se concentrations were about twice in the Pit treatment as in the TMF treatment (Table 1). Cadmium, Se and Zn concentrations in the tap water Control were below quantification limits or quantified under 5% of the measured concentrations in TMF, Pit and Pit(MeOH) (Table 1). Cu concentrations were detected in tap water (35.3 ± 14.4 ug/L) that were approximately 30% of the concentrations found in the TMF influent.

Table 1 Average and standard deviation for pH, SO_4, Cd, Cu, Se and Zn concentrations in the influents between Week 2 and 10 for each of the CW treatments. Values below quantification limit are assumed to be equal to the quantification limit of 0.05 ug Cd/L, 0.6 ug Cu/L, 0.7 ug Se/L and 0.4 ug Zn/L.

	Control	TMF	Pit	Pit(MeOH)
pH	7.9 ± 0.3	7.8 ± 0.1	7.9 ± 0.1	7.7 ± 0.1
Cd (ug/L)	0.07 ± 0.05	1.6 ± 0.9	6.1 ± 0.44	5.5 ± 0.74
Cu (ug/L)	35 ± 14	121 ± 33	644 ± 181	607 ± 192
Se (ug/L)	0.7 ± 0.0	2.8 ± 1.2	4.4 ± 1.7	4.5 ± 2.3
Zn (ug/L)	24 ± 3.7	525 ± 63	576 ± 53	540 ± 84
SO_4 (mg/L)	37 ± 3.3	600 ± 243	610 ± 237	496 ± 215

2.3. Laboratory-scale constructed wetlands operation and monitoring

The 8 CWs were operated and monitored over 10 weeks following 4 weeks of incubation in a greenhouse under northern summer conditions. Temperature was 11°C with no light from 23:00-5:00 and 16°C with 175 µmol/m^2/s of light from 5:00-23:00. Synthetic influents or tap water were pumped at the bottom of the substrate using a multi-channel peristaltic pump (Masterflex pump, head and C-flex tubing) at 5 ml/min with sub-surface vertical flow (Fig. 5). The hydraulic residence time was approximately 5 days. Effluents from the CWs were discharged into outlet collection containers. The volume of the effluent accumulated in the collection containers over a week were recorded while pH measurements and samples were collected weekly. Samples for total metal analysis were preserved with 5% HNO_3 (trace metal grade) and stored at 4°C and samples for sulfate analysis were stored frozen.

Figure 5 Synthetic influents or tap water being pumped at the bottom of the substrate using a multi-channel peristaltic pump (Masterflex pump, head and C-flex tubing) at 5 ml/min with sub-surface vertical flow.

At the end of the experiment period, Oxygen Reduction Potential (ORP) and pH were measured in the center of each CW at a depth of 5 cm and 10 cm from the outlet. CWs were drained and interstitial water that remained within the substrate was sampled and preserved with 5% HNO3 (trace metal grade) for total Cu and Se analysis. All plant materials were extracted from the wetland and above- and belowground biomass were carefully washed with DI water, brushing the materials to remove any remaining soil particles. Root and shoot length were recorded and dry biomass was determined following drying at 105°C for 72 hrs. Three replicates of live shoots and roots were further analyzed for metal content. Wetland substrates from each CW were thoroughly mixed, sampled and also analyzed for metal contents.

2.4. Contaminants Analysis

Total Cd, Cu, Se and Zn metal concentrations in effluents were measured using Perkin Elmer PinAAcle Atomic Absorption (AA) analyzer (Perkin Elmer, Waltham, MA). Cadmium, Cu and Se were analyzed by Graphite Furnace (GFAA) and Zn by Flame (FAA). The Quantification Limits (QL) used in this work have been defined for each element as 10-σ and are 0.05 ug Cd/L, 0.6 ug Cu/L, 0.7 ug Se/L and 0.4 ug Zn/L. Calibrations were completed on a daily basis using single element standards (SCP Science, Baie D'Urfé, QC), and blanks and mixed verification standards (Perkin Elmer, Waltham, MA) were analyzed every 15 samples. Up to ±20% deviation was tolerated for the verification standards at the low end of the calibration curve and up to ±10% on the high end of the calibration curve. Quality control reports and analysis details are reported in Appendix A. pH was measured using Oakton PCD650 meter (Vernon Hills, IL) with a double junction pH electrode. Sulfate was analyzed by spectrophotometry using a SmartChem 170® Automated Discrete Analyzer (Westco, Guelph, ON) according to the STM Method D516-90, 02. Biomass samples were digested with nitric acid (trace metal grade) according to the method described by Zarcinas et al (1987) while substrate samples were digested with aqua regia according to USEPA reference method 3050B.

2.5. Statistical analyses

All data were tested to meet the assumptions of ANOVA and log transformation and boxcox transformations were performed. Differences in contaminant outlet concentrations, pH and SO_4 consumption between CW treatments were examined using repeated measures ANOVA with TukeyHSD posthoc comparisons (significant differences indicated by $p<0.05$ for all comparisons). Due to independent replication for CW vegetation (i.e. *Carex aquatailis* and *Juncus balticus*) ANOVA was TukeyHSD posthoc comparisons ($p<0.05$) was used. All analyses were conducted in R (R package version 2.1.50). Mass balance calculations and partitioning of Cu and Se into CW elements (i.e. water, substrate and plants) was conducted by summing total Cu and Se contained in the plant (metal content in above and belowground biomass x biomass weight before and after the experiment), in the soil (metal content in the soil x dry weight of soil contained in each CW before and after the experiment including initial peat, natural substrate and fish fertilizer), the water flowing in and out of the wetlands (weekly measurements of metal concentrations and volumes) and the interstitial water contained within the CWs at the end of the experiment.

3. RESULTS

3.1. Heavy metal removal from contaminated waters

The laboratory-scale constructed wetlands demonstrated a strong ability to remove heavy metals from contaminated water. Total removal efficiencies above or equal to 96%, 99%, 79% and 97% were observed for Cd, Cu, Se and Zn respectively, across the four CWs treating Pit and TMF synthetic influents (Fig. 6). Although the Pit treatment had higher metal concentrations in the influent (Table 1), there were no significant differences in the outlet contaminant concentrations between the different CWs treatments (repeated measures ANOVA with Tukey posthoc, $p>0.05$ for all comparisons). These consistently high metal removal efficiencies across CW treatments, regardless of synthetic influent concentrations, suggest that the short-term metal removal capacity of these laboratory-scale CWs were not reached. Further studies that include higher concentrations of contaminant inputs, larger-scale wetlands and a greater duration of treatment would be highly useful in determining the long-term metal sequestration capacity.

Although the CWs were only at a small laboratory-scale, the Cd, Cu and Zn removal efficiencies observed were similar to the efficiencies observed in other pilot or full-scale wetlands. Removal efficiencies of 94-99% for Cd (Gammons et al 2000, Yang et al 2006), 89-97% for Cu (Banks et al 1997, Gammons et al 2000, Lesage et al 2007, Contango Strategies 2014) and 87-98% for Zn (Sobolewski 1996, Banks et al 1997, Yang et al 2006, Lesage et al 2007) have been reported. Selenium treatment of mine-impacted water by CWs seems less common than transition metals treatment and Se had the lowest average removal compared with the other contaminants. However, removal efficiencies above 83 % were observed in this study. In another study examining a northern wetland planted with the same *Carex* species, an efficiency of 26% was reported for Se removal (Contango Strategies 2014). This low efficiency was attributed to the elevated concentrations of nitrate, which competes over Se as an electron-acceptor.

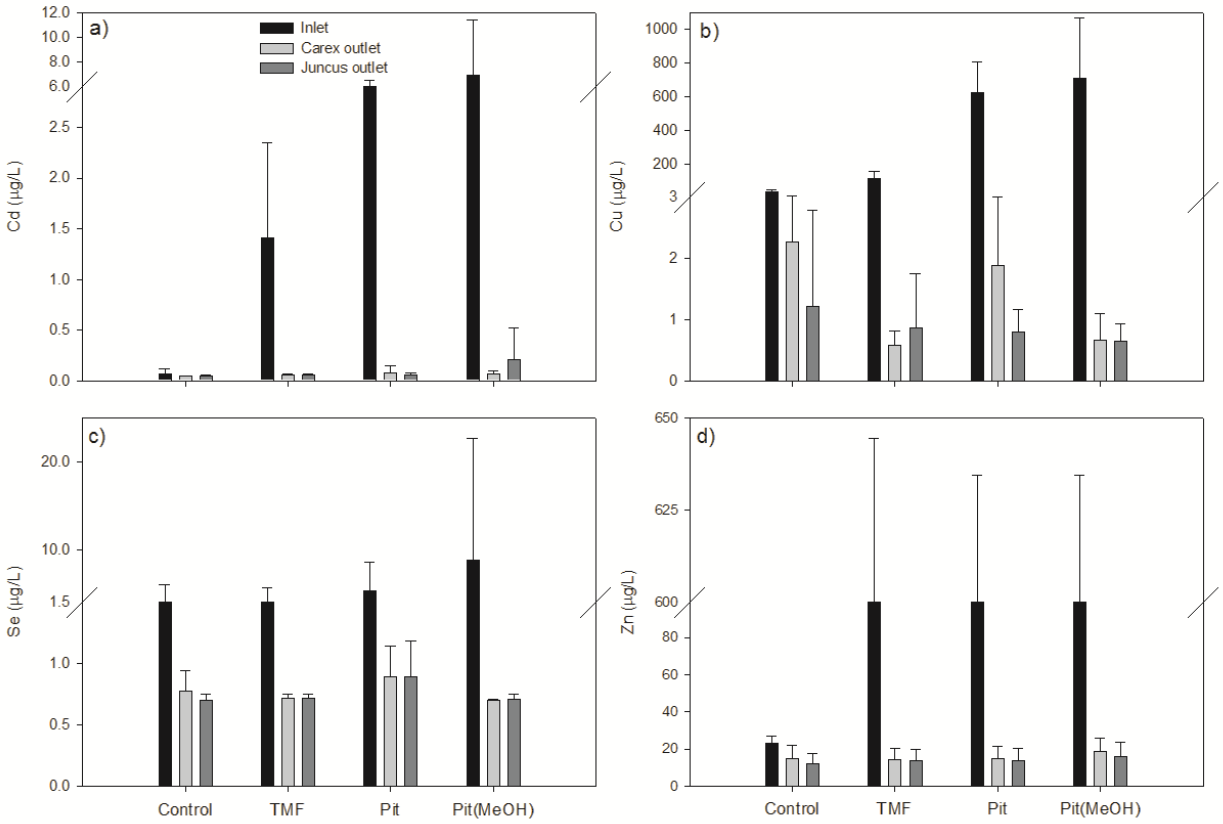

Figure 6 Cd (a), Cu (b), Se (c) and Zn (d) concentrations in CWs with C. aquatilis (Carex) and *J. balticus* (Juncus) fed with Control, TMF, Pit or Pit(MeOH) waters. Bars represent means with standard error. There were no significant differences in the outlet concentrations for any of the contaminants between the wetland treatments (repeated measures ANOVA with Tukey posthoc (p>0.05 for all comparisons). Note the broken Y-axis.

Over the trial a significant increase in pH in the TMF, Pit and Pit(MeOH) treatments was detected compared to the Control treatment (ANOVA with Tukey posthoc, $p<0.05$ for all comparisons) (Fig. 7). Starting at week 7 significant increases in pH were observed for the Pit(MeOH) treatment compared to all other treatments. In addition, higher consumption of SO_4 was observed for the Pit(MeOH) treatment where a carbon source (i.e.1% MeOH) was being added to the CWs. Both CWs with a Pit(MeOH) treatment had higher consumption of SO_4 compared with the Pit treatments starting at week 6 (Fig. 8). Although, the Pit(MeOH) with *J. balticus* was not significantly higher than the Pit treatment with *J. balticus*, both the Pit(MeOH) treatments were significantly higher than the Pit treatment with *C. aquatilis* (ANOVA with Tukey posthoc, $p=0.05$ for Carex and $p=0.02$ for Juncus). An increase in reducing conditions in the CW substrate of the Pit(MeOH) treatment was observed, with an average Oxygen Reducing Potential (ORP) of -341.9 mV, compared to an average of -109.4 mV when no MeOH was added (i.e. Pit). Black deposits on the wetland surface, characteristic of sulfide precipitates, and odiferous evidence of H_2S from the Pit(MeOH) CWs indicated a strong reducing environment (Fig. 9). Low ORP, increased SO_4 consumption and black deposits on the wetland surface for the Pit(MeOH) treatment likely indicate that

methanol addition to the CWs was stimulating microbial-induced sulfate reduction (Eq. 1) and subsequent metal sulfide salts precipitation (Eq. 2). Reduction of one mol of sulfate leads to the production of 3 moles of bicarbonate (HCO_3^-), which likely explains the increase in pH observed in Fig. 7 as bicarbonate consumes hydrogen ions (Eq. 3).

(Eq. 1) $$4\,CH_3OH + 3\,SO_4^{2-} \xrightarrow{microbial} 3\,HCO_3^- + 3HS^- + 5\,H_2O + CO_2$$

(Eq. 2) $$HS^- + M^{2+} \leftrightarrow MS(s) + H^+$$

(Eq. 3) $$HCO_3^- + H^+ \leftrightarrow H_2O + CO_2$$

In natural wetlands organic matter decomposition typically decreases the ambient redox potential. Organic carbon acts as an electron donor to microorganisms, such as sulfate-reducing bacteria, which reduce sulfate (SO_4) releasing sulfide (S^2) (Sobolewski 2010). Sulfide is highly reactive and forms insoluble metal salts, such as CdS, CuS and ZnS. To offset the reduction in organic matter decomposition often encountered in northern wetlands and bioreactors, addition of liquid carbon may be advantageous (Tsukamoto et al 2004, Sobolewski 2010, Alexco 2012, Gould et al 2012). The addition of liquid methanol at 1% (v/v) in the Pit(MeOH) treatment was intended to assess the impact of additional carbon sources on the substrate conditions and subsequently on the metal uptake by northern wetland plant species. It appears that the addition of liquid methanol did impact the substrate conditions and led to greater reducing conditions, although significantly higher heavy metal removal efficiency was not observed (Fig. 6). Therefore, the presence of electron donors in the substrate was likely not a limiting factor in the Pit CWs that were not fed with methanol. In addition, the Pit(MeOH) CWs may have produced HS^- in excess accounting for the odor associated with this treatment.

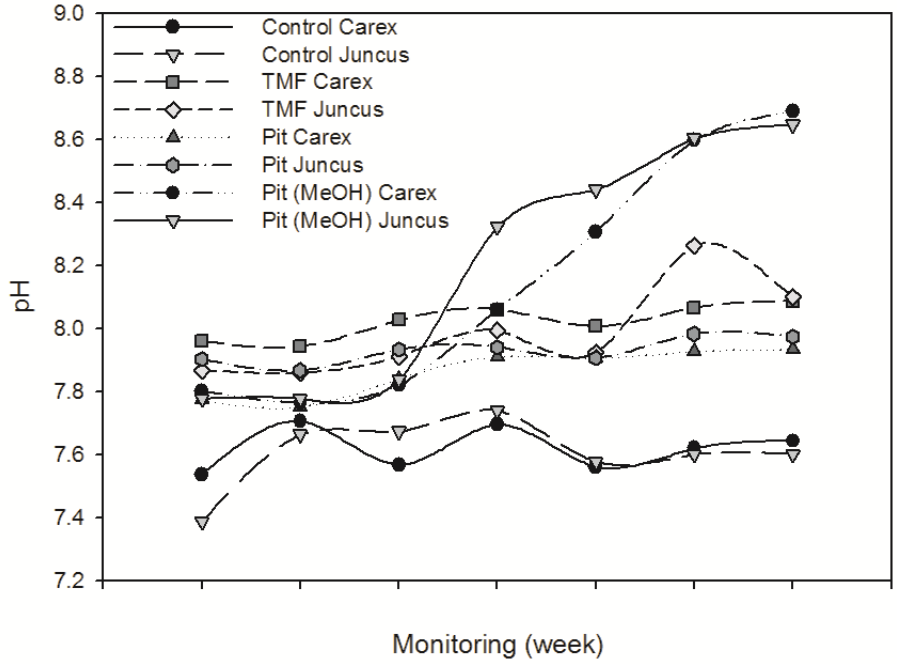

Figure 7 pH of outlet waters for each CW treatment monitored from week 4 to week 10 of the laboratory-scale trial. At week 7 significant increases in pH were observed

for the Pit(MeOH) treatment compared to all other treatments. Similarly, both the TMF and Pit treatment had significant increases in pH compared to the control (ANOVA with TukeyHSD, p<0.05 for all comparisons).

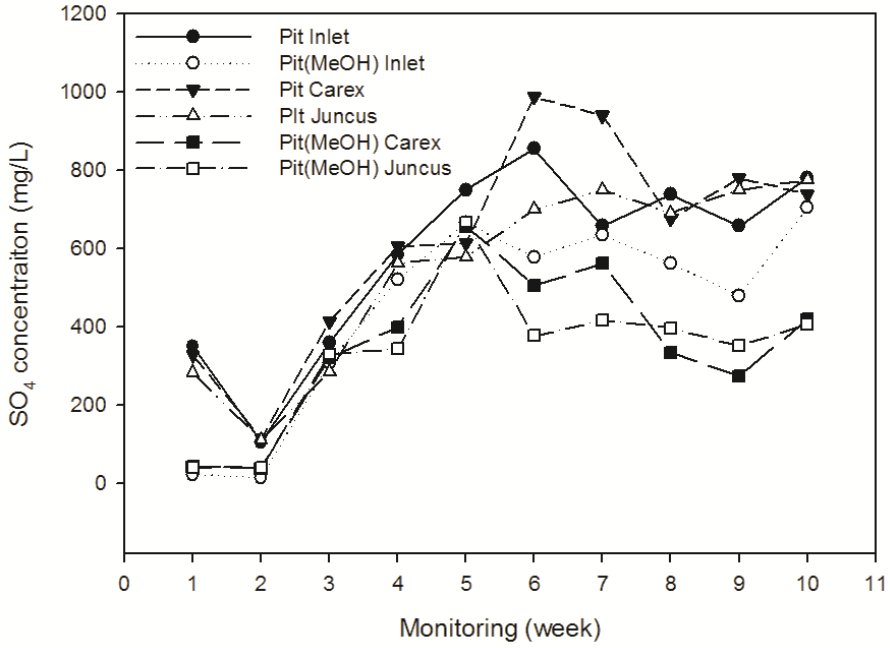

Figure 8 Sulfate concentration in the inlet and outlet waters of the Pit and Pit(MeOH) CWs with *C. aquatilis* (Carex) and *J. Balticus* (Juncus) monitored over the 10 week trial. Significantly higher sulfate consumption (i.e. Inlet-Outlet for each CW) for both Pit(MeOH) CWs compared with the Carex Pit treatment were detected (ANOVA with Tukey posthoc, p=0.05 for Carex and p=0.02 for Juncus).

Figure 9 Black deposits on the wetland surface, characteristic of sulfide precipitates found only in the Pit(MeOH) CW treatment. In addition, an odiferous evidence of H_2S from the Pit(MeOH) was present.

To better understand the mechanisms by which metal sequestration occurs in northern CWs further studies are required. In particular, characterization of metal endpoints, examination of the relative importance of sorption versus metal precipitation and characterization of the microbial community and its' activity are needed. Understanding the metabolic activities of SRB and the entire scope of the microbial communities present in wetlands at permanently low temperatures is crucial (Robador et al 2009). More importantly, studies are needed to determine if a relationship can be established between summer and winter metal removal rates and rates of sulfate reduction, carbon consumption, metal precipitation and sorption (Gammons et. al. 2000). Such seasonally-adjusted rates will support the development of seasonally-adjusted treatment performance and design criteria for northern CWs that function year-round.

Metal uptake by plants is thought to depend on the geochemistry in the substrate and is affected by the speciation and availability of the metals. At the end of 10 weeks of treatment in our laboratory-scale study shoots of both *C. aquatilis* and *J. balticus* were yellowed and dead in the Pit(MeOH) treatment. Sulfide is known as a strong phytotoxcin to plants by causing basic disturbance to cell metabolism and energy transfer, which can hamper plant nutrient uptake (Lamers et al 2013). Death of plants within the Pit(MeOH) treatment and the strong H_2S odour may indicate that the concentration of organic carbon used was too high. In addition, other sources of carbon may be more appropriate for use in northern CWs with northern plant species. Glucose, lactate/acetate, ethanol, methanol, ethylene glycol are all carbon sources that have been used to supplement northern bioreactors or CWs (Ness et al. 2014). Further studies are needed to examine the influence of sources and concentrations of carbon in northern CWs and how these may influence metal sequestration in both wetland substrates and plants.

3.2. Establishment, growth and metal uptake of northern wetland plants

There were no significant differences in metal removal efficiency or pH between CW treatments containing either *C. aquatalis* or *J. balticus*. Nor were there significant differences in the shoot and root length or in the above and belowground biomass across our different CW treatments for either of the northern plant species (Table 2; ANOVA with TukeyHSD posthoc, $p>0.05$ for all comparisons). While growth of belowground biomass was more difficult to quantify for the transplants, aboveground biomass was removed for both species prior to initiating treatment with contaminated synthetic influent; therefore, strong growth within 10 weeks with stems as long as 74 cm and 50 cm for *C. aquatalis* and *J. balticus*, respectively, was observed. With the exception of mortality of both species in the Pit(MeOH) treatment, discussed above, the establishment and growth of both plant species did not appear to be negatively impacted by the addition of contaminants into the CWs. Our study suggests that both of these species may be good candidates for northern CWs due to their vigorous growth, high tolerance to contaminants and limited uptake of Cu and Se.

Although no treatment effects on establishment were observed, *C. aquatalis* had a 53% survival rate and *J. balticus* had only a 38% survival rate following transplanting. The results suggest that if using locally transplanted materials high numbers of replicate plants may be needed to account for transplant related mortality. Although transplantation of plant materials is advantageous since plants are adapted to the local conditions (Galbrand et al. 2008), much higher rates of plant propagation success can be achieved by purchasing plugs from commercial native plant nurseries. However, plant materials for growing plugs should ultimately be sourced from as close as possible to the site of the CW. Further determination of species for northern CWs requires an evaluation of a much larger suite of locally available plants. To ensure effective naturalization of the vegetation community to be established in a CW, community modeling based on surveying of plant communities inhabiting similar local natural wetlands, including vegetation composition, structure and abundance should be conducted (Daigle and Havinga 1996, Hoag 2003). Based on the following criteria, species can be further screened for suitability in CWs: (a) phytoremediation potential (especially metal uptake), (b) sedimentation and erosion control, (c) habitat function, (d) public deterrent potential and (e) rate of plant establishment, tolerances and maintenance requirements (Galbrand et al. 2008).

Table 2 Average and standard deviation of root and shoot length and biomass (dry weight) *of Carex aquatilis* (Carex) and *Juncus balticus* (Juncus) after 10 weeks of growth in constructed wetlands (CWs) treated with either Control, Pit, TMF and Pit(MeOH) waters. There were no significant differences in root and shoot length or biomass between the CW treatments for either species (ANOVA, p>0.05 for all comparisons).

Plant species	CW Treatment	Root length (cm)	Shoot length (cm)	Root biomass (g)	Shoot biomass (g)
Carex	Control	20 ± 8.9	35 ± 21	0.38 ± 0.23	0.76 ± 0.47
	TMF	24 ± 21	35 ± 22	0.50 ± 0.23	9.2 ± 23
	Pit	25 ± 20	24 ± 23	0.42 ± 0.27	1.4 ± 1.2
	Pit(MeOH)	21 ± 9.1	28 ± 18	0.49 ± 0.23	0.91 ± 0.31

	TMF	11 ± 7.1	15 ± 12	0.27 ± 0.21	0.20 ± 0.14
	Pit	10 ± 6.1	21± 15	0.25 ± 0.15	0.21± 0.07
	Pit(MeOH)	7.2 ± 2.8	16 ± 8.8	0.30 ± 0.21	0.23 ± 0.09

No significant uptake of Cu or Se into the aboveground biomass by *C. aquatilis* or *J. balticus* was observed in this study. Furthermore, there was no significant difference in above or belowground Cu content in either plant species across the different CWs treatments (Fig. 10; ANOVA, p=0.51). Although in most treatments Cu content was observed to be slightly higher in the belowground biomass compared to the aboveground biomass this was not significant, suggesting an almost equal distribution of Cu throughout the biomass of *C. aquatilis* and *J. balticus*. Analysis of Cu content in *C. aquatilis* and *J. balticus* shoots taken directly from the natural wetland collection site found concentrations of 7.07 ± 2.79 and 7.14 ± 2.71 mg/kg respectively. Despite the differences in the root oxygen exchange

between these two species (*C. aquatilis* 6.7 µmol O_2 loss/g dry root/day vs *J. balticus* 9.9 µmol O_2 loss/g dry root/day (Taylor 2009)) there were no differences in their uptake of Cu within the CWs. Contango Strategies (2014) reported similar Cu contents (4 to 20 mg Cu/kg) in *C. aquatilis* growing in a natural wetland area where Cu-loaded seepages are known to occur within the Minto Cu-Au mine area in the Yukon Territory. Even though small-scale experiments have been shown to overestimate metal plant uptake capability (Conesa et al 2007), both the results from this study and those observed from the natural wetland located at Minto mine (Contango Strategies 2014) suggest a low tendency for Cu uptake in these wetland plants. Other studies have found Cu uptake in *Carex* spp. For example in a CW treating acid mine drainage in Sweden, *Carex rostrata* had Cu concentrations of 84 ± 9 mg/kg in belowground biomass and 12 ± 1.0 mg/kg in aboveground biomass, which exceeds the 3 ±1 mg/kg and 1.3 ±0.3 mg/kg found in the control plants respectively (Nyquist and Greger 2009). Similarly elevated levels of Cu were found in the biomass of *C. rostrata* grown on submerged tailings in northern Sweden (22.6 mg/kg) compared to untreated plants (4-15 mg/kg), but in both cases the aboveground biomass was well below levels that were deemed tolerable for animals (25-800 mg/kg in air dried forage) (Stoltz and Greger 2002).

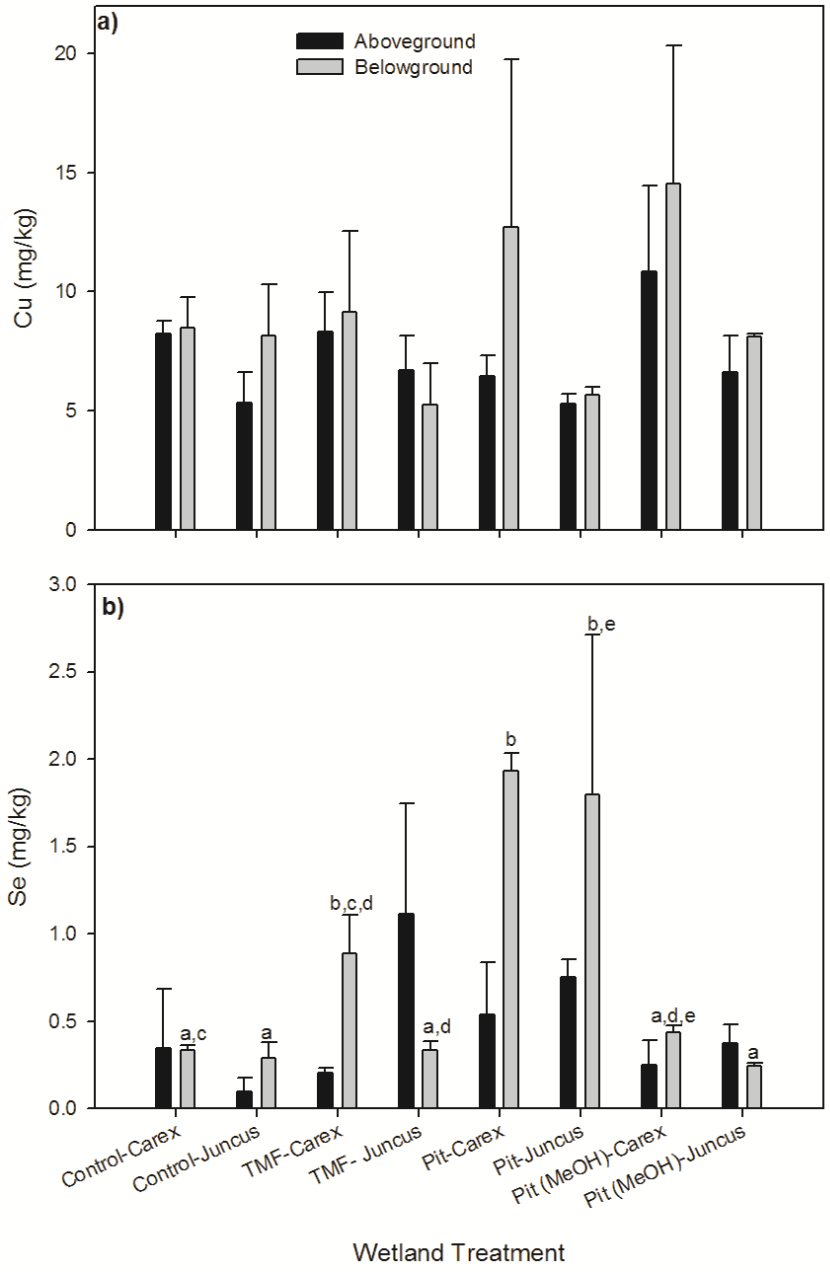

Figure 10 **Copper and Selenium content in *C. aquatilis* (Carex) and *J. balticus* (Juncus) in constructed laboratory-scale wetlands after 10 weeks of operation with tap water (Control), TMF, Pit or Pit (MeOH) synthetic waters. There was no significant difference in Cu content of above or belowground biomass across the treatments for either northern plant species (ANOVA, p=0.51). We detected significantly higher Se in belowground biomass in the Pit treatment compared with the control and pit (MeOH) treatments for both Carex and Juncus (ANOVA, p<0.05 for all comparisons). Bar represent means with standard error. Different letters indicate significantly different means.**

Se uptake into the aboveground biomass had a similar trend as Cu with no significant differences across the CWs treatments for either species (ANOVA, p=0.12). Analysis of Se content in *C. aquatilis* and *J. balticus* shoots taken directly from the natural wetland collection site had concentrations of 0.25 ± 0.01 and 0.29 ± 0.14 mg/kg respectively. Very few studies have examined Se uptake in CWs, however, the belowground systems of *Schoenoplectus californicus* and *Typha angustifolia* were observed to sorb and bioconcentrate Se in a pilot constructed wetland for flue gas desulfurization wastewater treatment (Sundberg-Jones and Hassan 2007). Sorption on roots accounted for 4.4 +2.7 mg/kg for *S. californicus* and 0.5 +0.4 mg/kg for *T. angustifolia*, however when both adsorption and plant tissue were considered Se concentrations were as high as 4224 +2843 mg/kg for *S. californicus* and 170 +109 mg/kg for *T. angustifolia*. In a CW vegetated mainly with *Scirpus robustus*, *Polypogon monspeliensis* and *Typha latifolia* treating oil-refinery effluent approximately 90% of the Se entering the CW was removed (Hansen et al 1998, de Sousa et al 1999), however these wetland plants accumulated Se in their tissues at concentrations that were at least 3 orders of magnitude above those in the effluent (deSousa et al 1999). It should be noted that the concentration of Se in both of these systems far exceeded the highest Se concentration the laboratory-scale CWs (4.5 µg/L) with concentrations of 8.5 mg/L and 1.6 mg/L respectively.

Water-saturated soil conditions and the resulting low ORP appear to limit the Se concentration in *Carex* spp., for example under saturated soil conditions the average Se concentration in *Carex* spp. was found to be 17.7 µg/L $\pm$11.0 versus 43.4 µg/L $\pm$ 15.9 in normal alpine soils (Michner et al 2007). The most highly oxidized species of Se is selenate ($SeO4^-$), which is water-soluble and readily assimilated by plants, and is the form commonly found in alkaline soil where cases of Se toxicity occur (Lakin 1972, van Dorst and Peterson 1984, Michner et al 2007). Since reduced forms of Se are less available it is the abundance of the various species of Se, rather than total concentration that governs availability. The overall low levels of Se uptake observed in both *C. aquatilis* and *J. balticus* therefore, may in part be related to the water-saturated and low ORP conditions typical of wetlands.

Both northern plant species had higher Se content in the Pit treatment compared with both of their respective Control and Pit(MeOH) treatments (ANOVA with TukeyHSD posthoc, *C. aquatilis*, p <0.01 and 0.03; *J. balticus*, p<0.01 for both comparisons; Fig 10). It is not surprising that the only uptake observed in this study occurred in the belowground biomass. Many other studies have observed that the concentrations of heavy metals in various parts of macrophytes growing in CWs and natural wetlands, generally decrease in the order of roots >rhizomes > leaves > stems (Vymazal and Březinová 2015). Higher belowground Se in the Pit treatment corresponds with the higher level of contaminants in the synthetic influent (Table 1). However, in the Pit(MeOH) treatment we did not see a similar increase in uptake of Se into the belowground biomass despite the same levels of Se being introduced to the system. In the Pit(MeOH) treatment we observed a 100% mortality rate of both species by week 10, which, as discussed above, is likely due to the phytotoxicity of sulphide. Progressive death of the belowground system would reduce Se uptake. Alternatively metal precipitation associated with increased SRB activity in the Pit(MeOH) CWs may have reduced the bioavailability of Se to *C. aquatilis* and *J. balticus.*

Hyperaccumulators are defined as plants that complete their life cycle with foliar metal concentrations exceeding (mg/kg dry weight, DW) Cd > 100, Ni and Cu > 1000, and Zn and

Mn > 10,000 (Zavoda et al 2001, Marchand et al 2010). However, to date, no emergent wetland plants have been identified as hyperaccumulators. As our results confirm, metal removal through uptake by macrophytes in wetlands is relatively minor compared to other processes. Although the concentrations of heavy metals in plants growing in CWs vary considerably between species and systems, the concentrations are generally within the range commonly found in natural stands (Vymazal and Březinová 2015). The importance of macrophytes in these systems is to provide organic matter needed to perpetuate the biogeochemical processes in the substrate through die-back, and organic compounds via exudation from the roots (Jenssen et al 1993, Marchand et al 2010). Although investigating potential uptake of contaminants in a greater number of northern plant species, both at higher influent concentrations and over longer time periods is advisable, examination of other functions that wetland plants provide may be more informative for northern CW design. For example, higher removal efficiency has been observed for Zn and Cu when monocots rather than dicots are used. Since uptake in plants is not an important factor in metal removal in wetlands, differences between monocots and dicots with respect to metal acquisition cannot account for the differences in removal (Marchand et al 2010). Differences in rooting morphology and exudation of organic compounds may be the cause of this variation. Monocots have adventitious rooting systems with a greater surface area and produce phytosiderophores that chelate metals such as ferric iron due to their amine and carboxyl groups (Kidd et al 2009), whereas dicots have vertical tap roots and no phytosiderophore production (Marchand et al 2010). Further examination of the functional characteristics of northern wetland plant species in relation to long-term metal sequestration would be highly valuable. In addition, heavy metal concentrations in wetland plant biomass vary considerably during the season, but do not follow the well-known pattern for nutrients (Vymazal and Březinová 2015). In cold climates maximum concentrations of nutrients, such as nitrogen and phosphorus, tend to occur early in the growing season, while the maximum standing stock for nutrients (i.e. nutrient concentrations within plants), tends to occur later in the season at the time of maximum biomass (Vymazal and Březinová 2015). However, the standing stock for heavy metals has no consistent temporal pattern and varies both between metals and between plant species (Vymazal and Kröpfelová 2008, Vymazal and Březinová 2015). Further studies examining the seasonal patterns of heavy metal concentrations in wetland plant biomass are needed to assist in predicting any potential contaminant availability to the surrounding environment.

3.3. Cu and Se distribution within the CWs

As discussed previously, high efficiencies were observed for removal of Cu (>99%) and Se (>79%) from influent waters by the wetlands (Fig. 6). Analysis of the distribution of both contaminants in the water, plants and substrate systems suggests that both Cu and Se were primarily contained within the substrate in all the CWs as indicated by high percentile amounts (Table 3). More than 99.8% of the total load of Cu and >90.2% of the total load of Se were measured in the substrate at the end of the experiment.

Conversely, in all of the CW treatments for both Cu and Se, <0.06% of Cu and <0.11% of Se was found in plant biomass, with the exception of the TMF treatment with *C. aquatilis* (i.e. <0.2% Cu and <0.4 % Se) (Table 3). The loads in mg of metal in biomass are calculated as

the metal contents (in mg/kg) times the weight of biomass (in kg). Noteworthy, although metal concentrations are generally smaller in the shoots than in the roots, the loads measured in the shoots are higher as it reflects the larger biomass produced aboveground. Nonetheless, metal uptake by *C. aquatilis* or by *J. balticus* is clearly not a major Cu or Se removal mechanism in the CWs studied. Similar observations were made for Fe uptake by Mitsh and Wise (1998) who observed <0.07 % uptake in a constructed wetland in Ohio and by August et al (2002) who measured <0.5 % uptake in a natural wetland in Colorado. In northern Sweden *Carex rostrata*, *Eriophorum angustifolium* and *Phragmites australis* were observed to uptake of Zn, Cu and Cd at <0.4%, 0.3% and 2.9% respectively (Nyquist and Greger 2009). In smaller-scale experiments in greenhouses, Allende et al. (2014) and Rahman et al (2011) reported that <0.11% and 1% of the total mass of As load in the wetlands was uptaken by *P. autralis* and *J. effuses* shoots respectively.

Overall, our study supports the findings of others that suggest metal removal mechanisms are most likely driven by chemical and microbial reactions occurring within the substrates (Sobolewski 1999, Sheoran and Sheoran 2006, Vymazal and Březinová 2015). In addition, we found a higher average removal efficiency for Cu (99%) than for Se (79%) and we also found a larger distribution of Cu in the substrate (>99.8%) compared with Se (90.2-98.0%). This higher removal efficiency of Cu appears to be primarily the result of metal sequestration within the wetlands substrate. With the exception of the TMF CW treatment with *C. aquatilis*, the percentage of total Se in plants was higher than for Cu in all of CW treatments. Although the percentages for both contaminants in plant biomass were still very low, the partitioning of Se into plants may be more of a concern than the partitioning of Cu into plants. Due to the lack of information on Se uptake into wetland plants and the observed trend in this study, further examination of Se uptake in plants is recommended.

Table 3 Distribution of total Copper and Selenium partitioned by water, plants and substrate for each constructed wetland (CW) treatment and plant species (*Carex aquatilis* (Carex) and *Juncus balticus* (Juncus)) after 10 weeks of treatment with synthetic contaminated waters. Values are given in mg Cu or Se and values in parentheses are percentile amounts of total mass of Cu or Se in the CWs.

Copper

4. SUMMARY OF KEY FINDINGS

The laboratory-scale CWs evaluated herein demonstrated a strong ability to remove contaminants from synthetically contaminated waters with average removal efficiencies above or equal to 96%, 99%, 79% and 97% for Cd, Cu, Se and Zn respectively. Even with increased contaminant concentrations in the influent waters (i.e. Pit treatment compared to TMF treatment) there was no decline in removal efficiencies suggesting that the short-term metal removal capacity of these laboratory-scale CWs was not reached. While transplant related mortality did reduce the overall biomass accumulation in our CWs, no treatment effects on the establishment and growth of the two northern plant species *C.*

aquatilis and *J. balticus* were observed. Furthermore, there was no evidence of Cu or Se uptake into the aboveground biomass of either species with increasing contaminant availability. Increased belowground uptake of Se was observed at the higher influent concentration in the Pit treatment. Overall, this study suggests that uptake of contaminants by these two northern species is very minor (i.e. <0.06% Cu and <0.11% Se, except for *C. aquatilis* in the TMF CW <0.2% Cu and <0.4 % Se) and likely does not pose a risk to the surrounding environment. This study concludes that CWs could operate as successful passive treatment solutions in a northern environment, at least during the summer months. Further studies are required to examine seasonal metal removal rates in relation to rates of sulfate reduction, carbon consumption, metal precipitation and sorption. In addition, potential contaminant uptake and the influence of functional plant characteristics on metal removal in a suite of northern plant species would further assist in the development of large-scale long-term northern CWs.

5. RECOMMENDATIONS FOR FUTURE WORK

- Further studies that include higher concentrations of contaminant inputs, larger-scale wetlands and a greater duration of treatment would be highly useful in determining the long-term metal sequestration capacity.

- To better understand the mechanisms by which metal sequestration occurs in northern CWs further studies are required. In particular, characterization of metal endpoints, speciation of the sequestered metals and characterization of the microbial community and its' activity are needed.

- Understanding the metabolic activities of SRB and the entire scope of the microbial communities present in wetlands at permanently low temperatures is crucial. Examination of the microbial community in natural wetlands, particularly those receiving contaminants would be highly informative.

- Studies are needed to determine if a relationship can be established between summer and winter metal removal rates and rates of sulfate reduction, carbon consumption, metal precipitation and sorption. Such seasonally-adjusted rates will support the development of seasonally-adjusted treatment performance and design criteria for northern CWs that function year-round.

- Further studies are needed to examine the influence of sources and concentrations of carbon in northern CWs and how these may influence metal sequestration in both wetland substrates and plants.

- Determination of species for northern CWs requires an evaluation of a much larger suite of locally available plants. To ensure effective naturalization of the vegetation community to be established in a CW, community modeling based on surveying of plant communities inhabiting similar local natural wetlands is needed.

- Local naturally occurring wetland species should also be screened for their suitability for inclusion in CWs based upon, phytoremediation potential,

sedimentation and erosion control, habitat function and rate of plant establishment, tolerance and maintenance requirements.

- Due to the lack of information on Se sequestration in CWs and Se uptake in plants, as well as, the observed uptake in the belowground systems of *Carex aquatilis* and *Juncus balticus*, special attention should be given to future studies focusing on Se.

- In addition to investigating potential uptake of contaminants in a greater number of northern plant species, both at higher influent concentrations and over longer time periods, examination of other functions that wetland plants provide may be more informative for northern CW design.

- Since contaminant concentrations within the biomass of wetland plants are known to be inconsistent both between metals and between species, further studies examining the seasonal patterns of heavy metal concentrations in wetland plant biomass are needed to assist in predicting any potential contaminant availability to the surrounding environment.

1 – INTRODUCTION

The Casino Copper-Gold Project is a venture by Casino Mining Copper Corporation to develop an Open Pit copper-gold-molybdenum mine in the Yukon Territory. The project is located in the Dawson Range Mountains of the Klondike Plateau, approximately 300 km northwest of Whitehorse, Yukon Territory, Canada. This area is somewhat unique in that the region was not glaciated during the Wisconsin Advance. The deposit is hosted by the Casino Complex, a suite of igneous intrusive rocks, with an intense hydrothermal alteration overprint. The deposit will be mined using Open Pit methods with a nominal mill throughput of approximately 125,000 tonnes/day (tpd) of ore.

The Tailings Management Facility (TMF) has been designed to provide environmentally secure storage for co-disposal of 956 million tonnes of tailings and 658 million tonnes of potentially reactive waste rock and overburden materials, placed in a Waste Storage Area within the TMF.

The current mine waste production schedule indicates that only a small quantity of the potentially reactive material will be classified as Hypogene in the initial years of mining (up to the end of Year 4), with the large majority comprising Supergene waste materials. Thereafter the production of Hypogene waste material increases significantly. After Year 4 of operations the mine waste reporting to the Waste Storage Area will be a mixture of Hypogene and Supergene materials in varying proportions each year.

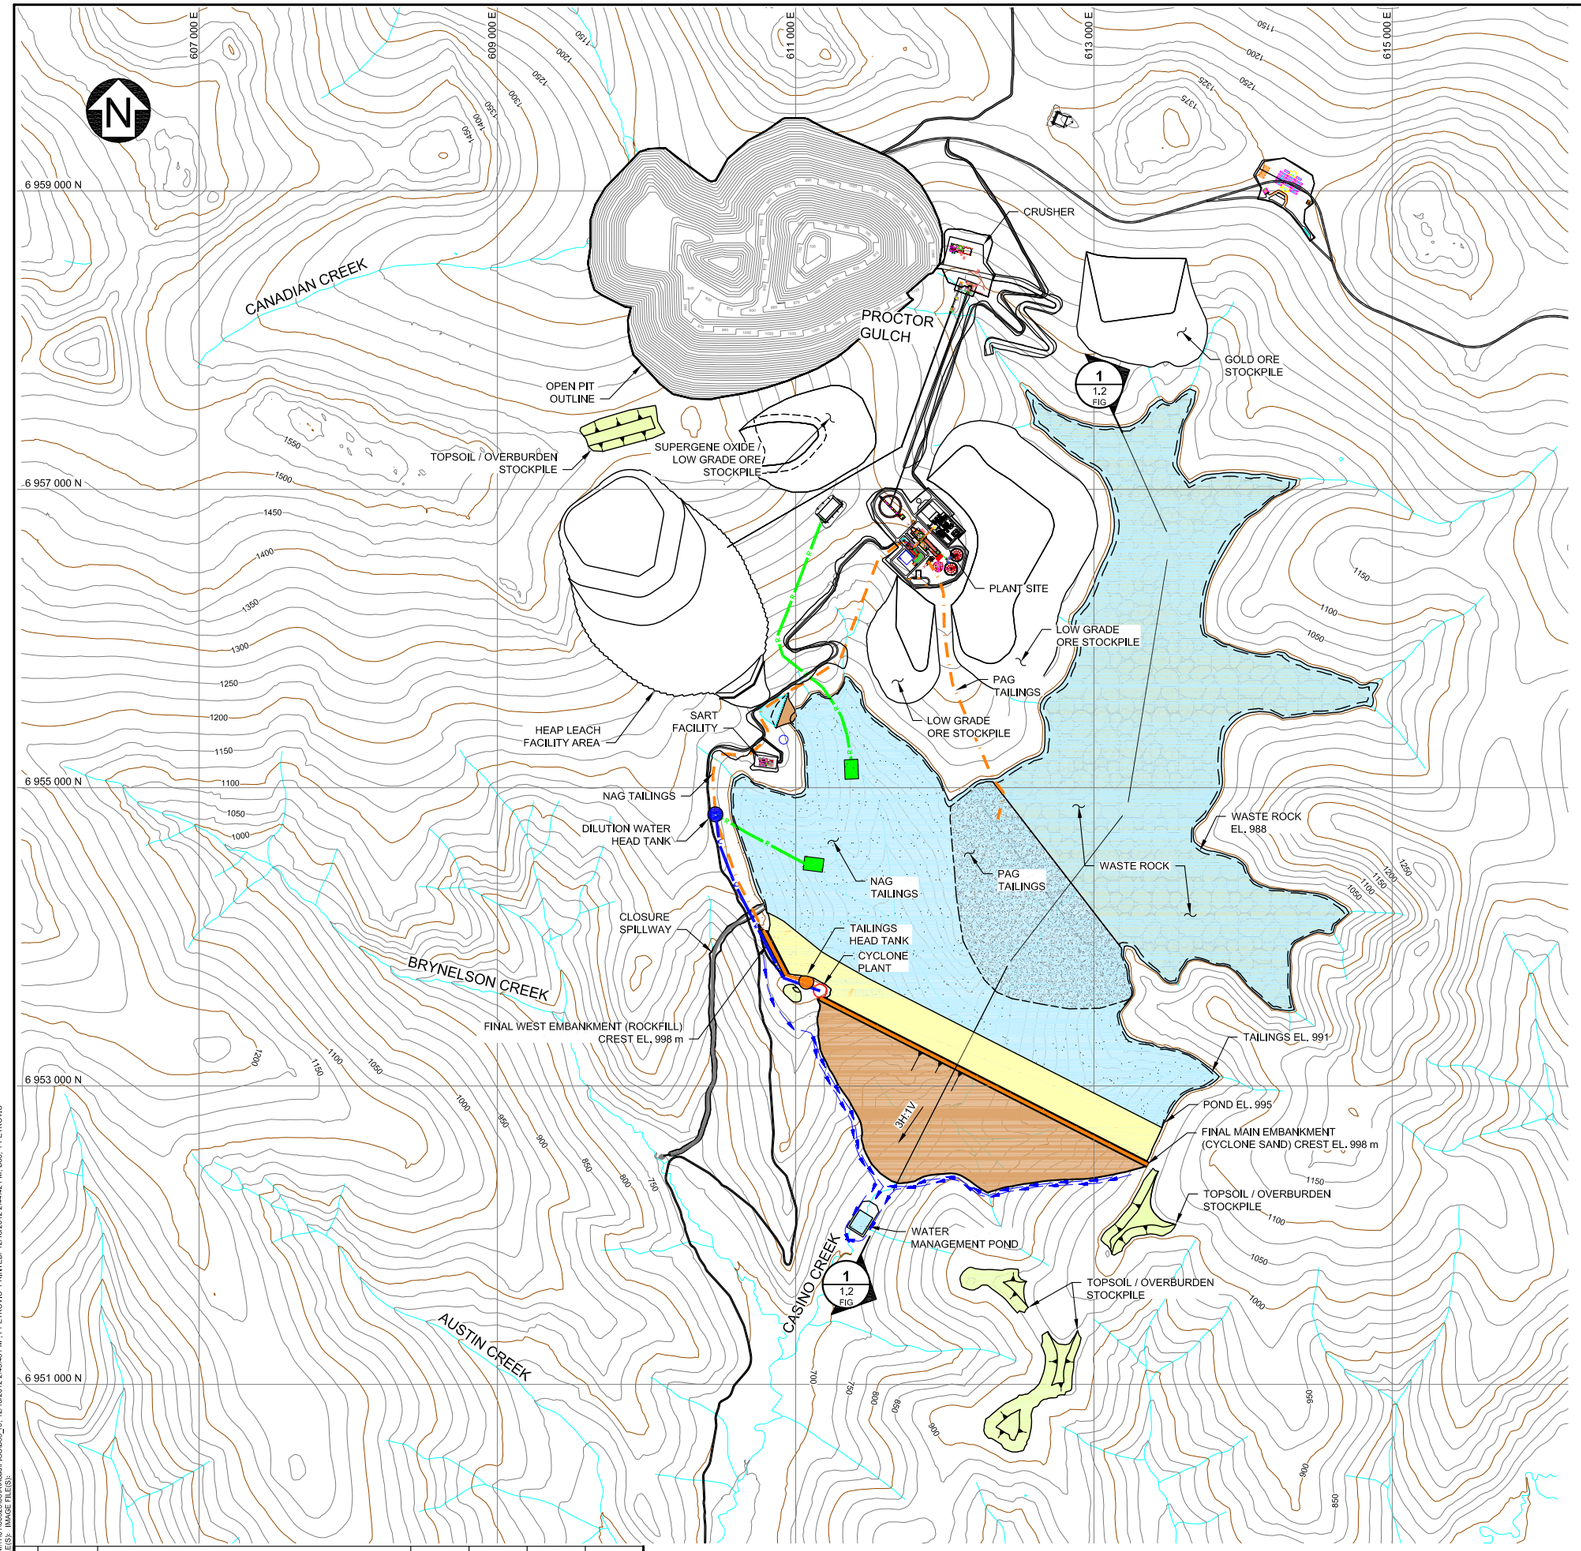
There will be two separate tailings streams reporting to the TMF from the mill. The principal rougher stream (approximately 80% of the total tailings) will be Non Acid Generating (NAG) tailings. A second stream (20%) will be Potentially Acid Generating (PAG) tailings material that will be handled and stored separately and maintained under water. For approximately nine months of each year (on average) the NAG tailings will be passed through a cyclone plant to produce clean sand (low fines) for embankment construction. The cyclone plant will also produce a low solids content cyclone overflow stream (finer fraction of the tailings) which will be discharged into the TMF.

Tailings confinement within the TMF is provided by a Main Embankment across the Casino Creek Valley and a smaller West Saddle Embankment located northwest of the Main Embankment. The embankments will be constructed as a water-retaining dam with a central core zone. The Main Embankment will be developed in stages throughout the life of the project using cycloned sand fill, suitable borrow materials, and non-reactive waste rock materials from initial stripping operations at the Open Pit. The West Saddle Embankment will be constructed at the south-western corner of the TMF and is required at the start of operations to provide a pipeline corridor at a suitable grade for tailings delivery to the cyclone sand plant and TMF. The West Saddle embankment will comprise an earth-rockfill dam, constructed from local borrow materials.

Seepage flows within and from the TMF will result from a combination of three primary processes:

- Consolidation seepage from the tailings deposit
- Steady-state seepage through the tailings deposit, through the confining embankments and also into original ground, and
- Percolation of process water directly into natural ground where the supernatant pond is in contact with natural soils or rock.

Seepage flows from the tailings deposit will occur throughout operations as tailings are discharged into the facility, and will continue after the end of operations until consolidation is complete. A



substantial component of the consolidation seepage will be expelled from the tailings into the overlying supernatant pond, particularly after the initial few years of operations as the depth of the tailings deposit increases.

It is anticipated that a significant portion of seepage losses from the TMF will be returned to the facility via a seepage collection and recycle system.

Detailed analyses have been carried out to predict seepage flows within and from the TMF. This has included tailings consolidation modelling and steady-state seepage analyses for conditions during operations and after closure. Figure 1.1 shows the final arrangement of the TMF at the end of operations. Figure 1.2 shows schematic sections through the final TMF, with the various components identified.

It is anticipated that the predicted seepage flows will be incorporated into a site wide water balance and water quality model to be developed for the project. The various flow components and corresponding seepage rates provided by the tailings consolidation modelling and seepage analyses can be used to predict water quality during operations and for several decades after the cessation of operations.

Details of the tailings consolidation modelling and steady-state seepage analyses for the TMF are presented in the following sections.

2 – TAILINGS CONSOLIDATION ANALYSIS

2.1 GENERAL

On-going consolidation of the tailings deposit is an important consideration in the prediction of seepage water flows within and from the TMF during operations and after closure. Consolidation occurs continuously within the tailings deposit during deposition, and will continue after completion of operations until all excess pore pressures have dissipated. Expulsion of pore fluids during consolidation of the tailings can add a substantial contribution to the total seepage from the tailings deposit. The process of consolidation also produces settlement of the tailings surface and a corresponding increase in the density of the tailings.

Knight Piésold Ltd. (KPL) has developed a one-dimensional finite difference computer model which predicts the magnitude and rate of tailings consolidation, the amount of consolidation seepage (water losses from the deposit) and the corresponding average density of the deposit. This model incorporates the expected consolidation characteristics of the tailings, the deposition rate (tailings and waste rock) and large strain consolidation theory.

Analyses were performed to predict average tailings densities and consolidation seepage rates during operation of the TMF and for several decades after closure of the facility.

2.2 PARAMETERS AND ASSUMPTIONS

The following parameters and assumptions were incorporated into the tailings consolidation model:

- 80% of the total tailings production was assumed to be NAG tailings and 20% PAG tailings.
- Actual NAG tailings tonnages assumed to report to the TMF for each year of operations were calculated to allow for NAG tailings material removed as cyclone sand for embankment construction (approximately 50% of the total NAG tailings production).
- For the tailings materials reporting to the TMF for disposal, 54% is assumed to be cyclone overflow (fine tailings), 26% whole NAG tailings and 20% PAG tailings. Whole NAG tailings are discharged into the TMF during periods when cycloning operations are suspended (typically during the colder winter months). The cyclone sand plant is assumed to be in operation for 9 months of the year (with a 90% sand plant availability during this period).
- Void ratio versus effective stress and coefficient of consolidation versus effective stress relationships for the cyclone overflow and whole NAG tailings were based on laboratory testwork carried out in 2012 on samples of Casino tailings. Details of the tailings laboratory testing are presented in KPL report “Laboratory Geotechnical Testing of Tailings Materials” (Ref. No. VA101-325/8-1, December, 2012).
- An initial settled dry density of 0.9 tonne/m^3 was used for the cyclone overflow material, based on the results of laboratory settling tests for a slurry sample with an initial solids content of approximately 24%. The low solids content is based on the expected cycloning requirements to achieve a clean sand product (less than 15% fines) for embankment fill material.
- An initial settled dry density of 1.1 tonne/m^3 was used for the NAG whole tailings, based on the results of laboratory settling tests for a tailings slurry sample with a design initial solids content of approximately 55%.
- Laboratory testing to define the consolidation and compressibility characteristics of the PAG tailings has not been completed to date. The PAG tailings material is finer-grained than the NAG

whole tailings (implying a lower density) but the specific gravity is higher (higher density of solids). Therefore, the PAG tailings are assumed to achieve in situ densities similar to the NAG whole tailings.

- Evaporative losses from the exposed tailings surface are not accounted for in the consolidation model. Surface desiccation of tailings beach areas will further assist in consolidation and densification of the deposit. Therefore, the predicted volume of tailings consolidation seepage is likely conservatively high.

Both undrained and drained base flow conditions were considered in the modelling and a weighted average used to best represent the impeded flow (permeability) characteristics of the TMF basin and confining embankments. The influence of lateral seepage flows towards the more free draining (sandier) tailings beach areas was also considered.

2.3 SUMMARY OF RESULTS

Average dry density and consolidation seepage amounts for the tailings deposit with time during operations were estimated from consideration of the relative proportion of NAG whole tailings, PAG tailings and cyclone overflow material reporting to the TMF.

An average tailings dry density of approximately 1.2 tonne/m^3 was predicted for the initial three years of operations, increasing to about 1.3 tonne/m^3 by Year 4 and 1.4 tonne/m^3 by Year 5. Thereafter, the average dry density is predicted to increase gradually to approximately 1.5 tonne/m^3 by the end of operations when tailings deposition ceases. The density of the deposit will increase once tailings deposition ceases at closure and self-weight consolidation continues, assisted by surface desiccation due to evaporation from exposed tailings beach areas. Following the end of operations the average dry density of the tailings deposit is predicted to increase to approximately 1.55 to 1.6 tonne/m^3 once fully consolidated conditions are achieved.

The tailings consolidation analysis was used to estimate the quantity of pore water liberated from the tailings deposit during operations and following cessation of operations (post-closure). Consolidation seepage rates have been estimated by multiplying the predicted unit seepage rate by the estimated plan area of the tailings deposit. The area of tailings increases with time during operations at the TMF, but will remain essentially constant after operations cease. The actual area has been adjusted (reduced) appropriately to account for the presence of the potentially reactive Waste Storage Area within the TMF. During operations (active tailings deposition) the consolidation seepage rates are predicted to be about 180 l/sec in Year 1, increasing thereafter to about 300 l/sec by Year 5 and approximately 400 l/sec by the end of operations. Following the end of operations the predicted consolidation seepage rate decreases substantially to less than 100 l/sec within one year and to less than 50 l/sec after 5 years. Consolidation seepage decreases further to less than 10 l/sec after about 30 years.

The large majority of consolidation seepage from the tailings deposit (typically about 80% to 90%) flows upwards and towards the supernatant pond. The upward seepage flow is due to excess pore water pressure conditions within the tailings deposit, particularly fresher tailings nearer to the surface. Most of the remaining consolidation seepage will likely flow toward the more free-draining tailings beach areas, confining embankments and Waste Storage Area. The percentage of downward consolidation seepage is minor. The low quantity of downward consolidation seepage is due to the increasing drainage path length during operations (between freshly deposited tailings and

the base of the TMF) and the low permeability of deeper, more consolidated, tailings at the base of the facility.

The tailings are predicted to remain partially consolidated during operations and for a period of time after closure until all excess pore water pressures have dissipated. The average degree of consolidation at the end of operations is estimated to be approximately 60% or higher for much of the tailings deposit. The degree of consolidation is predicted to be less than 50% in some areas where the tailings thickness is greatest (over 150 metres thick). However, those tailings closest to the embankments and discharge points are expected to consolidate faster due to the more free draining nature of sandier tailings forming the beach areas (due to segregation). The average degree of consolidation in these tailings is expected to be approximately 90% (close to fully consolidated).

The actual time taken for complete consolidation will be dependent on the in situ consolidation characteristics of the tailings material. Reduced consolidation seepage may continue for several decades until complete tailings consolidation is achieved.

3 – TMF SEEPAGE ANALYSIS

3.1 GENERAL

Steady-state seepage analyses for the TMF were carried out to estimate the amount of seepage through the embankments and foundation materials. The analyses were completed using the finite element computer program SEEP/W. Seepage rates through the Main Embankment, West Saddle Embankment and tailings basin were examined.

The seepage rate through foundation materials and embankment fill zones is influenced by the following factors:

- Permeability of the embankment zones
- Permeability of the foundation materials
- The thickness and permeability of the tailings stored within the TMF
- Distribution of potentially reactive waste rock within the TMF
- Seepage gradients in the embankment and foundation zones, and
- The seepage area available (increases with time during operations).

The seepage flow rate will vary over the life of the TMF as it gradually fills with tailings, mine waste rock and supernatant water. During operation of the TMF the tailings deposit will increase in thickness and generally decrease in permeability due to on-going consolidation. The seepage analyses have been performed to predict seepage flows from the TMF at various stages throughout operations (Stage 1, Year 10 and Final).

Foundation conditions incorporated into the seepage analyses are based on information provided by previous geotechnical site investigation programs carried out in 1993, 1994, 2010, 2011 and 2012. Details of the site investigations and the foundation conditions defined for the TMF basin are presented in the following KPL reports:

- "Report on Preliminary Surficial Geotechnical Investigations" (Ref. No. 1831/1, March, 1994)
- "Data Compilation Report on 1994 Geotechnical/Hydrogeological Investigations" (Ref. No. 1832/2, February 22, 1995)
- "2010 Geotechnical Site Investigation Data Report" (Ref. No. VA101-325/3-4, November 2, 2010)
- "2011 Geotechnical Site Investigation Data Report – Waste Management Facilities" (Ref. No., VA101-325/8-5, December, 2012), and
- "2012 Geotechnical Site Investigation Data Report" (Ref. No., VA101-325/8-14, December, 2012).

The seepage analyses have been based on representative simplified cross-sections through the TMF, as shown on Figures 3.1 to 3.5 for the Main Embankment and on Figure 3.6 for the West Saddle Embankment. Two cross-sections were defined for the Main Embankment, Section A at the middle of the dam (deepest section) and a generic Section B representing conditions at each of the two abutments.

Based on the present mine production schedule and development strategy, approximately three years of tailings deposition will occur after final placement of potentially reactive waste rock in the Waste Storage Area. This will result in a thin layer of tailings over the top of the waste rock (approximately 3 metres thick). This tailings layer will have a negligible influence on seepage flows

from the TMF and was conservatively omitted from the seepage analysis. However, there is potential for the layer to reduce upward diffusion into the supernatant pond. The potential benefit, if any, of the tailings layer will be considered as part of on-going water quality studies for the TMF.

3.2 SUMMARY OF MATERIAL PERMEABILITIES

Saturated and unsaturated permeabilities were determined for each of the embankment fill zones, tailings deposit and foundation materials. In assigning unsaturated permeability values, typical functions for similar material types were used.

All foundation saturated permeability values are based on the results of in situ testing performed during the 1994, 2010, 2011 and 2012 geotechnical site investigation programs. The saturated permeability values used for the embankments, tailings deposit and foundation materials are summarized in Table 3.1 and described below:

- The NAG tailings were assigned permeability values based on the results of laboratory testing, presented in the KPL report "Laboratory Geotechnical Testing of Tailings Materials" (Ref. No. VA101-325/8-1, December, 2012) and consolidation modelling described in Section 2.0 of this report. Tailings located at the base of the TMF were assigned a lower permeability to account for a higher degree of consolidation in these tailings. A vertical permeability of 1×10^{-5} cm/s was assigned to unconsolidated tailings located within the upper portion of the tailings deposit. The estimated vertical permeability of deeper consolidating tailings ranges from 2×10^{-6} cm/s (bottom of the deposit) to 5×10^{-6} cm/s (partially consolidated or shallower tailings) depending on the thickness of the tailings deposit and the time during operations. To account for sub horizontal laminations (layers) formed from material segregation during deposition, the horizontal permeability of the tailings deposit was assumed to be one order of magnitude greater than the vertical permeability.
- The PAG tailings were assumed to have the same permeabilities as the NAG tailings. The PAG tailings are finer-grained than the NAG whole tailings and cyclone overflow and therefore are likely to have permeabilities similar or lower than these materials.
- Potentially reactive mine waste (waste rock and overburden) materials within the Waste Storage Area were assigned an average permeability of 1×10^{-2} cm/s.
- Core Zone material was assigned a vertical permeability of 1×10^{-5} cm/s. The material is assumed to be isotropic. Laboratory permeability test results on compacted residual soil samples from 1993, 2010, 2011 and 2012 test pit samples indicate that permeabilities range from approximately 1×10^{-5} cm/s to 1×10^{-9} cm/s, depending on material gradation, moisture content, compactive effort and confining pressure. The more recent testing carried out in 2010, 2011 and 2012 indicate that permeability values in the range of approximately 1×10^{-6} cm/s to 1×10^{-5} cm/s are typically achievable for the finer grained soils present at the project site. However, additional investigations will be required to confirm the extent and availability of sufficient suitable borrow materials for embankment core zone construction throughout the life of the facility. The laboratory testing also suggests that the permeability will reduce at higher confining stresses, with a permeability decrease from 1×10^{-5} cm/s to 1×10^{-6} cm/s reported for an increase in confining stress from 200 kPa to 600 kPa. Confining stresses will exceed 600 kPa in the majority of the embankment core zone for the TMF Main Embankment (from about 30 metres below the dam crest). Therefore, it is expected that a permeability of about 1×10^{-6} cm/s, and perhaps less, will be achieved in the majority of the core material.
- A 5 m thick low permeability blanket of core zone material is placed under the upstream part of the starter dam to increase the seepage path length. The material was assigned a permeability of 1×10^{-6} cm/s.

- Embankment rockfill shell zones (Stage 1 Main Embankment and West Saddle Embankment) and filter/transition zones were assigned a vertical permeability of 1 x 10^{-2} cm/s. The results of the model reveal that these zones are essentially fully drained and do not affect the results of the analysis.
- Cycloned sand embankment fill in the upstream and downstream shell zones was assigned an average permeability of 1 x 10^{-3} cm/s, based on the results of permeability tests on a manufactured sample of cyclone sand material. The laboratory testing indicated that the permeability of the cyclone sand did not reduce significantly at high stresses. Details of the laboratory testing are provided in the KPL report "Geotechnical Laboratory Testing of Tailings Materials" (Ref. No. VA101-325/8-1, December, 2012).
- The foundation overburden (sands and gravels) was assigned a vertical permeability of 1.0 x 10^{-5} cm/s, based on in situ testing carried out during previous site investigations (packer permeability tests in 1994 and falling head permeability tests in 2010 and 2011). The material is assumed to be isotropic.
- It is assumed that granodiorite forms the basement of the TMF. Two layers within the granodiorite were modelled to represent the decreasing level of weathering and fracturing within the rock with depth. The top layer of granodiorite identified as highly fractured rock was assigned a vertical permeability of 5 x 10^{-5} cm/s. The bedrock underlying the highly fractured layer was identified as slightly to moderately fractured and assigned a vertical permeability of 1 x 10^{-5} cm/s. The rock is assumed to be isotropic. The adopted permeabilities are representative values provided by packer permeability tests carried out in 1994 and packer permeability and falling head tests in 2010 and 2011. Some of the in situ testing results indicate a lower permeability of about 1 x 10^{-6} cm/s or less. However, it is difficult to delineate the extent of lower permeability rock zones from the available data. The inclusion of a lower permeability bedrock layer at depth does not have a significant influence on predicted seepage values. Therefore, it has not been included in the seepage model.

Discontinuous permafrost is present along Casino valley, where the TMF is situated. Permafrost is primarily present at the valley bottom, north facing slopes and shaded areas. Saturated frozen soil and rock have a much lower permeability when frozen compared to a thawed or unfrozen state. Frozen overburden and bedrock that are underlying part of the tailings impoundment and embankment are expected to thaw over time, as the tailings and water stored in the TMF will act as a heat source. Permeabilities representing unfrozen overburden and bedrock were therefore used in the seepage model.

In situ hydraulic conductivity tests (falling head and packer permeability tests) were performed in the TMF area during previous site investigations. Test results showing very low hydraulic conductivities were excluded from the analysis as these potentially indicate frozen soil or rock. Thermistors were installed during the 2012 site investigations to provide a better understanding of the thermal regime in the bedrock.

Table 3.1 Tailings Management Facility – Summary of Material Permeabilities

Area	Material Type	Saturated Permeability, kv (cm/s)	Saturated Permeability, kh (cm/s)	kv/kh
Embankment	Compacted Low Permeability Core Zone	1.0E-05	1.0E-05	1.0
	Compacted Low Permeability Upstream Blanket	1.0E-06	1.0E-06	1.0
	Local Borrow Rockfill	1.0E-02	1.0E-02	1.0
	Filter/Transition Zone	1.0E-02	1.0E-02	1.0
	Cyclone Sand	1.0E-03	1.0E-03	1.0
Embankment Foundation	Overburden	1.0E-05	1.0E-05	1.0
	Highly Fractured Bedrock	5.0E-05	5.0E-05	1.0
	Slightly to Moderately Fractured Bedrock	1.0E-05	1.0E-05	1.0
Tailings Impoundment	Waste Rock (2)	1.0E-02	1.0E-02	1.0
	Unconsolidated Tailings (3)	1.0E-05	1.0E-04	0.1
	Consolidating Tailings (3)	5.0E-06	5.0E-05	0.1
	Consolidated Tailings (3)	2.0E-06	2.0E-05	0.1

NOTES:

1. kv = vertical permeability, kh = horizontal permeability.
2. Supergene and Hypogene waste rock are assumed to have the same permeabilities.
3. PAG and NAG tailings are assumed to have the same consolidation and permeability properties.

3.3 BOUNDARY CONDITIONS AND FLUX SECTIONS

Boundary conditions used in the seepage analyses were selected to represent the hydrogeological conditions expected during operations at the TMF. The boundary conditions used in the analyses are summarized as follows:

- Review boundary conditions were assigned downstream of the embankment core zone. This enables the location of the phreatic surface through the embankment and foundation materials to be determined during the seepage analyses.
- The right-hand boundary (downstream of the embankment) was assigned a hydrostatic head consistent with existing groundwater conditions.
- A total head (hydrostatic) boundary was used to represent the tailings pond elevation. For the Final embankment configuration a tailings pond elevation of 995 m was used. A tailings beach width of 250 m was assumed, separating the pond from the embankment.

The results of tailings consolidation modelling (described in Section 2.0) indicate that excess pore water pressures will likely exist within much of the tailings deposit during operations and for a period of time after closure of the TMF (particularly in zones of finer and deeper tailings) until fully consolidated conditions are achieved. However, the tailings beach areas adjacent to the embankments are expected to be more consolidated during operations (and likely close to fully consolidated conditions). Consequently, it is considered reasonable to assume hydrostatic pore water pressure conditions within the tailings for the embankment seepage modelling. Excess pore pressures within unconsolidated and consolidating tailings will produce consolidation seepage flows, with the majority flowing upwards to the supernatant pond, as discussed in Section 2.3.

Flux sections were included in the seepage models at appropriate locations to estimate seepage flows through the embankments and foundation units.

3.4 SUMMARY OF RESULTS

The results of the steady-state seepage analyses provided by the SEEP/W models are shown on Figures 3.1 to 3.3 for Section A through the Stage 1, Year 10 and Final Main Embankment, Figures 3.4 and 3.5 for Section B through the Year 10 and Final Main Embankment, and Figure 3.6 for the Final West Saddle Embankment. These figures include the computed location of the phreatic surface within the tailings deposit and confining embankment.

Computed seepage flux values for the Main Embankment and West Saddle Embankment sections were used with representative crest lengths to provide an estimate of the total seepage rate from the TMF. Flow rates were estimated for seepage components passing through the embankments and passing directly into the TMF foundation. An estimate was also provided for the average unit flow rates through the various materials stored in the impoundment (NAG tailings, PAG tailings and potentially reactive waste rock and overburden materials). The results of the steady-state seepage analyses are summarized in Table 3.2 and Figure 3.7.

The predicted total seepage rate from the TMF is approximately 6 l/s for the pre-production (Stage 1A) embankment with a start-up water pond only (prior to tailings deposition). The seepage rate is approximately 5 l/sec for Stage 1B (end of Year 1), increasing to about 20 l/sec by Year 10 and approximately 40 l/sec for the final embankment arrangement (El. 998 m). Reducing the permeability of the embankment core zone from 1×10^{-5} cm/s to 1×10^{-6} cm/s reduces the predicted seepage rates by only approximately 10%.

Approximately two-thirds of the total seepage is estimated to flow directly into original ground and about one-third through the low permeability core zones of the Main Embankment and West Saddle Embankment. For the final TMF arrangement approximately 97 % of the total seepage through the embankments is estimated to flow through the Main Embankment and 3 % through the West Saddle Embankment.

The quantity of seepage predicted to flow from the base of the waste storage area (Hypogene and Supergene Waste Rock) is estimated to be less than 10% of the total seepage passing directly into original ground (TMF foundation). The remaining seepage into the TMF foundation passes through the tailings deposit. Approximately 10 % of the foundation seepage is estimated to flow through the base of the PAG tailings. A significant portion of the seepage passing into the TMF foundation will likely flow towards the Main Embankment.

An embankment drainage system has been provided to collect excess water resulting from cyclone sand deposition and seepage through the embankment and foundation. The provision of embankment underdrainage will enable a significant portion of the total seepage to be intercepted and routed to seepage collection ponds for recovery and return to the TMF.

A schematic diagram of predicted seepage flow paths for the Final TMF (end of operations), are shown on Figure 3.7. The predicted seepage flows have been incorporated into a site wide water balance and can be used for water quality modelling.

Long-term (post-closure) seepage rates from the TMF are expected to be similar to the predicted values for the final embankment arrangement at the end of operations, but will be dependent on the reclamation and closure plan developed for the facility.

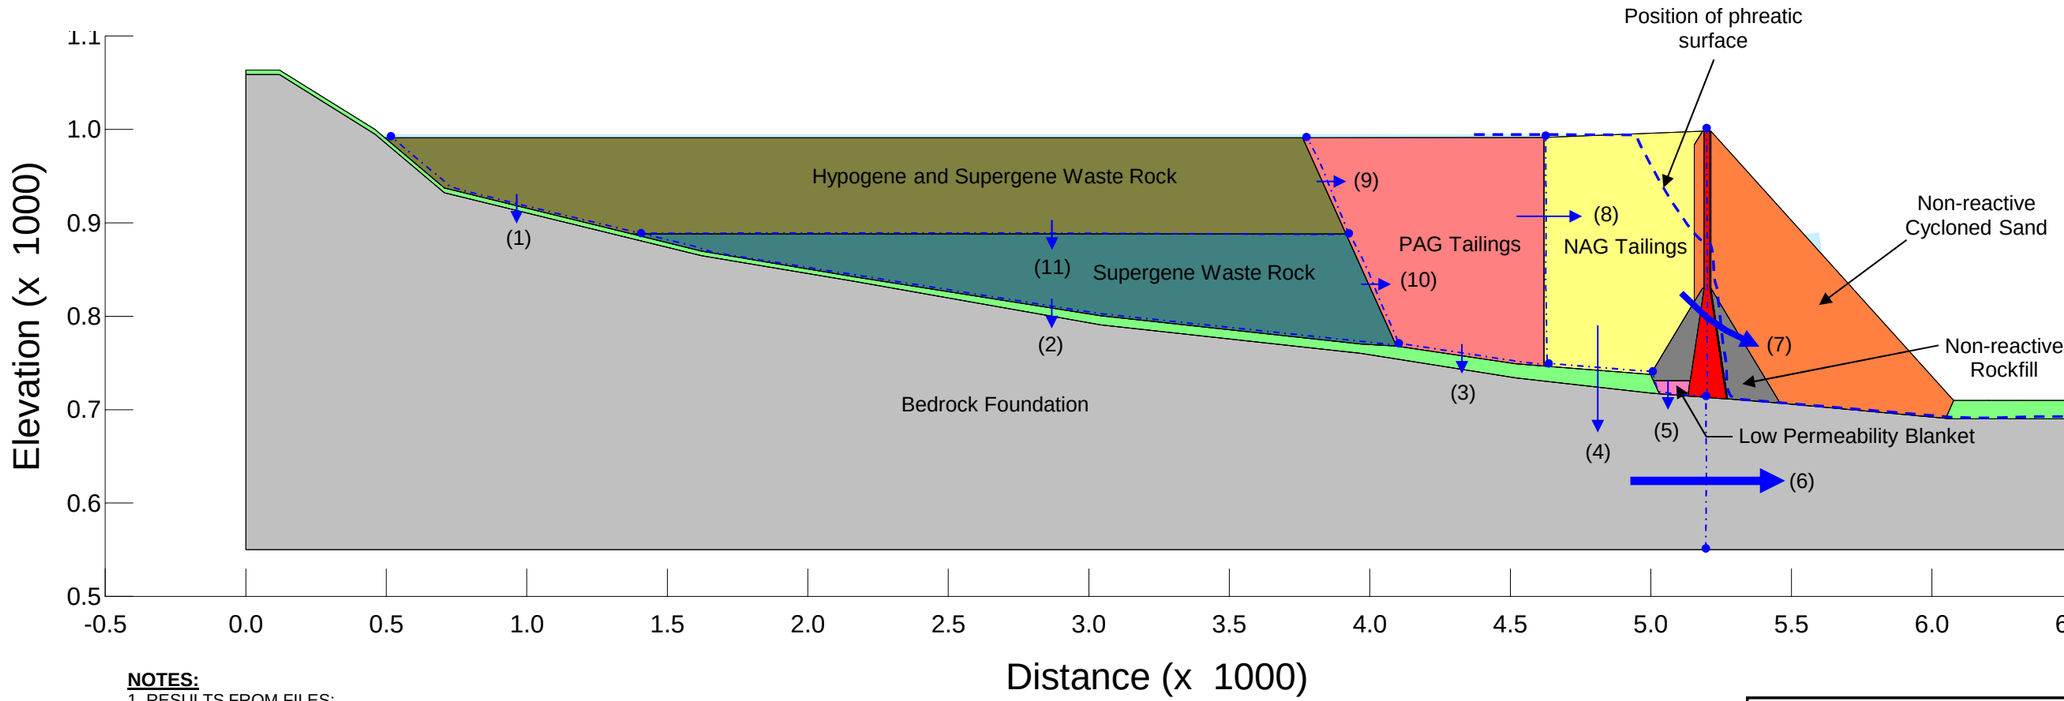

Table 3.2 Tailings Management Facility – Summary of Predicted Seepage Rates

Embankment	Year of Operations	Embankment Crest Elevation	Supernatant Pond Elevation	Estimated Seepage		
				Embankment	Foundation	Total
		(m)	(m)	(l/s)	(l/s)	(l/s)
Main	PP(1)	830	791	1	5	6
	1	830	819	1	4	5
	10	928	923	5	16	21
	22	998	995	13	26	39
West	22	998	995	<<1	1	1

NOTES:

1. Pre-production is prior to tailings deposition (start-up water pond only).

Seepage Component	Estimated Average Unit Flux ($m^3/s/m^2$)	Estimated Seepage (l/s)
(1) Seepage from Supergene and Hypogene Waste Rock to Foundation	3E-14	<1
(2) Seepage from Supergene Waste Rock to Foundation	7E-07	1
(3) Seepage from PAG Tailings to Foundation	3E-06	3
(4) Seepage from NAG Tailings to Foundation	4E-06	18
(5) Seepage from Upstream Starter Shell to Foundation	4E-05	4
(6) Total Seepage through Foundation under the Embankment	6E-05	27
(7) Seepage through Embankment Core	5E-05	13
(8) Seepage from PAG Tailings to NAG Tailings	4E-05	11
(9) Seepage from Hypogene and Supergene Waste Rock to PAG Tailings	6E-06	<1
(10) Seepage from Supergene Waste Rock to PAG Tailings	2E-05	1
(11) Seepage from Hypogene and Supergene Waste Rock to Supergene Waste Rock	2E-06	2

4 – SUMMARY

Detailed analyses have been carried out to predict seepage flows within and from the TMF. This has included tailings consolidation and seepage modelling and steady-state seepage analyses for conditions during operations and after closure of the TMF.

Tailings consolidation analyses were performed to predict average tailings dry densities and consolidation seepage rates during operation of the TMF and for several decades after closure. The tailings are predicted to remain partially consolidated during operations and for a period of time after closure. However, those tailings closest to the embankments are expected to consolidate faster due to the more free draining nature of sandier material forming tailings beach areas. Consolidation seepage rates are predicted to range from approximately 180 to 400 l/sec during operations (average of approximately 350 l/sec), reducing substantially after the end of operations to less than 100 l/sec within one year, less than 50 l/sec after 5 years and less than 10 l/sec within 30 years. The large majority of the tailings consolidation seepage will report to the supernatant pond. The actual time taken for complete consolidation will be dependent on the in situ consolidation characteristics of the tailings material. Reduced consolidation seepage may continue for several decades until complete tailings consolidation is achieved.

Steady-state seepage analyses indicate that the total seepage rate from the TMF is approximately 6 l/s during Preproduction (Stage 1A, with only a start-up water pond), 5 l/sec for Stage 1B (End of Year 1), increasing to about 20 l/sec by Year 10 and approximately 40 l/sec for the final embankment arrangement (Year 22, with a crest elevation of 998 m). The majority of the seepage is expected to flow directly into original ground, with only approximately one-third of the total seepage flowing through the low permeability core zones of the confining embankments. The quantity of seepage predicted to flow from the base of the potentially reactive waste storage area is estimated to be less than 10% of the total seepage passing directly into original ground (TMF foundation). The remaining seepage into the TMF foundation passes through the tailings deposit. Approximately 10% of the foundation seepage is estimated to flow through the base of the PAG tailings. A significant portion of the seepage will likely flow toward the Main Embankment.

For the final TMF arrangement approximately 97 % of embankment seepage is estimated to flow through the Main Embankment. The remaining 3 % of embankment seepage is through the smaller West Saddle Embankment.

Design provisions to minimize seepage losses include a low permeability core zone within the confining embankments, a low permeability upstream blanket for the Main Embankment, and development of tailings beaches (which isolate the supernatant pond from the embankments) to the extent possible while still maintaining subaqueous disposal of potentially reactive waste rock and PAG tailings during operations and post-closure.

An embankment drainage system has been provided to collect excess water resulting from cyclone sand deposition and seepage through the embankment and foundation. The provision of embankment underdrainage will enable a significant portion of the total seepage to be intercepted and routed to seepage collection ponds for recovery and return to the TMF.

The results of this seepage assessment have been incorporated into a site wide water balance model, developed to define and track the distribution of water inputs and outputs for the TMF. The various flow components and corresponding seepage rates provided by the tailings consolidation

modelling and seepage analyses can be used to predict water quality during operations and for long-term conditions after the cessation of operations.

1.0 Introduction

Western Copper Corporation is currently conducting a pre-feasibility assessment of the Casino Project, located 300 kilometres northwest of Whitehorse, Yukon. The deposit is described as porphyry mineralization with geological zones of oxide, supergene, and hypogene mineralization.

This study was designed and executed at the request of Dr. Paul West-Sells, Senior Metallurgist at Western Copper Corporation. On behalf of Western Copper Corporation, Mr. Adam Hesse and Mr. Stacy Freudigmann, of Canenco Canada Inc., also provided technical input on the design of the program. The objectives of this program, as described by Dr. West-Sells, were as follows:

- Develop a suitable process for extracting copper, molybdenum, and gold from a composite, designated SUP Composite 2010, representing the supergene mineralization zone of the deposit.

- Develop a flowsheet to optimize a sequential pyrite circuit.

- Produce sufficient pyrite concentrate and tailings in a pilot plant program, for subsequent environmental test work.

- Produce sands from the pilot plant tailings for further geochemical and geotechnical test work.

The composite used in this program represented the supergene zone and was constructed from 62 drill core samples. The program commenced in early August 2010 and was completed in January 2011. All test data was communicated to Mr. Adam Hesse and Mr. Stacy Freudigmann, as it was generated. Following the test work, preparation of this technical report commenced.

The following technical brief summarizes the key technical points of the program. All of the test data generated through the execution of this program can be reviewed in a series of appendices attached to this brief. The appendices are arranged as follows:

Appendix I - Sample Origin
Appendix II - Flotation Test Data
Appendix III - Particle Sizing Data
Appendix IV - Special Assay Data
Appendix V - Mineralogical Data

2.0 Ore Characteristics

The composition of chemicals and minerals in an ore and how they fragment from each other during the grinding process are important characteristics that effect flowsheet design and metallurgical performance. The following subsections discuss these characteristics for the Casino SUP Composite 2010.

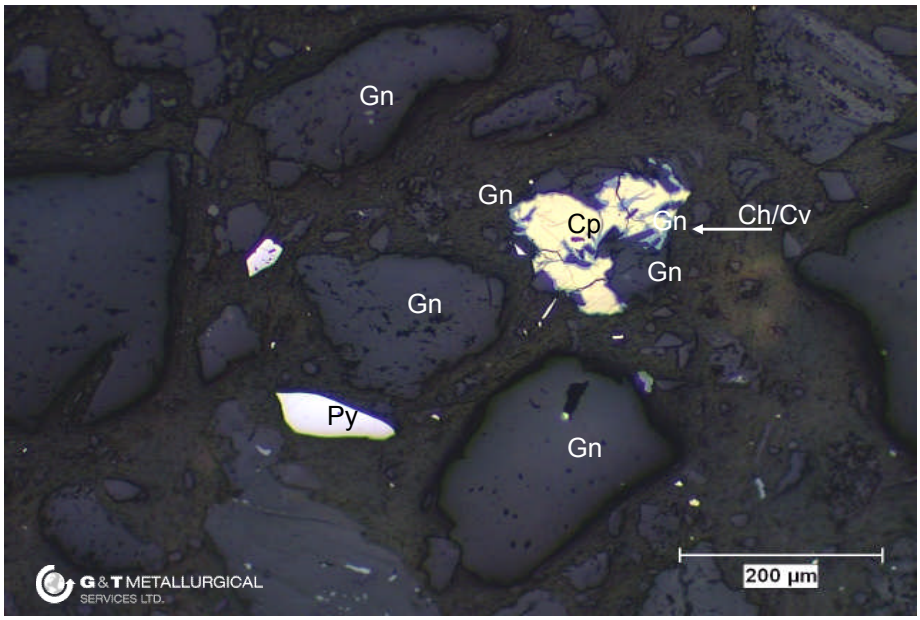
2.1 Chemical and Mineral Content

The chemical and mineral composition of SUP Composite 2010 were determined by standard assaying techniques and Particle Mineral Analysis (PMA) using QEMSCAN. The results are summarized in Table 1.

Approximately 0.3 percent copper was detected in this sample. Weak acid soluble copper accounted for 10 percent of the total copper. Copper measured by this acid dissolution method, typically carbonates and some oxides and hydroxides, are often difficult to recover using conventional flotation methodologies.

Approximately 37 percent of the total copper responded to cyanide digestion. This digestion protocol is an effective indicator of the presence of copper sulphides, chalcocite and covellite.

Gold and silver in the feed were present at 0.25 and 2.5 g/tonne, respectively. Molybdenum was also present in this sample at 0.04 percent.



Chalcopyrite accounted for the majority of the copper in the feed, followed by chalcocite and covellite. Small amounts of bornite were also detected in the sample. Pyrite accounted for the main sulphide mineral at 4.2 percent of the feed mass.

TABLE 1
CHEMICAL AND MINERAL CONTENT

Element or Mineral	Symbol	Units	SUP Composite 2010
Element			
Copper	Cu	%	0.30
Weak Acid Soluble Copper	Cu(ox)	%	0.03
Cyanide Soluble Copper	$Cu^{(CN)}$	%	0.11
Iron	Fe	%	3.5
Molybdenum	Mo	%	0.036
Sulphur	S	%	2.88
Gold	Au	g/t	0.25
Silver	Ag	g/t	2
Mineral			
Chalcopyrite	Cp	%	0.43
Bornite	Bn	%	0.01
Chalcocite/Covellite	Ch	%	0.15
Molybdenite	Md	%	0.05
Pyrite	Py	%	4.24
Gangue	Gn	%	95.1

Note: a) Detailed head assay and mineralogical data are located in Appendices IV and V.

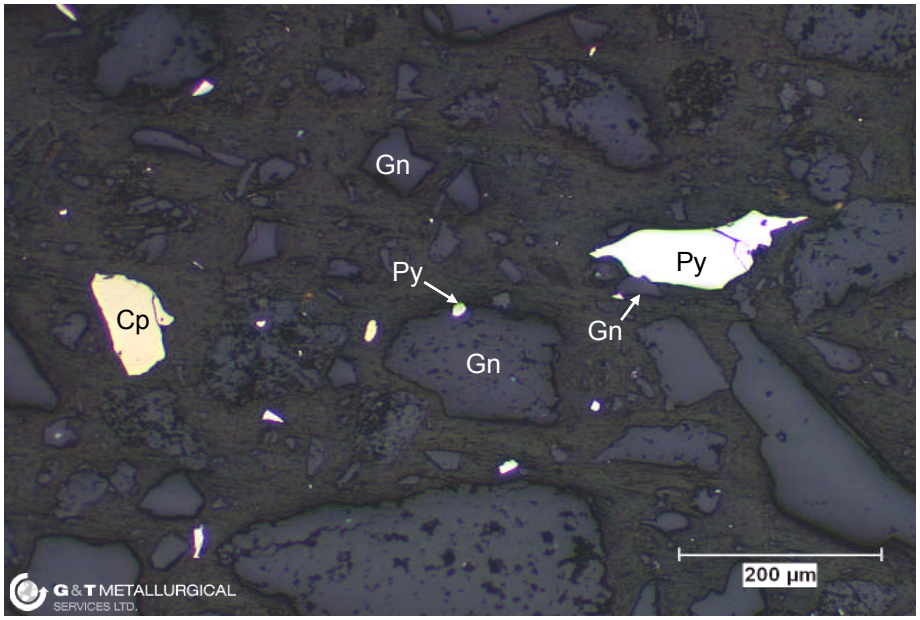
2.2 Mineral Fragmentation

The mineral fragmentation characteristics of SUP Composite 2010 were determined at a nominal grind sizing of 142µm K_{80}. This analysis was conducted on four sized fractions using PMA. An overall summary of the mineral fragmentation characteristics are displayed in Table 2.

TABLE 2
MINERAL FRAGMENTATION CHARACTERISTICS – 142µm K_{80}

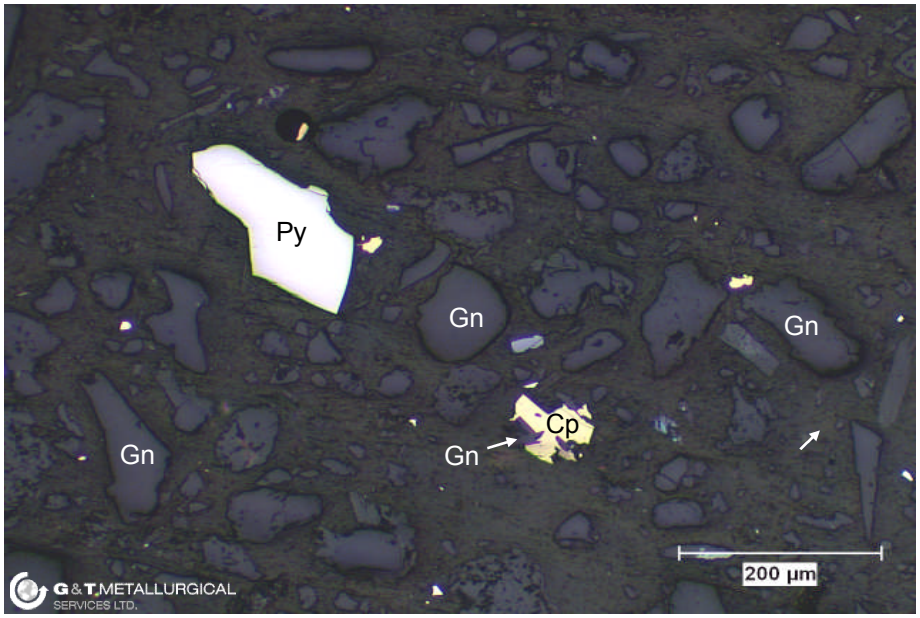
Mineral Status	Mineral Liberation-two-dimensional			
	Cs	Md	Py	Gn
Liberated	**53**	**41**	65	98
Binary - Cs		3	9	1
Binary - Md	<1		<1	<1
Binary - Py	14	5		1
Binary - Gn	**28**	**52**	24	
Multiphase	5	0	1	<1
Total	100	100	100	100

Note: Additional mineralogical data can be located in Appendix V.



Copper sulphide minerals in the sample were 53 percent liberated. The majority of the unliberated copper sulphides, at 28 percent, were locked in binary structures with non-sulphide gangue minerals. These particles were sufficiently rich in copper sulphide, to be recovered successfully into the rougher circuit concentrate.

An additional 14 percent of the copper sulphides were locked in binary form with pyrite. These particles contained a low concentration of copper sulphides and may be an obstacle in producing a high grade concentrate.



Molybdenite was 41 percent liberated when assessed in two dimensions. The majority of the unliberated molybdenite was locked in binary structures with gangue. These particles contained 40 percent molybdenite and, therefore are likely to be recovered in rougher flotation.

2.2 Mineral Fragmentation-continued

The mineral fragmentation data can be manipulated to estimate the effect of primary grind sizing on mineral liberation. These analyses are displayed in Figure 1A. Liberation values at four various grind sizes were extrapolated using the measured data at 142μm K_{80}.

As shown in Figure 1A, the changes in mineral liberation were relatively small over the primary grind size range shown. This data would indicate that rougher flotation will be relatively insensitive to changes in primary grind size.

The limiting grade recovery curve for this sample, ground to 142μm K_{80}, is displayed in Figure 1B. This graph displays the maximum achievable grade and recovery points, based on recovery from the feed into the rougher concentrate. Operating plants, constrained by equipment inefficiencies, usually operate just below the indicated curves.

The charts indicate that high grade concentrates can be produced. However, additional regrinding will be required to efficiently produce both high grade concentrates and at high copper recoveries.

Achieving high copper mineral recovery, while maintaining selectivity against pyrite, will be critical to developing a successful process for this sample.

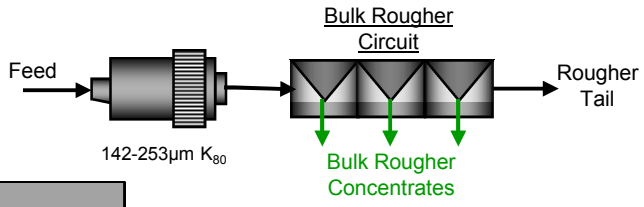
3.0 Flotation Testing

A series of rougher and cleaner flotation tests were conducted on SUP Composite 2010 to investigate the metallurgical response of the sample to conventional flotation processing. The test program culminated with a series of locked cycle tests.

3.1 Flowsheet Development

The flowsheets and range of test conditions that were utilized in this test program are illustrated in Figure 2.



Primary grind sizes ranging between 142 and 253µm K_{80} were targeted in these tests. Various reagents were also evaluated. These included fuel oil as the molybdenum collector and, for the majority of the test work, 3418A and 208 were used for collecting copper and gold into a bulk concentrate. Rougher flotation response was investigated at natural pH, which was around 6.6 and up to pH levels of 11.0, modulated through the addition of lime.

The rougher concentrate was reground to a target sizing of 17 to 33µm K_{80}, prior to the three stages of lime modulated dilution cleaning. The initial regrind targets were based on estimates of liberation, observed in the flotation feed streams.

A series of locked cycle tests investigated the estimates of metallurgical performance anticipated from a continuous operation. The effect of a subsequent pyrite circuit was also investigated to: a) increase gold recovery from the feed, and b) to desulphidize the final tailings stream. The addition of a cleaner scavenger stage in order to increase molybdenum recovery to the final concentrate was also investigated.

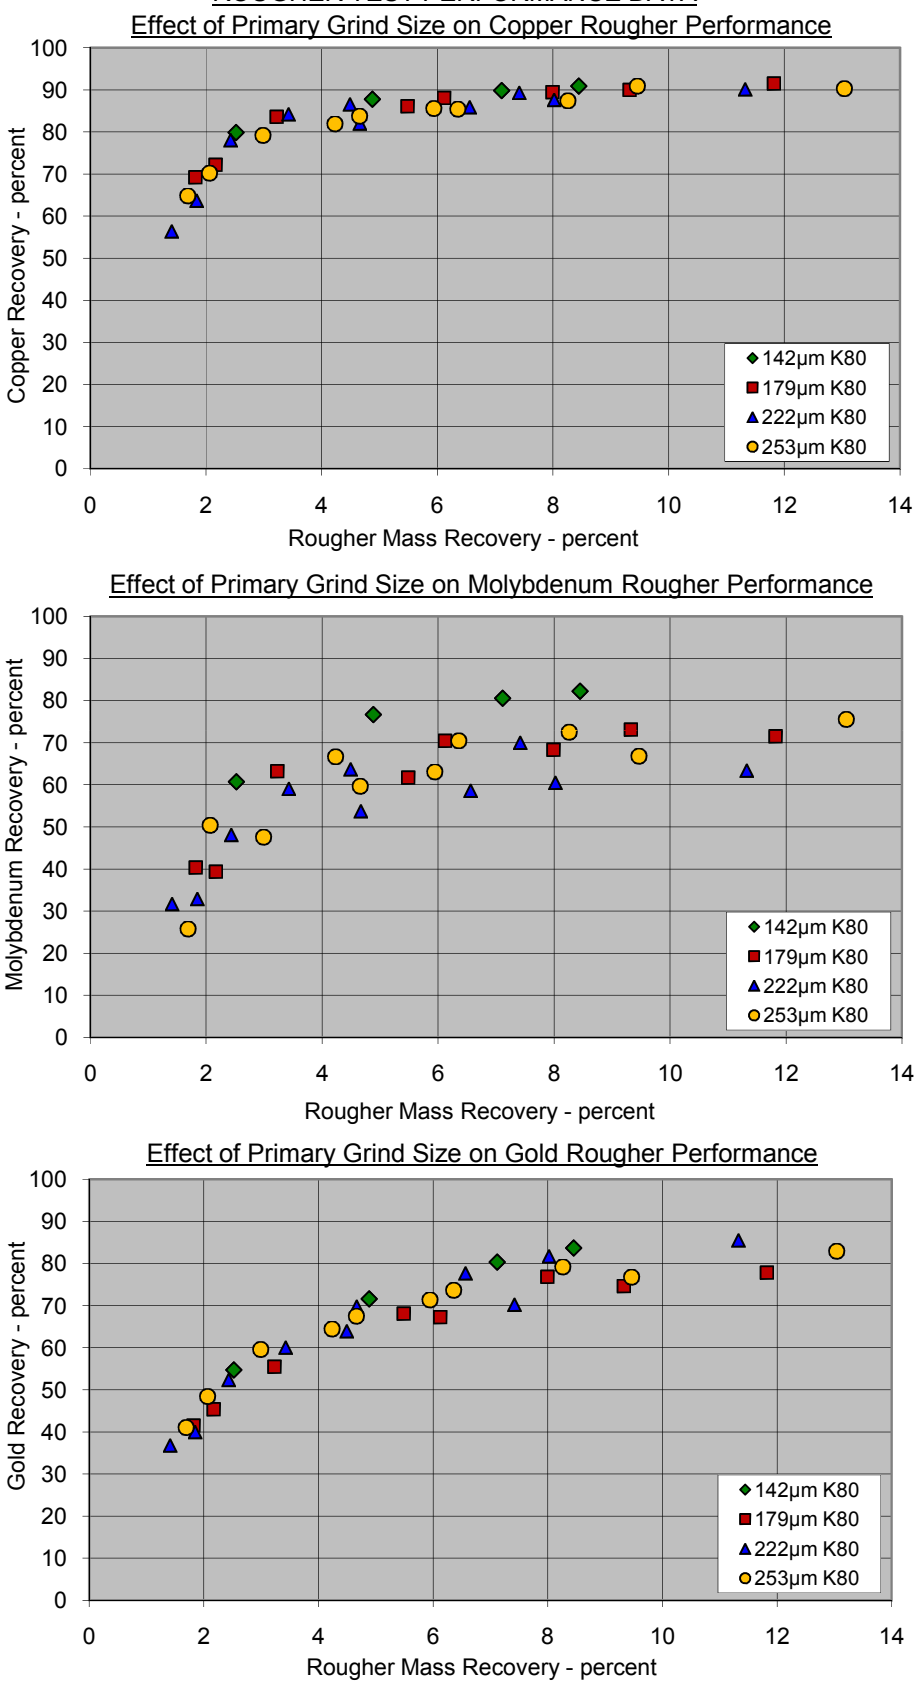
3.2 Rougher Test Results

A total of 17 rougher flotation tests were conducted in this program to investigate variables such as primary grind size, pH, and collector type. A graphical representation of the relevant test results are displayed in Figures 3 and 4.

3.2.1 Effect of Primary Grind Size on Rougher Flotation



Tests aimed at investigating the effect of primary grind size on rougher flotation performance were conducted in this program. The results indicated that there was no perceptible effect of primary grind size on copper rougher flotation response over the range of primary grind sizes tested; 142µm to 253µm K_{80}.

For these tests, on average, copper was 90 percent recovered into a rougher concentrate, containing approximately 10 percent of the feed mass.

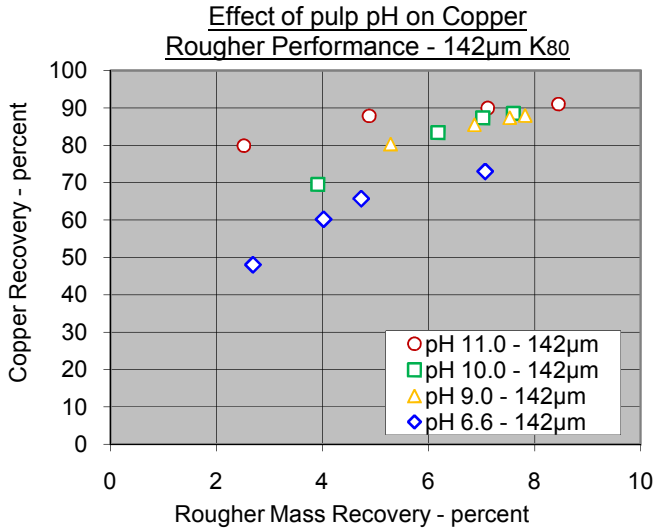
The test results suggest a slight decrease in molybdenum and gold performance when primary grind size was increased to 179µm K_{80}. However, between 179 and 253µm K_{80}, both molybdenum and gold recovery to the rougher concentrate was mainly unaffected.

At a primary grind size of 142µm K_{80}, molybdenum and gold were, 82 and 84 percent respectively, recovered into a rougher concentrate, containing approximately 8 percent of the feed mass. At coarser primary grind sizes, molybdenum and gold were, on average, 70 and 77 percent recovered into a rougher concentrate, containing 10 percent of the feed mass.

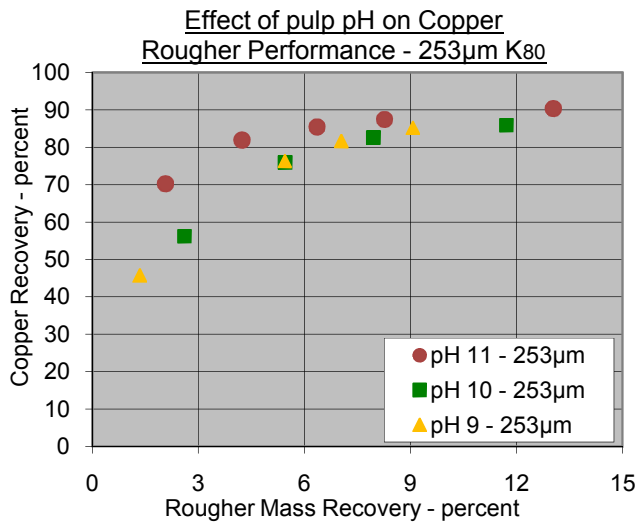
FIGURE 3
ROUGHER TEST PERFORMANCE DATA

3.2.2 Effect of pH on Rougher Flotation

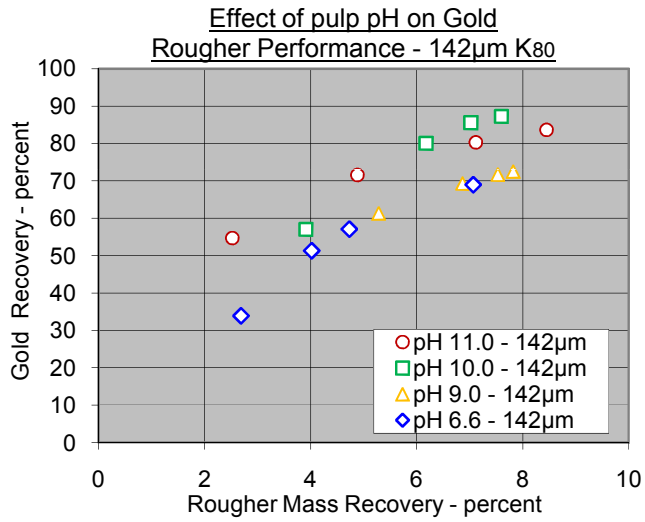
Tests aimed at investigating the effect of pH on rougher circuit* metallurgical response showed that elevated pulp pH improved initial flotation kinetics for copper as well as resulted in copper recoveries of 90 percent. At a coarser primary grind size, tests conducted at pH 9.0 and 10.0, resulted in lower copper recoveries of approximately 85 percent to the rougher concentrate. Tests conducted at the composite's natural pH of approximately 6.6, resulted in poor copper metallurgical performance.



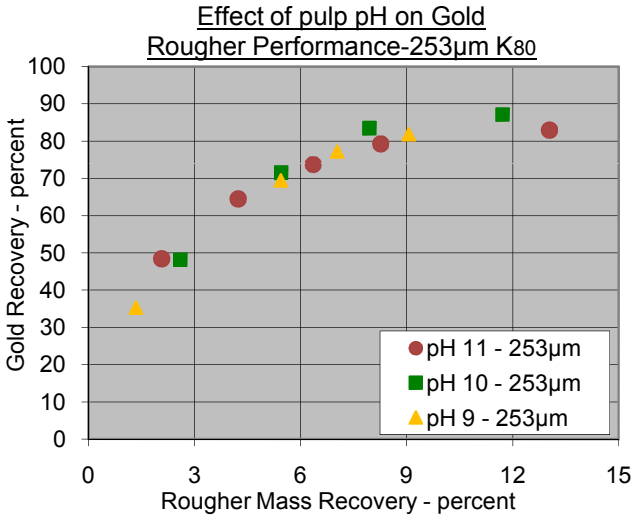
In general, the most favorable molybdenum metallurgical performance was observed at lower rougher pulp pH, while gold rougher metallurgical performance was mainly unaffected by pH levels, at the coarser primary grind size.



Due to the high pyrite content in this sample, the majority of the rougher test work in this program was conducted using selective collectors 3418A and 208 as the copper and gold collecting agents, and fuel oil to collect molybdenum.



The optimum test conditions used to carry on with the test program were at a primary grind size of approximately 222µm K_{80}, pH 11.0, using 3418A, 208, and fuel oil. At these conditions, at a rougher mass recovery of approximately 8 percent, copper, molybdenum, and gold were, on average, 91, 67, and 78 percent, respectively, recovered into the rougher concentrate.



* At the request of the client, two tests were conducted using NaHS and AM28 as the collecting agents in an attempt to increase oxide copper recovery to the rougher concentrate. These tests were not successful in doing so. Results are displayed in Figure IV-2 found in Appendix IV-Special Assay Data.

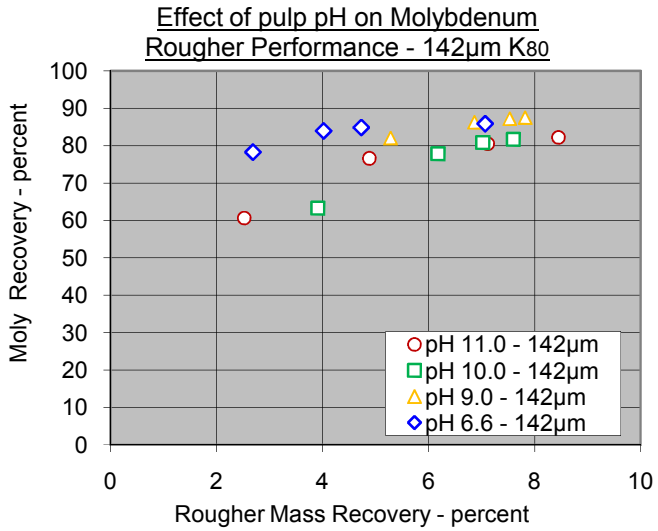


FIGURE 4
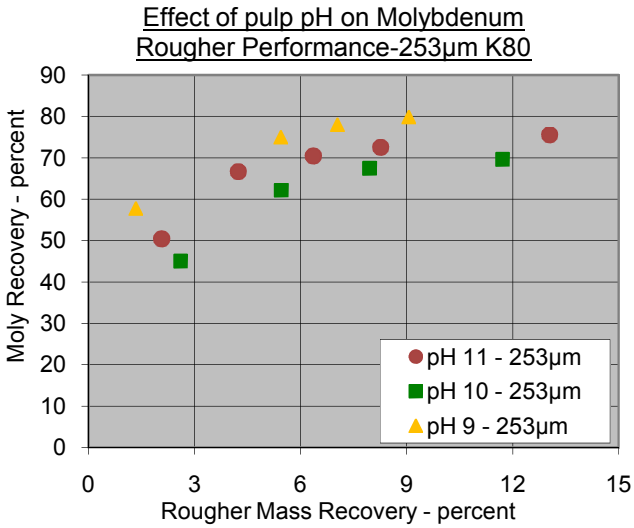
ROUGHER TEST PERFORMANCE DATA

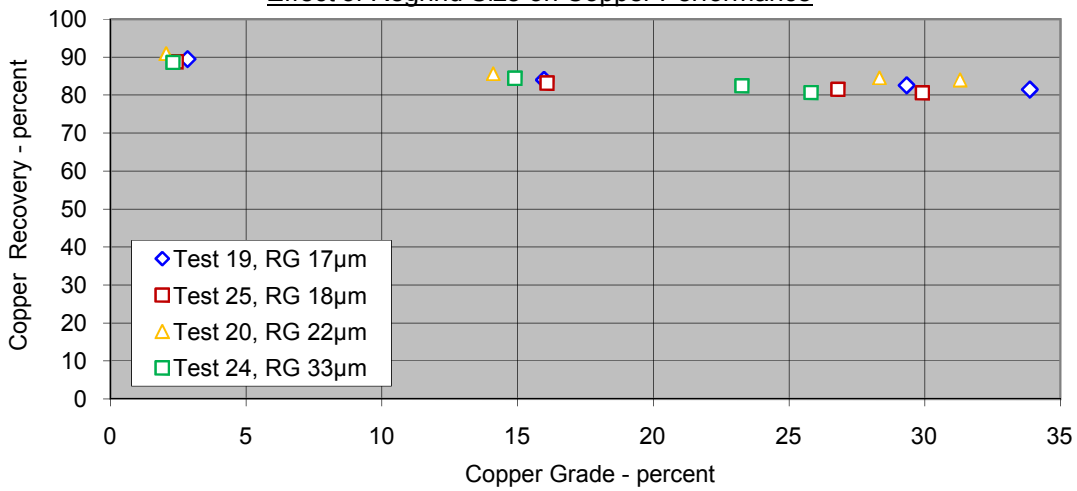


Note: Detailed test data is located in Appendix II.

3.3 Cleaner Test Results

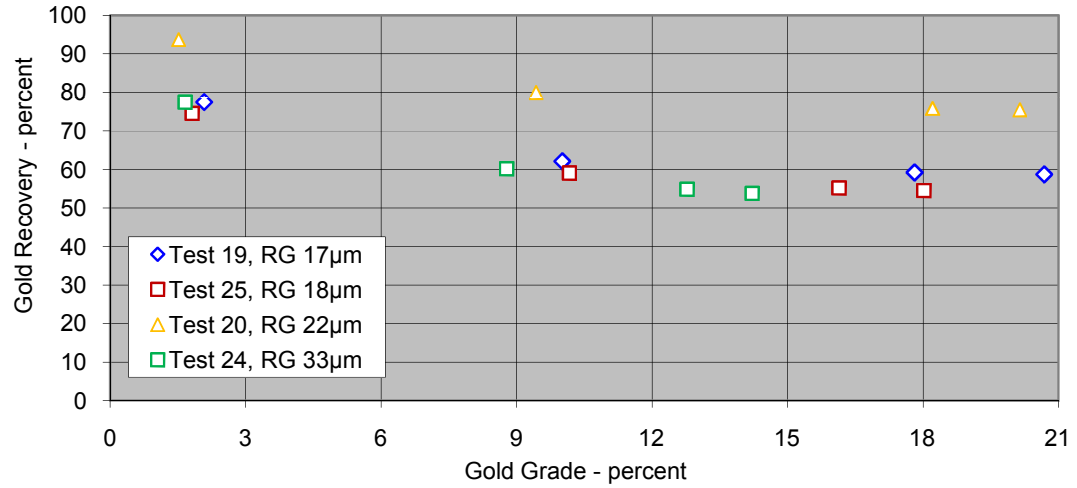
Ten open circuit batch cleaner tests were conducted in this test program. As indicated by the mineralogical analysis, regrind product sizing would be a key variable governing the efficiency of the flotation process. Most of the batch cleaner tests were focused on assessing regrinding effects. A number of open circuit batch cleaner tests were also conducted to examine the effect of using a stronger collector. A summary of the test results, displayed in Figure 5, indicate the following points of interest:

- Regrinding the rougher concentrate to a nominal 20µm K_{80} produced the best metallurgical performance for the copper sulphides and gold. For these tests, copper and gold were, on average, 82 and 63 percent recovered into a bulk concentrate, grading 32 percent copper and 20 g/tonne gold.



- Regrind sizing did not perceptibly influence the molybdenum metallurgy on the cleaner blocks. At a nominal regrind discharge size of 20µm K_{80}, molybdenum was, on average, 42 percent recovered into the bulk concentrate, grading 1.9 percent molybdenum.

- Increasing regrind size to approximately 33µm K_{80}, resulted in a decline in both copper and gold performance.



A series of cleaner tests, not shown in Figure 5, were conducted using a stronger collecting reagent, potassium amyl xanthate (PAX). For these tests, enough selectivity against pyrite, in the cleaner circuit, was not obtained, resulting in a low grade bulk concentrate. Two additional cleaner tests were also conducted at the request of the client, examining the effect of a target grind size of 200µm K_{80}, and the effect of two stage regrinding. No improvement on metallurgical performance was observed for these tests. The results are presented in Appendix IV, Figure IV-1.

FIGURE 5

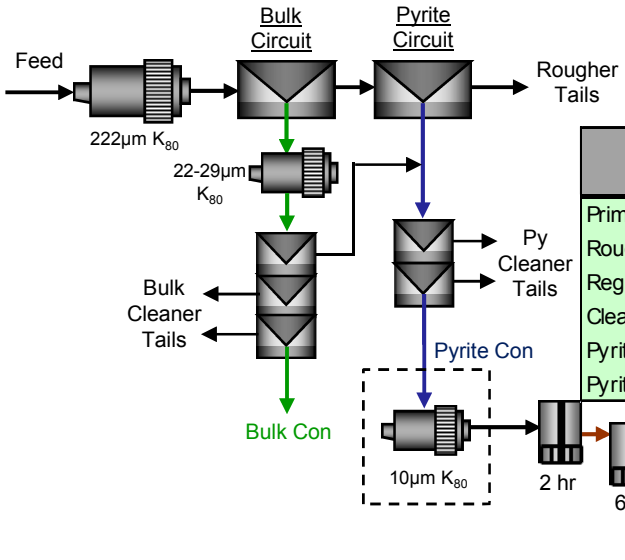
Note: Additional test data is located in Appendix II.

3.4 Pyrite Flotation and Cyanidation Test Results

A series of two product cleaner tests were conducted with the objective of desulphidizing the final tailing streams and increasing gold recovery from the feed. In these tests, the bulk circuit rougher tailings were subjected to an additional pyrite flotation step. The pyrite rougher concentrate, along with the bulk first cleaner tailings, were then cleaned using three stages of dilution cleaning.

The pyrite cleaner concentrate from these tests were then subjected to cyanide leaching with and without a regrind stage prior to leaching. Cyanide levels were maintained at 1,000 ppm, while the pH level was modulated to 11.0. A schematic of the test flowsheets and a summary of test results are displayed in Figure 6. The following key points follow from an inspection of the data:

- The final tailing stream contained 3.3 percent of the feed sulphur, grading 0.1 percent sulphur.



- On average, 15 percent of the feed gold was recovered into the pyrite concentrate, grading 0.76 g/tonne gold. This concentrate also contained, on average, 6 percent of the feed copper, assaying at 0.41 percent copper.

- Approximately 76 percent of the gold and 99 percent of the copper contained in the pyrite concentrate were extracted into solution after 48 hours of cyanide leaching. For this test, cyanide consumption was extremely high at 7.8 kg/tonne. Lime consumption was measured to be 1.4 kg/tonne.

- Regrinding the pyrite concentrate to approximately 10µm K_{80}, prior to leaching, did not improve gold extraction into solution. Cyanide consumptions were lower at 5.3 kg/tonne while lime consumption increased to 2.5 kg/tonne.

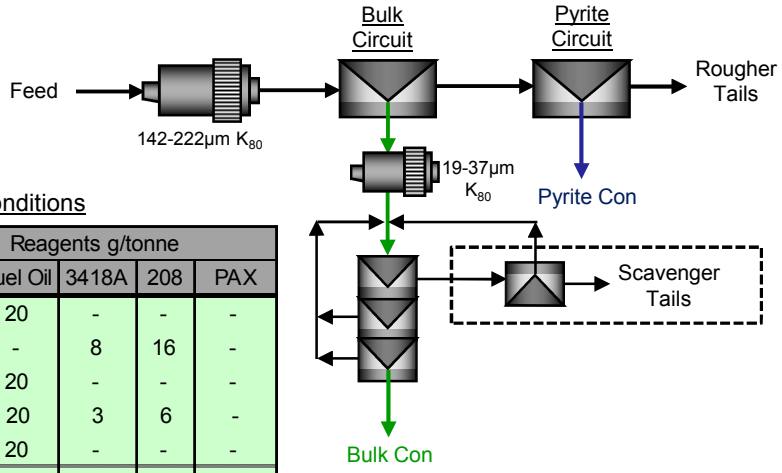
3.5 Locked Cycle Test Results

A series of locked cycle tests were conducted in this program to establish the estimates of metallurgical performance, anticipated from a continuous process. Figure 7 displays the flowsheet schematic used in these samples, along with a summary of test results.



The results of these tests determined that, by implementing a cleaner scavenger step, molybdenum recovery to the final concentrate can be increased. At a primary grind size of 222µm K_{80}, and following a regrind target size of 20µm K_{80}, a copper recovery to the final concentrate of 88 percent, grading 26 percent copper, was obtained. For this test, molybdenum was 47 percent recovered into the final concentrate, grading 1.6 percent molybdenum.

In an attempt to reduce the loss of fine molybdenum particles to the final concentrate, a locked cycle test was conducted to investigate a coarser regrind size, targeting 31µm K_{80}. For this test, molybdenum recovery increased to approximately 57 percent in the final concentrate grading 1.5 percent molybdenum. However, as indicated by cleaner test data, at a coarser regrind size, copper performance declined. For this test, copper was 84 percent recovered from the feed to the final concentrate grading 21 percent copper.

For the purpose of comparison to previously tested Casino samples, and at the request of the client, a single locked cycle test was conducted at a finer primary grind size of 142µm K_{80}. Again, as determined by initial rougher test work, molybdenum performance increased while copper performance was unaffected. For this test, molybdenum from the feed was 56 percent recovered into the final concentrate grading 1.8 percent molybdenum. Copper recovery to the final concentrate was 87 percent, grading 26 percent copper.

4.0 Mineralogical Assessment of The Process

To assess opportunities for metallurgical improvements, Particle Mineral Analysis (PMA) using QEMSCAN was performed on the exit streams produced in locked cycle Test 34. The results of this assessment provided information regarding the potential to improve the grade of the final copper concentrate. The analysis also determined the opportunities for reducing copper losses to the tailings streams.

4.1 Quality of the Concentrate

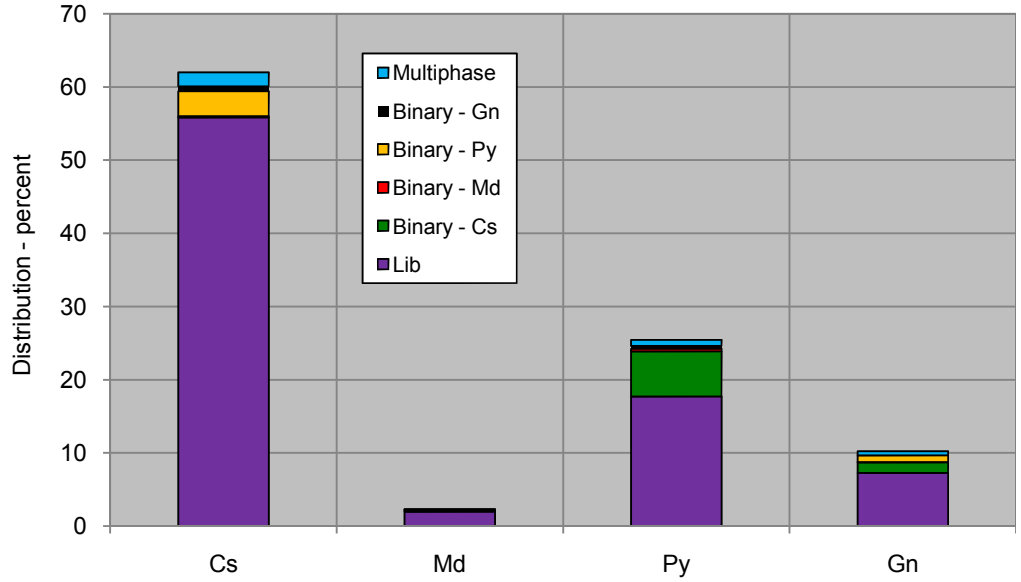
A summary of the status of diluents contained in the final bulk concentrate is displayed in Figure 8A. The following points may be of interest:

- Most of the diluents contained in the concentrate occurred as liberated pyrite. Chemical changes to the flotation circuit would be required to reject more of the pyrite from the concentrate. More selective conditions of flotation, however, would likely result in lower copper recovery.

- Gangue was the second highest diluent in the bulk concentrate. The majority of the gangue reporting to the bulk concentrate was observed to be liberated particles finer than 14µm K_{80}, likely a result of froth entrainment.

- The limiting grade recovery chart for the bulk concentrate indicates that concentrates assaying between 38 and 40 percent copper could theoretically be produced from this composite as a result of rejecting all non-copper sulphide bearing particles. Typically, losses in copper recovery are incurred when higher grade concentrate are targeted.

FIGURE 8A
DISTRIBUTION OF MINERALS BY SIZE AND CLASS INTO THE BULK CONCENTRATE - TEST 34



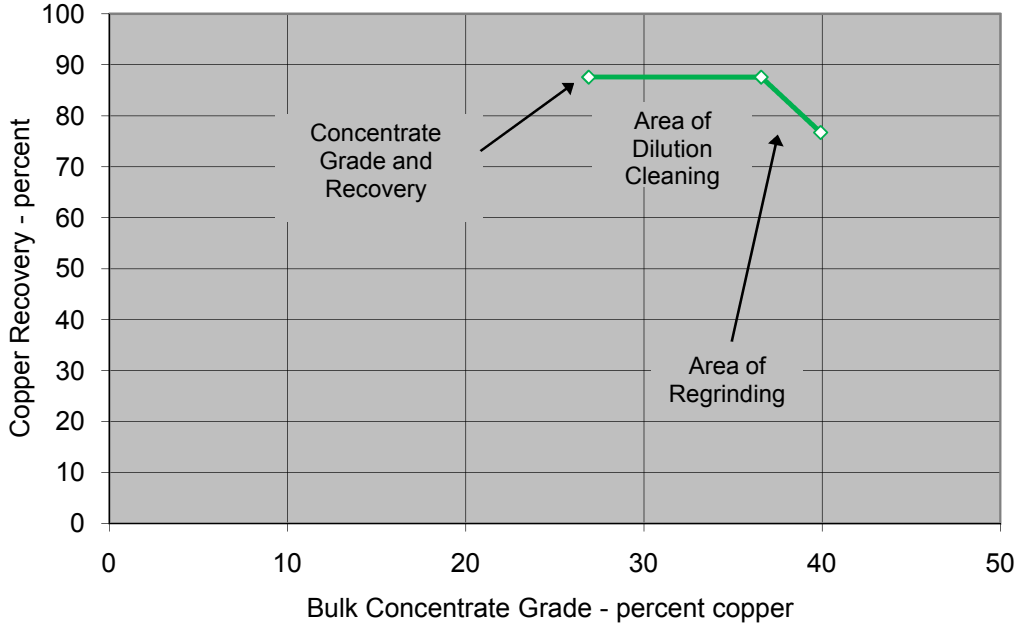


FIGURE 8B
MINERALOGICALLY LIMITING GRADE RECOVERY CHART
Based on Recovery into Test 34, Bulk Concentrate from the Bulk Rougher Feed

4.2 Losses to the Final Tails

A modal analysis was carried out on the scavenger tailing, pyrite concentrate and pyrite rougher tailing streams produced in Test 34. Analysis of the modal data, with respect to losses to the tailing streams*, is shown in Figure 9. The following comments may be of interest:

- The majority of the copper losses to the bulk rougher tails occurred as binary particles with non-sulphide gangue. Most of these particles are either coarser than 150µm or finer than 13µm K_{80}.

- Liberated copper sulphides accounted for 28 percent of the copper losses in the bulk rougher tailing stream. Most of these particles were sized finer than 13µm K_{80}. Liberated copper sulphide particles in this size range are generally difficult targets to recover by flotation.

- About 25 percent of the copper sulphide in the scavenger tailing was liberated. The majority of liberated and non-liberated copper sulphide in this stream was finer than 13µm. There is a limited scope for improving copper recoveries from this stream.

- The majority of the molybdenite lost to the bulk rougher tails occurred as coarse binary particles with non-sulphide gangue. Test 35 results, not shown in the figure, indicate molybdenum losses to this stream may be reduced at a finer primary grind size.

- Liberated molybdenite accounted for the majority of molybdenite losses to the scavenger tails. About half of these particles were finer than 13µm K_{80}. This loss profile is often observed in operating plants.

* The pyrite concentrate and pyrite rougher tailing stream analysis were combined in this section to represent losses to the bulk rougher tailing stream. For individual stream data, see Appendix V-Mineralogical Data.

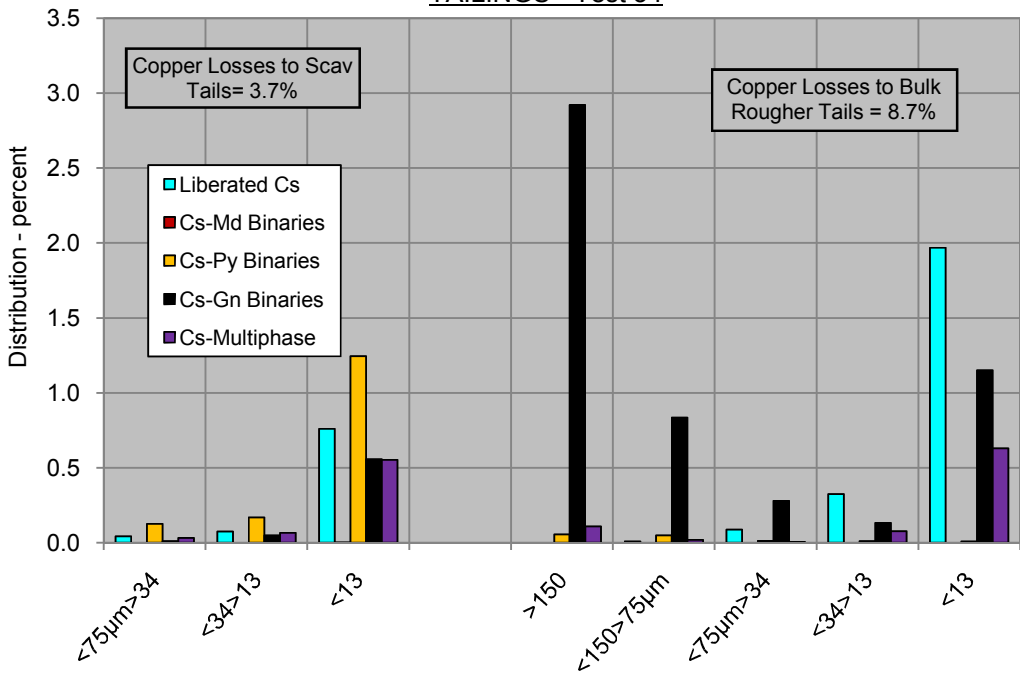

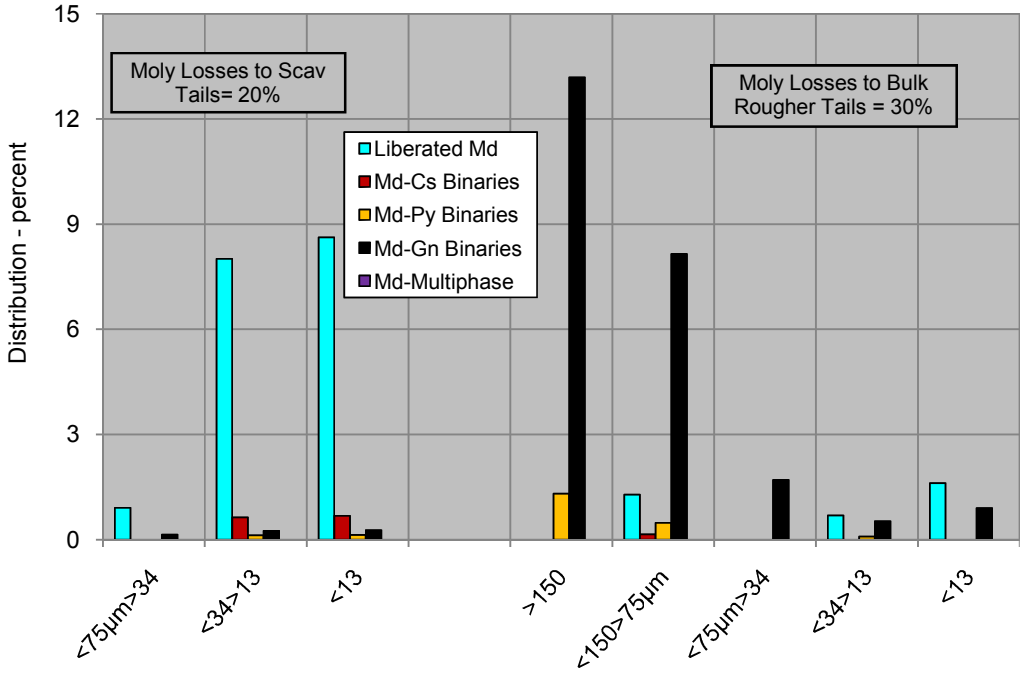

FIGURE 9B
DISTRIBUTION OF MOLYBDENUM LOSSES BY SIZE AND CLASS INTO THE TAILINGS - Test 34

Note: Detailed modal anlysis data can be located in Appendix V.

5.0 Concentrate Quality

The bulk concentrates taken from locked cycle Test 33 were subjected to a detailed chemical analyses. Major components and minor elements present in the concentrate were determined using specific element assay techniques.

The principal objective of this test work was to determine if the floatation concentrate produced from the Casino deposit contained any components, which might adversely affect smelter acceptance. The results are presented in Table 3.

The bulk concentrate was relatively free of deleterious elements that may attract a smelter penalty.

Gold and silver content in the concentrate were present at approximately 21 and 179 g/tonne, respectively.

It is recommended that specific advice from experts in the field of smelter contracts be sought regarding the trigger points for the imposition of penalty payments.

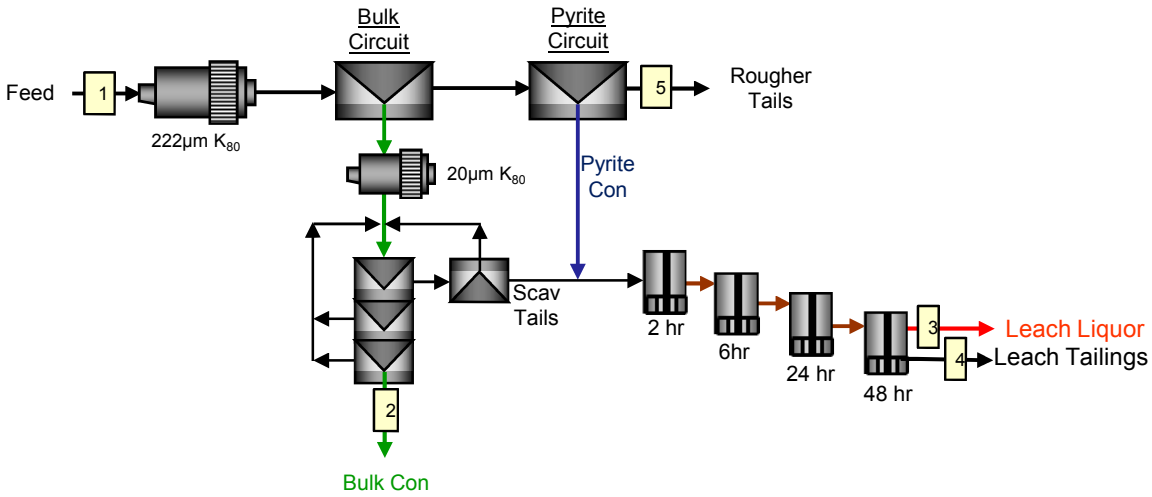
6.0 Ancillary Studies



At the request of the client, the pyrite rougher concentrate and cleaner scavenger tailings from locked cycle Test 34 were combined and split into two, approximately 500 gram, charges. The two charges were subjected to two standard cyanide leaching bottle roll tests in order to assess the potential for extracting gold from this sample. The flowsheet used for this test is displayed in Figure 10.

The product was then fed to a 48 hour cyanidation bottle roll test. The sodium cyanide concentration was maintained at 2,000 ppm and the cyanidation pH at 11.0 using lime.

At a target sodium cyanide concentration of 2,000 ppm, the average sodium cyanide consumption was about 2.3 kg/tonne. Lime consumption was about 2.5 kg/tonne under these conditions. After 48 hours of cyanide leaching, on average, 74 percent of the gold from the pyrite concentrate and cleaner scavenger tails were extracted to solution. This converts to a gold recovery of approximately 12.5 percent from the locked cycle test feed.

FIGURE 10

CYANIDE LEACH TEST FLOWSHEET AND DATA

Locked Cycle Test Conditions

Stage	pH	Reagents g/tonne				
		Lime	Fuel Oil	3418A	208	PAX
Primary Grind	11.0	2900	20	-	-	-
Roughers	11.0	-	-	8	16	-
Regrind	11.0	500	20	-	-	-
Cleaners	11.0	√	20	3	6	-

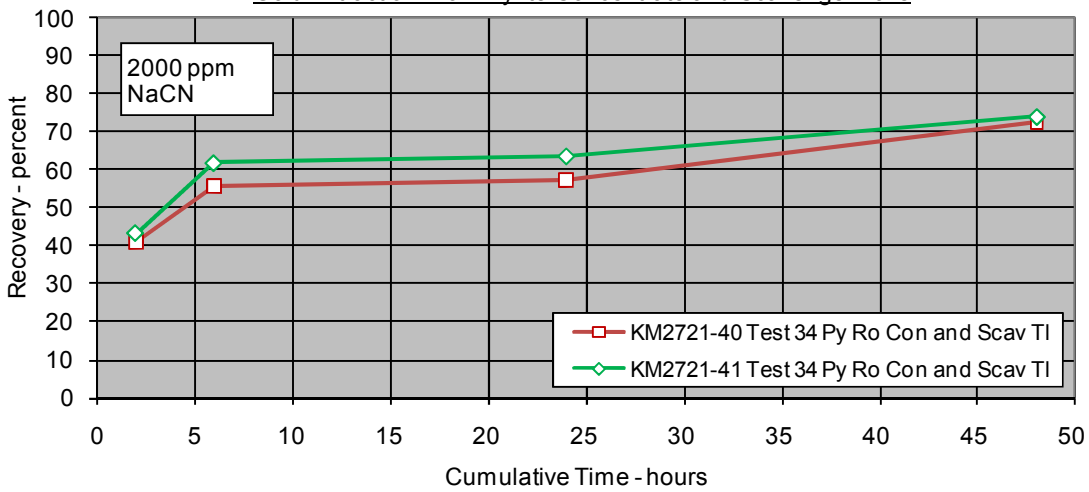
Pyrite Roughers	11.0	-	-	-	-	60



Cyanide Leach Test Conditions

pH	Reagent Consumed - kg/t	
	Lime	NaCN
11.0	2.5	2.3

Overall Gold Recovery from the Feed

Stream		Grade	Recovery from Feed
Number	Name	g/tonne	percent
1	Feed	0.26	100
2	**Bulk Concentrate**	**18.8**	**66.4**
3	**Leach Liquor**	**-**	**12.5**
4	Leach Tails	0.07	4.5
5	Pyrite Rougher Tails	0.05	16.6

Gold Extraction From Pyrite Concentrate and Scavenger Tails

Notes: a) Detailed test conditions and results can be found in Appendix II.
b) Leach liquor gold recovery is based on the average of Test 40 and 41.

7.0 Conclusions and Recommendations

Samples from the Casino deposit, designated SUP Composite 2010, were used in this program of study. The composite contained approximately 0.30 percent copper and 0.037 percent molybdenum. Chalcopyrite accounted for the majority of the copper in this sample. Pyrite accounted for the main sulphide mineral at 4 percent of the feed mass.

At a primary grind sizing of 142µm K_{80}, the two-dimensional copper sulphide liberation was 53 percent. The mineral fragmentation characteristics of the composite indicated that liberations of copper sulphides were only slightly affected by primary grind size. The data suggests that coarser levels of primary grind size, up to 250µm K_{80} may be instituted to produce adequate flotation performance in the rougher circuit.

Molybdenite at 142µm K_{80} primary grind size was 41 percent liberated when assessed in two dimensions. The majority of the molybdenite interlocking occurred in binaries with non-sulphide gangue particles, which were rich in molybdenite and likely to be recovered in rougher flotation.

Rougher test results in this program indicated that copper flotation response is virtually unaffected by primary grind size over the range of 142 to 253µm K_{80}. Molybdenum performance, however, declined at a primary grind size of 179µm K_{80} and coarser.

It was also determined from the rougher test results that increased pH levels improved copper performance.

Cleaner test results indicated that a nominal regrind size of 20µm K_{80}, results in the most favorable copper and gold performances. Regrind size over the range of 17 to 33µm K_{80}, did not affect molybdenum performance. However, copper and gold performance declined at the coarser regrind size.

Cleaner tests, involving a sequential pyrite circuit, were successful in desulphidizing the rougher tails. Following the pyrite circuit, the rougher tailings contained less than 0.1 percent sulphur.

An attempt to recover more gold from the pyrite cleaner concentrate, through cyanide leaching, resulted in approximately 11 percent of the feed gold being extracted into solution after 48 hours of cyanide leaching. Approximately 6 percent copper was also present in the pyrite concentrate, 99 percent of which was extracted to solution. Due to the high cyanide soluble copper content, cyanide consumption for this test was extremely high at approximately 7.8 kg/tonne.

At a primary grind size of 222µm K_{80}, following a regrind of approximately 20µm $K_{80,}$ and a pulp pH of 11.0, copper was, at best, 88 percent recovered into a final concentrate, grading 26 percent copper. For this test, molybdenum and gold were 47 and 66 percent recovered into the final concentrate, respectively, grading 1.6 percent molybdenum and 18.8 g/tonne gold. The tests results indicated that by implementing a cleaner scavenger stage molybdenum recovery to the final concentrate improved.

Locked cycle test results indicated that by increasing the regrind size to approximately 35µm K_{80}, an improvement in molybdenum metallurgical performance can be obtained. However, copper metallurgical performance decreased significantly.

The locked cycle test results also confirmed that at a finer primary grind size of 142µm K_{80}, molybdenum metallurgical performance increased, while copper performance was unaffected.

Mineral analysis of the locked cycle test exit streams determined that the main diluent in the bulk concentrate consists of mainly liberated pyrite particles. More selective flotation conditions may assist in the rejection of these particles,

however, this would likely result in lower copper recoveries. The majority of the copper losses to the final tailings occurred as very fine liberated particles, which are generally difficult targets to recover by flotation and were typical of similar operating circuits.

Minor element scans on the bulk concentrate from a selected locked cycle test showed that the concentrate is generally free of deleterious elements, however, advice from experts in the field of smelter contracts should be sought regarding this matter.

APPENDIX I – KM2721

SAMPLE ORIGIN

1.0 Sample Origin

Samples for this Casino Project were received at G&T Metallurgical Services Ltd. in three shipments, on August 5, 10, and 13 of 2010. Table I-1 displays the mass and identification of samples received. Upon receipt, samples were checked and certain samples disposed of, based on instructions from Mr. Adam Hesse, metallurgical consultant for Western Copper Corporation. All individual samples were stage crushed to -6 mesh and homogenized. Representative cuts were removed and assayed for elements of interest in this project as shown in Table I-2.

Following Mr. Hesse's instructions, a single global composite was constructed from select samples. Samples for the composite were homogenized and rotary split into 2 kilogram charges. Table I-3 displays the mass and identification of samples, used to construct the global composite, designated Master Composite 1.

Representative duplicate cuts were removed and assayed for elements of interest in this project as shown in Table I-4. Near the end of the program, at the request of Dr. Paul West-Sells, the Master Composite 1 sample name was changed to SUP Composite 2010.

A second SUP Composite 2010 was constructed from the drill core material for environmental test work. This material was constructed based on the same compositing instructions as the initial composite and was designated SUP Composite 2010-2. Head assays were conducted on this composite to confirm uniformity with the original sample. The results are displayed in Table I-5.

PROJECT NO: KM2721-01

PURPOSE: Preliminary Rougher Rate Test.

PROCEDURE: Perform a standard one product rougher test.

FEED: 2 kg of SUP Composite 2010 ore ground to a nominal 142µm K_{80}.

FLOWSHEET: 1

Stage	Reagents Added g/tonne				Time (minutes)			pH
	Fuel Oil	3418A	208	MIBC	Grind	Cond.	Float	
Primary Grind	20				14			6.6

PROJECT NO: KM2721-30

PURPOSE: To Repeat Test 28 but with Regrind.

PROCEDURE: Standard bottle roll procedure. Agitate on rolls using cyanide and lime.

SAMPLE: 287 g KM2721-29 Pyrite Concentrate ground for 30 minutes to reach a nominal 10µm $K_{80.}$ Cyanidation Tails 10µm K_{80}.

PROJECT NO: KM2721-36

PURPOSE: To Investigate a Coarser Regrind in a Locked Cycle Test.

PROCEDURE: Perform a standard two product locked cycle test.

FEED: 5 x 2 kg of SUP Composite 1 ore ground to a nominal 222µm K_{80}.
Bulk Regrind Discharge Size - 37µm K_{80}.

FLOWSHEET: 3

Stage	Reagents Added g/tonne					Time (minutes)			pH

Analytical Methods

CV-AAS	Cold vapour flameless atomic absorption spectrometry
FAAS	Flame atomic absorption spectrometry
ICP-OES	Inductively coupled plasma - optical emission spectroscopy
Leco	Leco induction furnace
ISE	ion selective electrode
Titr	Classical wet method titration

Digestion Methods

2 Acid	Hydrochloric acid and nitric acid
2 Acid*	Hydrochloric acid, nitric acid and potassium chlorate
2 Acid**	Nitric acid and bromine
3 Acid	Hydrochloric acid, nitric acid and perchloric acid
4 Acid	Hydrochloric acid, nitric acid, hydrofluoric acid and perchloric acid
AR	Aqua regia - 3:1 hydrochloric acid:nitric acid
ESHKA	Magnesium oxide, sodium carbonate sinter
FA	Fire assay fusion
Fusion	Sodium peroxide fusion
Leco	Combusion
LeForte rt	Reverse aqua regia - 1:3 hydrochloric acid:nitric acid, at room temperature
WR	Hydrochloric acid, nitric acid and hydrofluoric acid

Multiphase	4.8	2.1	4.9	0.0	1.4	0.1	6.0	2.3	6.2	0.0	1.8	0.1
Total	100	100	100	100	100	100	100	100	100	100	100	100

Notes 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.

2) 0.0 Indicates these minerals were not observed during the counting procedure.

3) The 150µm and 75µm sizing fraction corresponds to the Tyler 100 and 200 mesh sieve. C1 to C5 indicates cyclones 1 to 5 on the cyclosizer.

4) The Total line is the distribution of mineral in the size fraction. Original data is from the size by assay and distribution tables.

5) The calculated liberation of the unsized product as measured in two dimensions has been converted to three dimensions using correction factors developed by G & T Metallurgical Services.

6) The three dimension liberation is zero if the liberation in two dimensions is less than 20 percent.

Total	100	0.43	0.01	0.15	0.05	4.24	95.1	100	100	100	100	100	100

Notes: 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.
2) Mineral assays are based on gravimetric factors to convert the metal to the pure mineral.
3) See appendix I for details of gravimetric factors.
4) An assay value of "0" indicates the assay value is less than the detection limit.

Notes 1) The two-dimensional proportion of minerals is a weighted estimate which is based on the liberation and the mineral content of the unsized sample.
2) The three-dimensional data is based on converting the two dimensional liberation data using G & T Metallurgical Services correction factors.
3) Composition values of "0" represents values <2% and "100" represents values >98%.

Ti Mineral Group	0.19	0.29	0.42	0.58	0.58	0.40
Apatite	0.10	0.29	0.48	0.54	0.41	0.35
Tourmaline (Dravite)	0.11	0.35	0.21	0.29	0.18	0.24
Garnet	0.04	0.06	0.05	0.14	0.65	0.20
Ankerite	0.13	0.17	0.08	0.19	0.13	0.14
Amphibole (Hornblende)	0.06	0.14	0.04	0.10	0.42	0.16
Others	0.21	0.36	0.37	0.37	0.79	0.43
Total	100	100	100	100	100	100

Note: 1) Tennantite-Tennantite and Tetrahedrite.
2) Feldspars includes Plagioclase Feldspar, K-Feldspar, Feldspar-Albite, and Alkali-Feldspar.
3) Iron Oxides-Hematite and Goethite.
4) Ti-Minerals includes Rutile/Anatase, Ilmentite and Sphene.
5) Garnet includes Grossular and Almamdine.
6) Ankerite-Ankerite, Calcite and Dolomite.
7) Amphibole includes small amount of Pyroxene group minerals.
8) Others includes trace amounts of Barite, Sphalerite, Galena and unresolved mineral species.

Binary - Gn	1.1	0.5	1.0	0.3	1.6		1.4	0.5	1.2	0.4	2.0	
Multiphase	1.7	31.0	6.2	1.9	3.2	5.5	2.1	36.6	7.8	2.3	4.0	6.8
Total	100	100	100	100	100	100	100	100	100	100	100	100

Notes 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.

2) 0.0 Indicates these minerals were not observed during the counting procedure.

3) The 150µm and 75µm sizing fraction corresponds to the Tyler 100 and 200 mesh sieve. C1 to C5 indicates cyclones 1 to 5 on the cyclosizer.

4) The Total line is the distribution of mineral in the size fraction. Original data is from the size by assay and distribution tables.

5) The calculated liberation of the unsized product as measured in two dimensions has been converted to three dimensions using correction factors developed by G & T Metallurgical Services.

6) The three dimension liberation is zero if the liberation in two dimensions is less than 20 percent.

TABLE 2B
SIZE BY ASSAY AND DISTRIBUTION BASED ON METAL CONTENT
Test 34 Bulk Concentrate I to V, 27µm K80

Size Fraction	Mass %	Assays-percent						Distribution

<C2>C5	26.5	42.6	0.89	15.6	3.76	34.5	2.8	23.3	23.1	32.7	42.9	35.9	7.1
<C5	53.0	65.0	1.36	14.4	1.27	4.5	13.4	71.2	70.8	60.6	29.0	9.4	69.4
Total	100	48.4	1.02	12.6	2.32	25.4	10.2	100	100	100	100	100	100

Notes: 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.
2) Mineral assays are based on gravimetric factors to convert the metal to the pure mineral.
3) See appendix I for details of gravimetric factors.
4) An assay value of "0" indicates the assay value is less than the detection limit.

TABLE 2D
ESTIMATED RELATIVE PROPORTION AND COMPOSITION OF MINERAL GRAINS
Test 34 Bulk Concentrate I to V, 27µm K80

Binary	Proportion by Weight-2D						Proportion by Weight-3D						Composition of Grains					
Component	Cp	Bn	Ch	Md	Py	Gn	Cp	Bn	Ch	Md	Py	Gn	Cp	Bn	Ch	Md	Py	Gn

Ankerite	0.00	0.00	0.04	0.05	0.12	0.08
Amphibole (Hornblende)	0.00	0.00	0.02	0.00	0.05	0.03
Others	0.00	0.00	0.28	0.36	1.01	0.69
Total	0.00	0.00	100	100	100	100

Note: 1) Tennantite-Tennantite, Tetrahedrite and Enargite.
2) Iron Oxides includes Goethite, Limonite, Magnetite and Hematite.
3) Feldspars includes Plagioclase Feldspar, K-Feldspar, Feldspar-Albite, and Alkali-Feldspar.
4) Ti-Minerals includes Rutile/Anatase, Ilmentite and Sphene.
5) Garnet includes Grossular, Andradite and Almamdine.
6) Ankerite includes Calcite and Dolomite.
7) Amphibole includes a small amount of Pyroxene group minerals.
8) Others includes trace amounts of Sphalerite, Diaspore, Chromite and unresolved mineral species.

Binary - Gn	17.8	0.0	23.4	3.4	3.0		22.2	0.0	29.3	4.2	3.7	
Multiphase	2.3	26.0	8.2	1.3	0.0	0.0	2.9	30.2	10.3	1.7	0.0	0.0
Total	100	100	100	100	100	100	100	100	100	100	100	100

Notes 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.

2) 0.0 Indicates these minerals were not observed during the counting procedure.

3) The 150µm and 75µm sizing fraction corresponds to the Tyler 100 and 200 mesh sieve. C1 to C5 indicates cyclones 1 to 5 on the cyclosizer.

4) The Total line is the distribution of mineral in the size fraction. Original data is from the size by assay and distribution tables.

5) The calculated liberation of the unsized product as measured in two dimensions has been converted to three dimensions using correction factors developed by G & T Metallurgical Services.

6) The three dimension liberation is zero if the liberation in two dimensions is less than 20 percent.

TABLE 3B
SIZE BY ASSAY AND DISTRIBUTION BASED ON METAL CONTENT
Test 34 Bulk Cleaner Scavenger Tailing IV & V, 16µm K80

Size Fraction	Mass %	Assays-percent						Distribution					
		Cu	Fe	Mo	S			Cu	Fe	Mo	S

Total	100	0.14	0.01	0.04	0.07	22.9	76.8	100	100	100	100	100	100

Notes: 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.
2) Mineral assays are based on gravimetric factors to convert the metal to the pure mineral.
3) See appendix I for details of gravimetric factors.
4) An assay value of "0" indicates the assay value is less than the detection limit.

Binary - Gn	0.03	0.00	0.01	0.00	0.7		0.03	0.00	0.01	0.00	0.9		6	0	89	12	29	
Multiphase	0.00	0.00	0.00	0.00	0.0	0.0	0.00	0.00	0.00	0.00	0.0	0.0	17	17	16	5	5	39
Average Composition	0.14	0.01	0.04	0.07	22.9	76.8	0.14	0.01	0.04	0.07	22.9	76.8	15	32	52	55	92	99

Notes 1) The two-dimensional proportion of minerals is a weighted estimate which is based on the liberation and the mineral content of the unsized sample.
2) The three-dimensional data is based on converting the two dimensional liberation data using G & T Metallurgical Services correction factors.
3) Composition values of "0" represents values <2% and "100" represents values >98%.

Kaolinite (clay)	0.74	0.91	1.13	3.45	2.24	1.35
Chlorite/Epidote	1.31	0.96	1.24	2.53	1.81	1.50
Pyrophyllite	0.22	0.28	0.41	1.50	1.07	0.54
Ti Mineral Group	0.35	0.41	0.41	0.61	0.65	0.46
Apatite	0.11	0.11	0.45	0.58	0.27	0.21
Tourmaline (Dravite)	0.08	0.12	0.26	0.56	1.26	0.42
Garnet	0.03	0.03	0.08	0.17	0.55	0.17
Ankerite	0.09	0.17	0.14	0.31	0.04	0.10
Amphibole (Hornblende)	0.03	0.02	0.02	0.06	0.25	0.08
Others	0.12	0.20	0.29	0.43	0.81	0.33
Total	100	100	100	100	100	102

Note: 1) Tennantite-Tennantite, Tetrahedrite and Enargite.
2) Iron Oxides includes Goethite, Limonite, Magnetite and Hematite.
3) Feldspars includes Plagioclase Feldspar, K-Feldspar, Feldspar-Albite, and Alkali-Feldspar.
4) Ti-Minerals includes Rutile/Anatase, Ilmentite and Sphene.
5) Garnet includes Grossular, Andradite and Almamdine.
6) Ankerite includes Calcite and Dolomite.
7) Amphibole includes a small amount of Pyroxene group minerals.
8) Others includes trace amounts of Sphalerite, Diaspore, Chromite and unresolved mineral species.

Binary - Py	1.3	0.0	0.0	0.0		0.1	1.6	0.0	0.0	0.0		0.2
Binary - Gn	64.1	6.5	45.6	90.9	71.1		80.1	8.1	57.0	100	88.8	
Multiphase	1.8	2.6	10.9	0.0	0.0	0.0	2.2	3.2	13.6	0.0	0.0	0.0
Total	100	100	100	100	100	100	100	100	100	100	100	100

Notes 1) Cp-Chalcopyrite and Tennantite/Tetrahedrite group minerals, Bn-Bornite, Ch-Chalcocite and Covellite, Md-Molybdenite, Py-Pyrite, Gn-Non-Sulphide minerals.

2) 0.0 Indicates these minerals were not observed during the counting procedure.

3) The 150µm and 75µm sizing fraction corresponds to the Tyler 100 and 200 mesh sieve. C1 to C5 indicates cyclones 1 to 5 on the cyclosizer.

4) The Total line is the distribution of mineral in the size fraction. Original data is from the size by assay and distribution tables.

5) The calculated liberation of the unsized product as measured in two dimensions has been converted to three dimensions using correction factors developed by G & T Metallurgical Services.

6) The three dimension liberation is zero if the liberation in two dimensions is less than 20 percent.

TABLE 5B
SIZE BY ASSAY AND DISTRIBUTION BASED ON METAL CONTENT
Test 34 Pyrite Rougher Tailing IV & V, 213µm K80

Garnet	0.10	0.10	0.11	0.16	0.53	0.20
Ankerite	0.22	0.17	0.49	0.59	0.21	0.28
Amphibole (Hornblende)	0.09	0.06	0.10	0.13	0.41	0.16
Others	0.21	0.34	0.37	0.44	0.67	0.38
Total	100	100	100	100	100	100

Note: 1) Tennantite-Tennantite, Tetrahedrite and Enargite.
2) Iron Oxides includes Goethite, Limonite, Magnetite and Hematite.
3) Feldspars includes Plagioclase Feldspar, K-Feldspar, Feldspar-Albite, and Alkali-Feldspar.
4) Ti-Minerals includes Rutile/Anatase, Ilmentite and Sphene.
5) Garnet includes Grossular, Andradite and Almamdine.
6) Ankerite includes Calcite and Dolomite.
7) Amphibole includes a small amount of Pyroxene group minerals.
8) Others includes trace amounts of Sphalerite, Diaspore, Chromite and unresolved mineral species.

1.0 Introduction

Western Copper and Gold Corporation is currently conducting a feasibility assessment of the Casino Project, located 300 kilometres northwest of Whitehorse, Yukon. The deposit is described as porphyry mineralization with geological zones of oxide, supergene, and hypogene mineralization.

Previous test programs have developed a flotation process to extract a bulk copper-molybdenum and gold concentrate. This program of study was intended to produce tailings samples for environmental testing and investigate the copper-molybdenum separation process. The program also provided an opportunity to evaluate the process using fresh hyrogene drill core. Many of the previous test programs had been conducted on core sample that had been in storage for a long time and could have possibly oxidized.

This study was commissioned at the request of Dr. Paul West-Sells, President and CEO at Western Copper and Gold Corporation. On behalf of Western Copper and Gold Corporation, Mr. Jeff Austin of International Metallurgical and Environmental provided technical input on the design of the program. The objectives of this program, as described by Mr. Austin, were as follows:

- Prepare six composites for laboratory and pilot scale testing; three composites representing geological sub-types of the hypogene zone were designated for laboratory testing. Two separate composites of hypogene and supergene fresh drill core sample were prepared for pilot scale testing. A third commissioning composite for the pilot plant was also prepared from old reject sample.

- Evaluate the metallurgical performance of the hypogene composites using batch and locked cycle flotation tests.

- Process the pilot composites using the developed flowsheet. From the pilot testing, obtain samples of tailings and concentrate for subsequent testing.

- Conduct preliminary copper-molybdenum testing on the concentrate produced from the pilot campaign.

- Assay the concentrates for minor payable and deleterious elements.

The following technical brief summarizes the key technical points of the program. All of the test data generated through the execution of this program can be reviewed in a series of appendices attached to this brief. The appendices are arranged as follows:

Appendix I - Sample Origin
Appendix II - Flotation Test Data
Appendix III - Particle Sizing Data
Appendix IV - Special Assay Data
Appendix V - Pilot Plant Data

2.0 Properties of the Hypogene Composites

The chemical content of composite samples were determined by standard assaying techniques. The results are summarized in Table 1.

Copper averaged about 0.17 percent for all of the composites. This grade was slightly lower than some of the other samples previously investigated. Weak acid soluble copper was low for the hypogene composites, averaging about 3 percent of the total copper. This level is very low, indicating the samples should respond well to the developed copper flotation process.

Gold in the samples ranged between 0.18 and 0.22 g/tonne. Molybdenum in the sample was relatively high ranging from 0.019 to 0.071 percent by weight. The high relative levels of molybdenum to copper should result in high levels of molybdenum in the bulk copper concentrate.

The IX and WR samples averaged about 2.3 percent by weight sulphur. Comparatively, the PP Composite had relatively low levels of sulphur. Although no mineralogical analyses were conducted, past programs would suggest that pyrite would account for most of the remaining sulphur in the sample.

On this basis, anticipated pyrite levels in the IX and WR Composites would be high relative to the copper sulphides in the sample. Careful control of flotation pulp conditions will be required to optimize pyrite rejection from the concentrate.

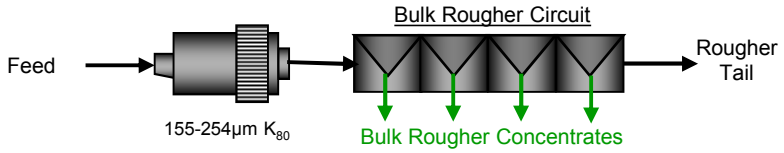
3.0 Flotation Testing – Hypogene Composites

3.1 Rougher Test Results

A total of 14 rougher flotation tests were conducted in this program. The tests were used to establish the initial response of the composites using previously developed flotation conditions. Primary grind size and rougher pH were the two primary variables investigated. A summary of the test conditions and a graphical display of the results are shown in Figure 1. The following conclusions were reached when reviewing the test data:

- The results indicated that there was a negligible effect of primary grind size on copper rougher flotation response over the range of primary grind sizes tested; 150µm to 250µm K_{80}.

- For the hypogene composites, copper in the feed was about 88 to 95 percent recovered into the feed at a rougher mass recovery of about 8 to 10 percent. The performance of the samples appeared to be better than previously tested samples despite lower feed grades*.



- Rougher pH appeared to have an effect on the metallurgical performance. Tests conducted at higher pH had better rougher response curves. It is assumed that the pyrite in the feed was better depressed at higher pH allowing more aggressive copper sulphide flotation.

- Molybdenum recovery to the rougher concentrate was also highly variable. The samples had superior performance when compared to the other composites. Molybdenum was about 80 percent recovered from the feed into the rougher concentrate at 9 percent rougher mass recovery. Molybdenum flotation data is graphically displayed in Appendix IV, Figure IV-1.

- Gold recovery data was not generated for the rougher tests.

* Quantitative mineralogy on ground feed samples should be conducted to determine if the fragmentation properties were more favourable for these samples.

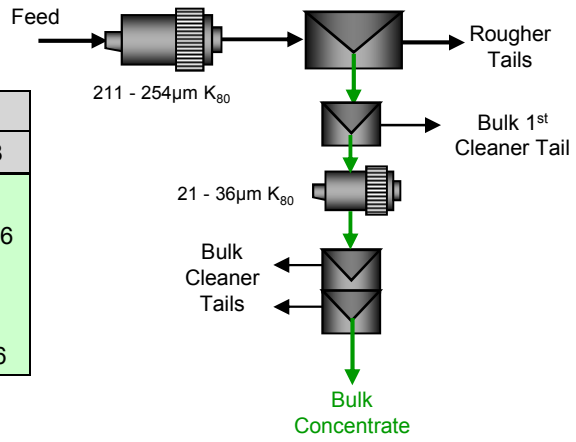
3.2 Cleaner Test Results

Based on the latest flowsheet configuration testing*, batch cleaner test utilized regrind on the first cleaner concentrate. The flowsheet is presented in Figure 2 along with a graphical presentation of the metallurgical results. The tests also investigated a lower pH in the cleaner circuit in an effort to improve molybdenum recovery.

As shown in the top graph of the figure, copper grade and recovery performance was negatively affected by the reduction of pH in the cleaner. For molybdenum, there was no clear benefit to metallurgical performance by operating at a lower pH. It was, therefore, recommended to perform a locked cycle test at pH 11 in the cleaner circuit.



A series of tests on IX Composite were performed to optimize the chemical conditions for the first cleaner regrind (Test 22) and a comparison to rougher regrind (Test 21). Both tests indicated an improvement in metallurgical performance for copper and molybdenum over the baseline test. Test 21 also indicated a slight metallurgical performance gain with the rougher regrind circuit. The operating and capital cost will be higher for the rougher regrind flowsheet compared to the first cleaner regrind circuit. Further testing would be required to confirm these test results.

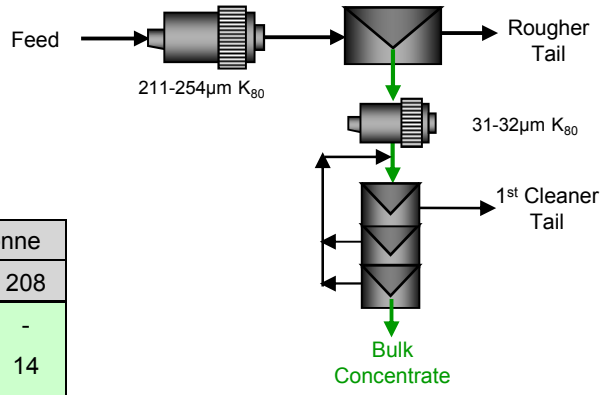
3.3 Locked Cycle Test Results

A series of locked cycle tests were conducted in this program to establish the estimates of metallurgical performance anticipated from a continuous process. Both the first cleaner regrind and rougher regrind flowsheets were tested in locked cycle for all three composites. Figure 3 displays the rougher regrind flowsheet schematic used in these samples, along with a summary of test results.

The first cleaner concentrate regrind data is displayed in Appendix IV, Figure IV-2. Overall the first cleaner regrind cycle tests did not perform as well. The reagent dosages in these tests did not appear to be full optimized as losses of copper were high in the cleaner tailings streams.



Overall, the metallurgical performance of the rougher regrind flowsheet was very good. Copper in the feed was 89.9, 87.2 and 91.9 percent recovered into the bulk concentrate for IX, PP and WR Composites, respectively. The concentrate grades range between 18 and 25 percent copper. The concentrate grades were lower for IX and PP samples due to high levels of molybdenum in the concentrate. The WR Composite was also lower due to higher levels of pyrite*.

Similarly, molybdenum was 78, 79 and 89 percent recovered into the bulk concentrates. Molybdenum grade ranged from 7.5 to 1.5 percent. Finally, gold recoveries ranged from 55 percent to 67 percent to the bulk concentrate.

The apparent use of recently drilled sample has resulted in arguably better overall metallurgical performance. Additional mineralogy on these ground feed samples should be performed to verify that the copper and molybdenum characteristics for these samples are similar to previously tested composites. If the characteristics are the same, this would increase confidence that a gain in metallurgical performance will be realized by treating fresh ore.

* The sulphur grades are high on this concentrate, perhaps indicating higher levels of pyrite.

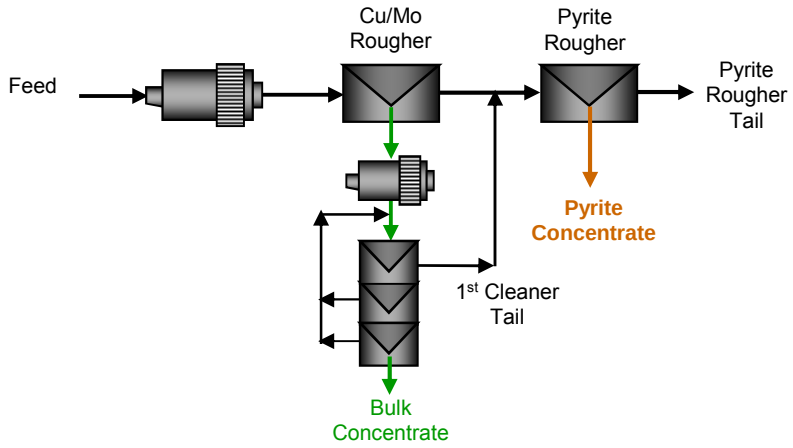
4.0 Pilot Plant Testing

Pilot plant testing was performed on three composites of Casino mineralization. The initial pilot plant calibration was conducted on a composite constructed from old sample from previous programs. The main campaigns were performed on two composites constructed from fresh drill core sample. The samples represented hypogene and supergene mineralization. Pilot runs P2 and P3 were on the PP Hypogene Composite, runs P4 and P5 were completed on the PP Supergene Composite.



The primary objective of the pilot campaign was to produce tailings for environmental studies. Concentrate form the program was also used to investigate separation of copper and molybdenum. The flowsheet used to process the sample is shown in Figure 4, along with a summary of conditions and results.

The primary mill was operated at a nominal 100 kg per hour; copper rougher flotation was performed in 6, 12 litre flotation cells. Pyrite flotation was conducted in another 6, 12 litre cells. Rougher concentrate was reground in a 2 litre IsaMill and graded in a conventional first cleaner and column cell cleaner for stages two and three.

Overall, the performance copper flotation circuit never stabilized. Copper recoveries from the feed to bulk concentrate ranged between 73 and 87; however, the concentrate grades were very low. The concentrates were very high in iron and sulphur, indicating pyrite as the principle diluent.

The pyrite circuit used Potassium Amyl Xanthate (PAX) as the primary collector. The collector dosages were high to produce a low sulphur tailing required for the environmental sample. The PAX dosages were not optimized and it was likely that PAX was recycled to the copper circuit as part of the tailing water recycle. Elevated levels of PAX in the recycle would cause activation and flotation of pyrite in the copper circuit.

5.0 Copper – Molybdenum Separation

The concentrate from the pilot plant was retreated to remove excess pyrite ahead of copper-molybdenum testing. This work was reported in pilot runs P6 to P8. While the concentrate grade improved, the bulk concentrate would be considered low grade.

Despite the lower concentrate grade, the bulk concentrate from the P6 to P8 campaigns was combined and a single cleaner test was conducted to evaluate the copper-molybdenum process. Conventional copper depression with Sodium Hydrosulphide (NaHS) and flotation with nitrogen was conducted. The flowsheet, reagent conditions and metallurgical balance for the test is displayed in Figure 5.

As shown, the concentrate produced contained low levels of copper and was high grade. Molybdenum was 94 percent recovered into a concentrate grading 51 percent molybdenite. This data indicates the molybdenum would respond well to a conventional molybdenum separation process.

6.0 Quality of the Concentrates

The minor element concentrations of the concentrates were measured with element specific analyses to increase the accuracy. The results of the analyses are displayed for the composites tested by locked cycle in Table 2. To have sufficient sample to assay, cycles IV and V were combined. The following comments may be relevant when reviewing the table:

- The bulk concentrates for some composites showed elevated levels of arsenic, lead and zinc. However, none of the levels measured would cause a significant barrier to marketability.

- Silver levels in the bulk concentrate ranged from 82 to 126 g/tonne. At these levels, payment of silver might be possible.

- The molybdenum concentrate was relatively free of deleterious elements. Arsenic, lead and zinc may be elements to reassess when more molybdenum concentrates become available. Rhenium in the concentrate was 134 g/tonne. See Appendix IV-Special Data for the Rhenium Certificate.

- Fluorine assays were not reproducible and therefore not reported. Additional fluorine assays should be conducted when sample becomes available.

- The minor element data should be reviewed by a specialist to provide specific advice on the current concentrate market.

7.0 Conclusions and Recommendations

The testing of three hypogene composites produced very good metallurgical performance, despite relatively low copper feed grades. On average, copper was 90, 87 and 92 percent recovered into bulk concentrates for the IX, PP and WR composites, respectively. The concentrate grades were within expected ranges considering the high levels of molybdenum in the bulk concentrate. The WR Composite had lower concentrate grade perhaps due to pyrite.

Molybdenum was also well recovered to the bulk concentrate at 78, 79 and 89 percent for the IX, PP and WR Composites, respectively. The high relative grade of molybdenum to copper in the feed resulted in concentrates containing between 1.5 and 7.5 percent molybdenum in the concentrate. The gold in the feed was 57, 55 and 67 percent recovered to the bulk concentrates for IX, PP and WR Composites, respectively. These results were in line with previous results.

The metallurgical performance of these fresh drill composites were better than previously tested hypogene composites constructed of old drill core sample. Mineralogical assessment of the ground feed samples is recommended. If the fragmentation properties are similar to previously tested samples performed on old core, this would increase confidence that these latest results should be expected when treating fresh ore.

The best metallurgical results (quoted above) were produced with a rougher regrind flowsheet. The first cleaner concentrate regrind circuit locked cycle tests produced inferior results; however, the tests were not fully optimized for reagents in the cleaner circuit. This first cleaner regrind circuit has lower capital and operating cost and, as previously shown, can provide similar metallurgical results when fully optimized.

The pilot recessing of the hypogene and supergene composites was completed to produce tailings sample for environmental testing. This objective was effectively completed with the addition of a pyrite rougher circuit after the bulk copper-

molybdenum and gold circuit. Tailings samples of each composite were shipped to the required third party testing groups.

Unfortunately, there was insufficient sample to stabilize bulk concentrate production for subsequent copper and molybdenum testing. The concentrate was consistently contaminated with pyrite, resulting in low concentrate grades.

As per normal plant practice, tailings water in the pilot was recycled to the primary grinding mill. The addition of a pyrite recovery circuit and reagent (PAX) to recover pyrite was believed to have been the source of the problem.

In an effort to derive some basic copper-molybdenum separation data, the bulk concentrate was further cleaned to reject pyrite. This concentrate was combined tested using a conventional copper-molybdenum separation process. The results should be used with caution as the bulk concentrate was essentially unrepresentative due to the additional cleaning stages.

APPENDIX I – KM3512

SAMPLE ORIGIN

1.0 Sample Origin

On July 19, 2012, half drill core intervals from several drill holes were received at ALS Metallurgy Kamloops for testing. The total weight of the shipment was approximately 3,524 kg. The drill core was identified by drill hole and sample ID number. Each sample was weighed; Table I-1 displays the details of the samples received and their respective weights.

Based on instructions from the client, select intervals were crushed and screened to 6 mesh in preparation for compositing. Five separate composites were constructed for testing; three hypogene composites for bench testing and two for pilot plant testing. The details of the composite construction are displayed in Table I-2.

Not all of the drill core was used, some intact drill core intervals were retained in storage.

The hypogene composites used for laboratory testing were homogenized and rotary split into 2 kg charges for metallurgical testing. The charges were sealed into plastic bags under nitrogen. These samples were stored frozen until their subsequent use in the test program. Representative head assays of the composites are displayed in Table I-3.

The pilot plant samples were crushed and screened to pass 5 mm. The samples were blended with a mechanical loader using a cone and quartering method. The samples were stored in plastic totes at ambient temperature prior to processing in the pilot plant.

A commissioning composite was constructed from old test sample. This material, approximately 1,353 kg, was used to calibrate the grinding and mass flow rates in the pilot plant.

DATE: August 28, 2012

PROJECT NO: KM3512-01

PURPOSE: Preliminary Rougher Test.

PROCEDURE: Perform a standard one product rougher test.

FEED: 2 kg of PP Composite ore ground to a nominal 178μm K_{80}.

FLOWSHEET: 1

Stage	Reagents Added g/tonne					Time (minutes)			pH
	Lime	Fuel Oil	3418A	208	MIBC	Grind	Cond.	Float	
Primary Grind	2000	10				11			11.1
BULK CIRCUIT:									
Rougher 1	-		2	4	8		1	2	11.0
Rougher 2	√		2	4	-		1	2	11.0
Rougher 3	√		2	4	-		1	2	11.0
Rougher 4	√		1	2	8		1	3	11.0

Flotation Data	Rougher	
Flotation Machine:	D2A	
Cell Size in liters:	4.4	
Aspiration:	Air	
Water Type:	Fresh	
Impeller Speed in rpm:	1100	

Grinding Data	Primary Grind
Mill:	M3-Mild
Charge/Material:	20kg-Mild
Water:	1000 ml

DATE: November 29, 2012

PROJECT NO: KM3512-29

PURPOSE: Preliminary Cleaner Test.

PROCEDURE: Perform a standard one product cleaner test.

FEED: ~1 kg of P6 to P8 Cleaner Concentrate.
Moly Regrind Discharge - 63µm K_{80}.

FLOWSHEET: 2

Stage	Reagents Added g/tonne			Time (minutes)			pH	Redox
	NaHS	Fuel Oil	MIBC	Grind	Cond.	Float		
Natural							8.4	130
MOLY CIRCUIT:								
Rougher 1	1680	20	-		10	11	11.2	-580
Regrind				5			8.9	
Cleaner 1	1400	60	60		7	8	10.7	-580
Cleaner 2	1750	20	60		3	5	10.6	-575
Cleaner 3	1750	12	60		3	3	10.7	-580

Flotation Data	Rougher	Cleaner
Flotation Machine	D2A	D1B
Cell Size in liters	4.4	2.2
Aspiration	N2	
Water Type	Fresh	
Impeller Speed in rpm	1100	1200

Grinding Data	Moly Regrind
Mill:	RM3-Mild
Charge/Material:	6kg-Stainless Steel
Water:	estimated

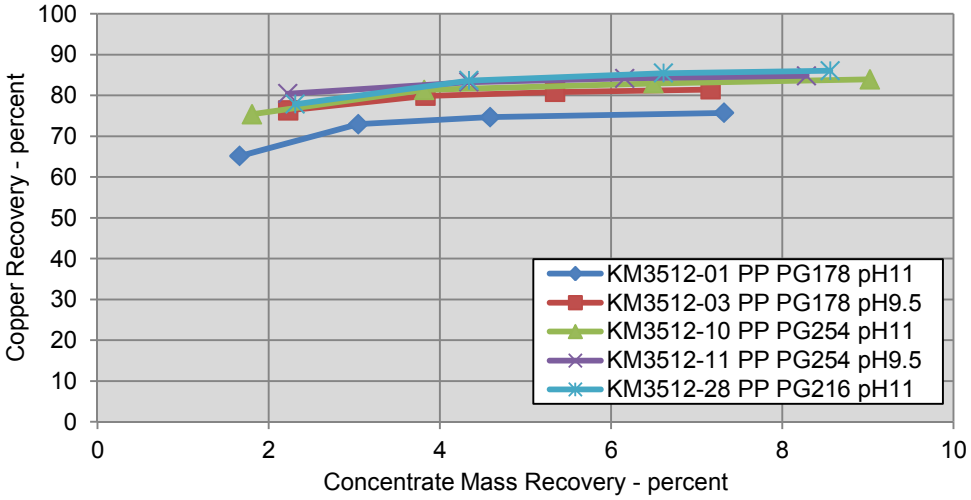
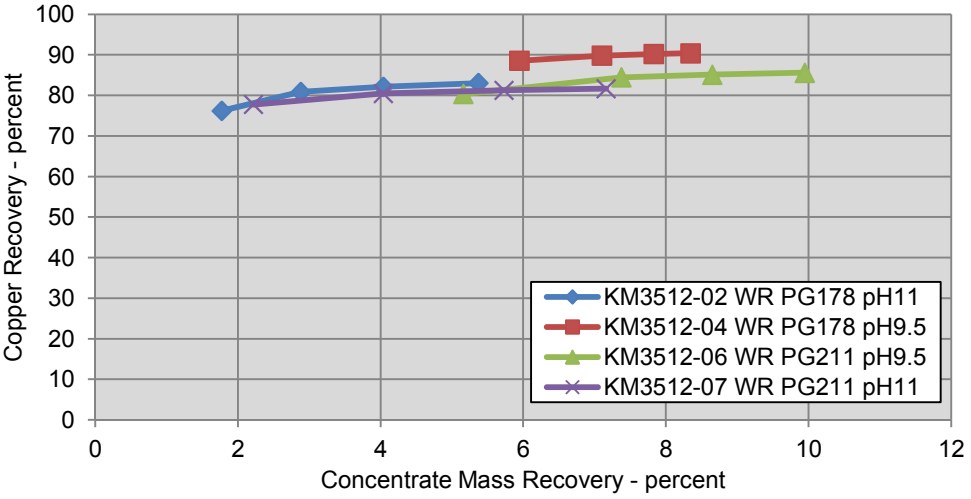
Analytical Methods



CV-AAS	Cold vapour flameless atomic absorption spectrometry
FAAS	Flame atomic absorption spectrometry
ICP-OES	Inductively coupled plasma - optical emission spectroscopy
Leco	Leco induction furnace
ISE	ion selective electrode
Titr	Classical wet method titration

Digestion Methods



2 Acid	Hydrochloric acid and nitric acid
2 Acid*	Hydrochloric acid, nitric acid and potassium chlorate
2 Acid**	Nitric acid and bromine
3 Acid	Hydrochloric acid, nitric acid and perchloric acid
4 Acid	Hydrochloric acid, nitric acid, hydrofluoric acid and perchloric acid
AR	Aqua regia - 3:1 hydrochloric acid:nitric acid
ESHKA	Magnesium oxide, sodium carbonate sinter
FA	Fire assay fusion
Fusion	Sodium peroxide fusion
Leco	Combusion
LeForte rt	Reverse aqua regia - 1:3 hydrochloric acid:nitric acid, at room temperature
WR	Hydrochloric acid, nitric acid and hydrofluoric acid

Mass Start	975	kg	Time Start	7:50	am
Mass Finish	284	kg	Time Finish	15:50	pm
Total Feed	691	kg	Moisture	-	%

Notes:
1. Float Feed Density taken with Marcy Cup and Scale.
2. Sizings reported above are on Operational grab samples.
3. Mill was down from 9:00-9:40 because of sanding in cells.

Grinding Mill Data

Parameters	Rod Mill 1
Mill Dimensions	24" dia x 30" Mild
RPM	As above
Motor HP	3
No Load Power (amps)	Varies with speed
Starting Mill Charge (kg)	180 kg mild steel rods

Notes:
1. Recycled water was used in grinding circuit.

Total Feed	678	kg	Moisture	-	%

Notes:
1. Float Feed Density taken with Marcy Cup and Scale.
2. Sizings reported above are on Operational grab samples.
3. Mill went down at 8:25 and back up at 8:40 because of cells sanding.
4. At 8:40 sped mill up to 1200rpm .
5. At 15:20 ran out of rock.

Grinding Mill Data

Parameters	Rod Mill 1
Mill Dimensions	24" dia x 30" Mild
RPM	As above
Motor HP	3
No Load Power (amps)	Varies with speed
Starting Mill Charge (kg)	180 kg mild steel rods

Notes:
1. Recycled water was used in grinding circuit.

Dr. Paul West-Sells
Senior Metallurgist
Western Copper Corporation
2050 – 1111 West Georgia St.
Vancouver, BC
V6E 4M3

Dear Dr. West-Sells:

Re: Production of Environmental Tailings Samples for the Casino Deposit – KM2459

We are pleased to inform you that a program to produce tailings from samples of the Casino Deposit is now complete. The program was initiated in September 2009 and was completed by November 2009. The tailing samples generated were intended for environmental testing.

Three composites were tested in this program and reportedly represent three ore types from the Casino deposit. The samples for each composite were taken from single drill holes and were provided as half drill core from the 2008 drilling season.

A few standardized batch cleaner tests were performed on each composite using test protocols established in KM2084 "Metallurgical Assessment of the Casino Deposit". Once the performance of the samples was deemed acceptable, additional tests were performed to produce the required tailings samples. The samples were not dried, but shipped to CEMI for environmental testing on November 20, 2009. CEMI will provide an independent report on the environmental testing.

The flotation response of the samples, particularly Composites 2 and 3 was very good. Composite 1 had inferior flotation performance, but available data would suggest this composite may have elevated levels of non-sulphide copper.

There is a possibility that the fresh drill core samples produced better metallurgical response when compared to the data generated in the previous study. This study utilized old samples of drill core. Further mineralogical and flotation testing would be required to verify this hypothesis.

Thank you for choosing G & T Metallurgical for your testing needs. If you have any questions, please don't hesitate to contact us.

Thank you,

Tom Shouldice, P.Eng.

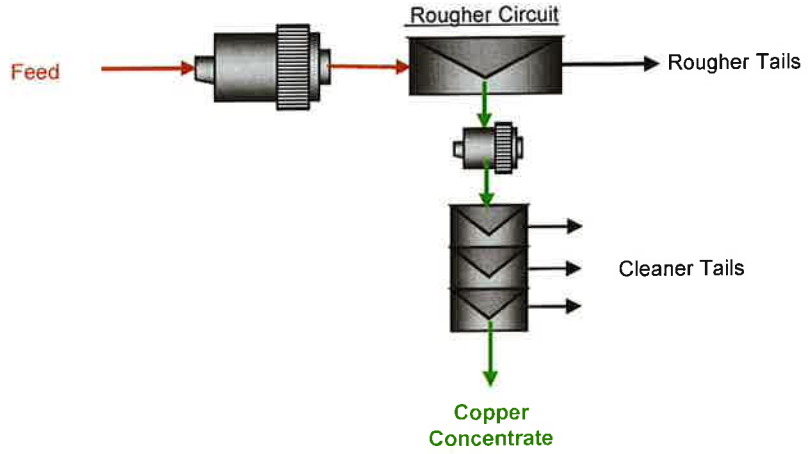
1. Metallurgical Flotation Response



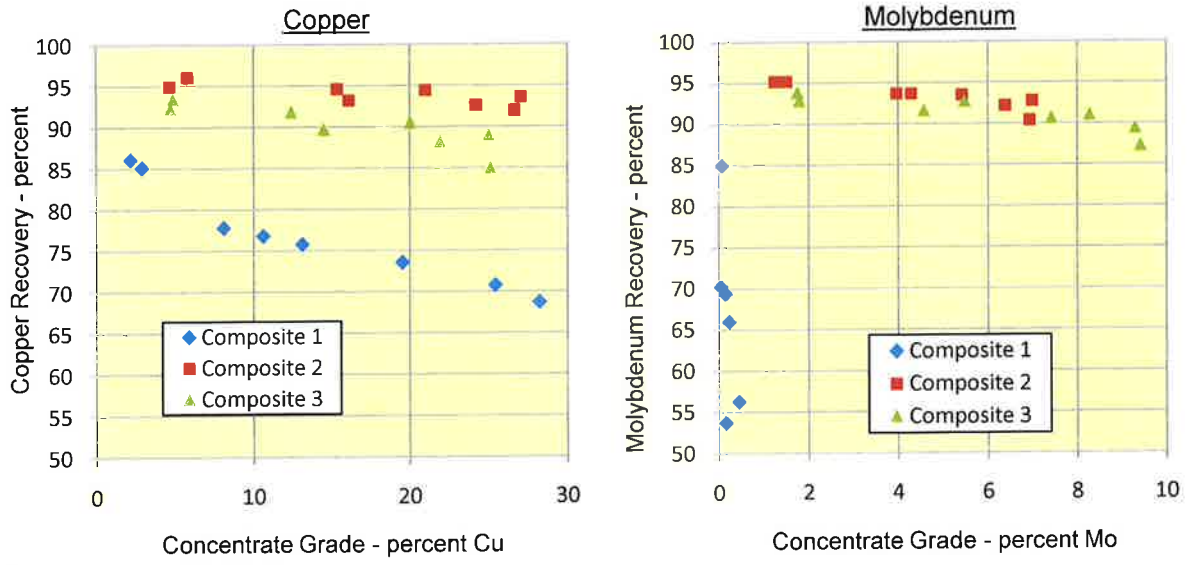
A total of ten batch cleaner tests were performed using conditions previously developed in KM2084. This conventional process utilized a primary grind size of about 150μm K_{80} and regrind size of 30μm K_{80}. The flotation pulp was modulated to pH 11.0 to control the activation and flotation of pyrite. Copper collectors selective against pyrite were also used. Finally, molybdenum in the feed was collected with fuel oil.

Figure 1 displays a schematic of the flowsheet summary of reagents used. Shown at the bottom of the figure are graphs indicating the metallurgical performance of the composites. The following comments may be of interest:

- Composites 2 and 3 performed very well in batch cleaner tests. Composite 2 had 92 percent copper recovery into a concentrate grading about 28 percent copper. Similarly, Composite 3 had 87 percent of the copper in the feed recovered into a concentrate grading 26 percent copper. Molybdenum was also very well recovered into the concentrates for these composites; about 90 percent of the molybdenum was recovered from the feed into the concentrate. Final molybdenum grade was about 7 to 9 percent.

- The flotation performance of Composite 1 was inferior to the other composites. Copper in the feed was about 70 percent recovered into a concentrate grading 28 percent copper. The cause of inferior performance was not determined. However, this sample had elevated levels of weak acid soluble copper, suggesting perhaps non-sulphide forms of copper were contained in this sample.

FIGURE 1
COPPER CLEANER TEST FLOWSHEET AND TEST CONDITIONS
Composite



SUMMARY OF TEST CONDITIONS

Composite	Grind Size um K80		pH	Rougher - g/t			Cleaner - g/t		
	Primary	Regrind		Fuel Oil	3418A	AP208	Fuel Oil	3418A	AP208
1	130	20-29	11	20	7	7	6-26	7-12	7-12
2	166	28-33	11	20	5	5	26	7	7
3	167	30-31	11	20	7	7	26	7	7

Note a) Detailed test data can be found in Appendix III

BATCH CLEANER TEST PEFORMANCE

APPENDIX I – KM2459

SAMPLE ORIGIN

1.0 Sample Origin

Drill core samples from the Casino project were received on August 27, 2009. The samples were received as half drill core; a listing of drill core inventory is displayed in Table I-1.

TABLE I-1
INVENTORY OF DRILL CORE RECEIVED

Composite	Drill Hole	Interval (m)	Mass (kg)
Composite 1	CAS 002	206.10 – 211.06	6.8
	CAS 002	211.06 – 216.94	12.4
	CAS 002	216.33 – 220.59	2.0
Composite 2	CAS 002	632.25 – 636.13	7.5
	CAS 002	637.03 – 640.55	6.1
	CAS 002	640.43 – 643.13	4.4
Composite 3	CAS 003	182.88 – 183.42	3.2
	CAS 003	183.42 – 189.68	16.6
	CAS 003	189.68 – 192.68	8.7

The drill core was stage crushed and prepared into composites as shown in Table I-1. Representative head assay samples were pulverized and assayed for the elements of interest in this project. These assays are summarized in Table I-2. All test charges were kept in the freezer.

EXECUTIVE SUMMARY

Casino Mining Corporation proposes to build an Open Pit copper-gold-molybdenum mine in the southwestern Yukon. The purpose of this report is to identify potential borrow sources to provide construction materials for project facilities at the Mine Site.

All borrow materials must be free of organics, geochemically innocuous, and thaw stable. Based on geochemical characterization by Lorax, it is expected that geochemically innocuous borrow materials can be derived from all areas, except within the proposed Open Pit limits. The materials also have to be well-graded within specified limits, and comply with other requirements that are set for the specific type of borrow material. Borrow sources are not considered feasible if the targeted material is overlain by a thick layer of unsuitable material.

The material quantities required for construction of the mine site were derived from the Feasibility study. The quantity of available borrow materials was derived by assessing the extent of the borrow areas and the thickness of suitable layers using site investigation data.

Borrow sources were identified and evaluated for the following construction materials:

Low Permeability Soils

Residual soils having at least 15% fines are considered potentially suitable for use as low permeability borrow material. The findings from the hydraulic conductivity tests indicate that residual soil needs to have a fines content of at least 20% to provide a sufficiently low permeability (1×10^{-5} cm/s or less). Processing will be required to increase the fines content from 15% to 20%, by removing gravel and cobbles from the borrow material.

The borrow sources contain insufficient low permeability material for construction of the proposed mine site facilities. Alternative methods to mitigate the shortage of low permeability material include addition of bentonite to borrow materials with low fines content, import of Glacial Till from outside the project area, optimisation of the tailings dam design to reduce the size of the low permeability core zone, and redesign the tailings dam using alternative seepage control measures, such as geosynthetic liners and an asphalt core.

Filter and Transition Zone Material

The filter and transition zone materials will comprise sand and gravel with little fines and no cobbles or boulders, in order to satisfy the filter relationship between low permeability soil and coarse material. The primary borrow materials for the filter and transition zones are coarse residual soils and highly weathered bedrock. These materials are present below the low permeability material borrow materials. Locations with surficial residual soils that are too coarse for use as low permeability material may also be suitable filter and transition zone borrow areas.

The coarse residual soils may be supplemented with alluvial channel deposits located in Casino Creek valley. The presence of shallow permafrost in the valley bottom necessitates extensive stripping, melting and stockpiling to provide access to and facilitate drainage of the coarse grained alluvial materials. The coarse alluvium underlying the embankment may be used despite these unfavorable conditions, as all overburden in this area will be excavated to provide a competent dam foundation.

The borrow materials will require screening in order to comply with the grading limits. Rejected material that is too fine may be suitable for use as low permeability material, and particles that are too coarse may be used as general fill. It is recommended that the effects of compaction and high confining stress on the gradation and strength of residual soils are investigated.

The identified borrow sources are expected to contain sufficient filter and transition zone material for construction of the proposed mine site facilities.

General Fill

General fill has to be free draining, durable, coarse grained material. General fill is expected to be sourced primarily from bedrock on site, as well as residual soils and alluvial channel deposits that are too coarse for use as core or filter zone material. Waste rock from the proposed Open Pit may also be used, provided that this material is geochemically innocuous.

Large boulders will have to be removed from general fill to allow for proper compaction. The general fill borrow source is limited to the upper layer of bedrock where the rock can be excavated with modest effort. Unaltered Granodiorite and Quartzite are expected to be suitable rock types for use as general fill. Highly altered Granodiorite and other types of bedrock are not considered for use as general fill, due to the presence of clay minerals and the potential for acid rock drainage and metal leaching.

The identified borrow sources contain sufficient general fill for construction of the mine site facilities.

Aggregates

Aggregates are required for the production of concrete and for use as bedding material in foundations. Samples of fine and coarse aggregates were tested at the Levelton Consultants laboratory in Richmond, B.C., for concrete aggregate suitability as per CSA standard A23.1/2-09.

The alluvial channel deposits that are located on a ridge along the Britannia Creek Access Road were identified as a suitable fine aggregate source. Processing will be required to meet the specified gradations, including removal of material greater than 5mm, and washing to remove fines. The alluvium contained trace organic impurities but within the allowable range specified by the CSA. Petrographic analysis revealed some minerals in the alluvium that have the potential for alkali-aggregate reactivity with Portland cement. However, the mortar bar test indicated a reactivity that is below the specified maximum.

Alluvial channel deposits at Casino Creek are considered less suitable for use as fine aggregate as these are typically frozen or saturated, and contain slightly more organics than the alluvium along Britannia Creek Access Road. It is recommended to conduct test CSA A23.2-8A “Measuring mortar-strength properties of fine aggregate” on alluvial samples to determine the effect of organic impurities on mortar strength.

Field observations suggest that sufficient material may be present at the borrow source along Britannia Creek Access Road to satisfy the fine aggregate requirements for the mine site. Additional site investigations are required to confirm the depth and areal extent of this proposed borrow source, and to determine the variability of this material.

Fresh, unaltered Granodiorite was identified as a suitable source of coarse aggregate. Crushing and screening will be required to satisfy the gradations specified in the CSA. Laboratory tests indicate

that crushed Granodiorite is a durable and sound material that complies with all CSA specifications for coarse aggregate. The aggregate is interpreted to have a low reactivity, however, some minerals were identified that may promote an alkalicarbonate reaction in concrete. The mortar bar test indicated a very low reactivity that is far below the specified maximum. Therefore alkali-reactivity of the Granodiorite is not of concern.

An area with fresh, unaltered Granodiorite approximately 3km to the North of the proposed Gold Ore Stockpile has been identified as a potential borrow source for use as coarse aggregate. This borrow area is expected to provide sufficient coarse aggregate, but additional site investigations are required to determine the extent of this borrow source.

1 – INTRODUCTION

Casino Mining Corporation proposes to build an Open Pit copper-gold-molybdenum mine in the southwestern Yukon. The purpose of this report is to identify potential borrow sources to provide construction materials for project facilities at the Mine Site.

This report provides an overview of general suitability criteria for borrow materials and describes the geotechnical units and conditions encountered on site. The geotechnical units are characterized and their properties are determined based on findings from site investigations and laboratory tests. This information is used to identify potential borrow sources for specific types of construction materials, including low permeability material, filter and transition zone materials, general fill, and aggregates. The available quantities of suitable borrow material are compared to the estimated quantities required for construction of the mine (based on the Feasibility design study) to determine if sufficient materials are available or if additional site investigations or alternatives should be pursued.

The borrow materials assessment is based on previous geotechnical information collected by Knight Piésold (KP) for the mine site area between 1993 and 2013. Details of the previous investigations are available in the following KP reports:

- Report on Preliminary Surficial Geotechnical Investigations (Ref. No. 1831/1, March 1994).
- Data Compilation Report on 1994 Geotechnical and Hydrogeotechnical Investigations (Ref. No. 1832/2, February 1995).
- KP report “2010 Geotechnical Site Investigation Data Report” (Ref. No. VA101-325/3-4, November 2010).
- KP report “2011 Geotechnical Site Investigation Data Report – Plant Site” (Ref. No. VA101-325/8-4, December 2012).
- KP report “2011 Geotechnical Site Investigation Data Report – Waste Management Facilities” (Ref. No. VA101-325/8-5, December 2012).
- KP report “2011 Geomechanical Site Investigation Data Report – Open Pit” (Ref. No. VA101-325/8-6, December 2012).
- KP report “2012 Geotechnical Site Investigation Data Report” (Ref. No. VA101-325/8-14, December 2012).
- KP report “2013 Geotechnical Site Investigation Data Report – Mine Site” (Ref. No. VA101-325/16-1, January 2014).

An overview of the site investigations at the mine site area is presented on Figure A.1 in Appendix A.

2 – GENERAL SUITABILITY CRITERIA AND DERIVATION OF QUANTITIES

Potential borrow sources have been identified based on a comprehensive review of site investigation data collected to date. Soils and rock throughout the mine site area were evaluated using both general criteria and specific requirements for the intended purpose of the borrow source, such as a minimum required fines content for low permeability material. Borrow material must meet the following general criteria to be considered potentially suitable:

- The material shall be free of organic material. Organic material can oxidize over time, potentially causing settlements and leading to preferential seepage paths.
- All materials shall be well-graded within specified limits, gap-graded soils are not acceptable.
- All materials shall be durable.
- The maximum dimension of any particle shall not be greater than two-thirds the required thickness of the layer in which it is to be placed. This requirement is met by removing coarse particles such as cobbles and boulders from the borrow materials, if necessary.
- All frozen materials shall be thaw stable. Frozen soils are thaw unstable if the amount of ice present will produce more water upon thawing than can be held in the voids. Thaw unstable soils are unsuitable as melting ice results in loss of soil strength and difficult handling. The soil is considered thaw stable if all the melt water can be absorbed by the soil voids without significant settlement and loss of strength.
- All materials shall be geochemically innocuous. Geochemical test results indicate that there is some potential for metal leaching (ML) and acid rock drainage (ARD) from borrow materials in the Open Pit area and low to no ML/ARD potential from other areas (Lorax, 2014). Based on these findings, it is expected that geochemically innocuous borrow materials can be derived from all areas, except within the proposed Open Pit limits. Lorax recommends implementation of a ML/ARD Management Plan to be developed prior to excavation of the borrow sources to confirm suitability.

Additionally, potential borrow sources are rejected if excessive amounts of unsuitable material overlie the targeted borrow material. The thickness of the potential borrow material has to be greater than the overlying unsuitable material in order to be acceptable.

The material quantities required for the construction of the mine site are derived from the Feasibility study. The majority of the earthworks at the mine site are required for the Tailings Management Facility and the Heap Leach Facility. Additional information on the material requirements for construction of the mine site facilities is provided in the following reports:

- M3 Engineering and Technology Corporation, “Casino Project Feasibiltiy Study Volume II”, January 2013.
- KP report “Report on Feasibility Design of the Tailings Management Facility” (Ref. No. VA101-325/8-10, December 2012).
- KP report “Feasibility Design of the Heap Leach Facility” (Ref. No. VA101-325/8-9, December 2012).

The quantity of available borrow materials was derived by identifying potentially suitable areas using the results of terrain mapping. These areas were assessed in detail by studying site investigation data (primarily drillhole and test pits logs) and laboratory test results. This was used to determine the extent of the borrow areas, the thickness of suitable layers, and the thickness of overlying unsuitable soil requiring excavation.

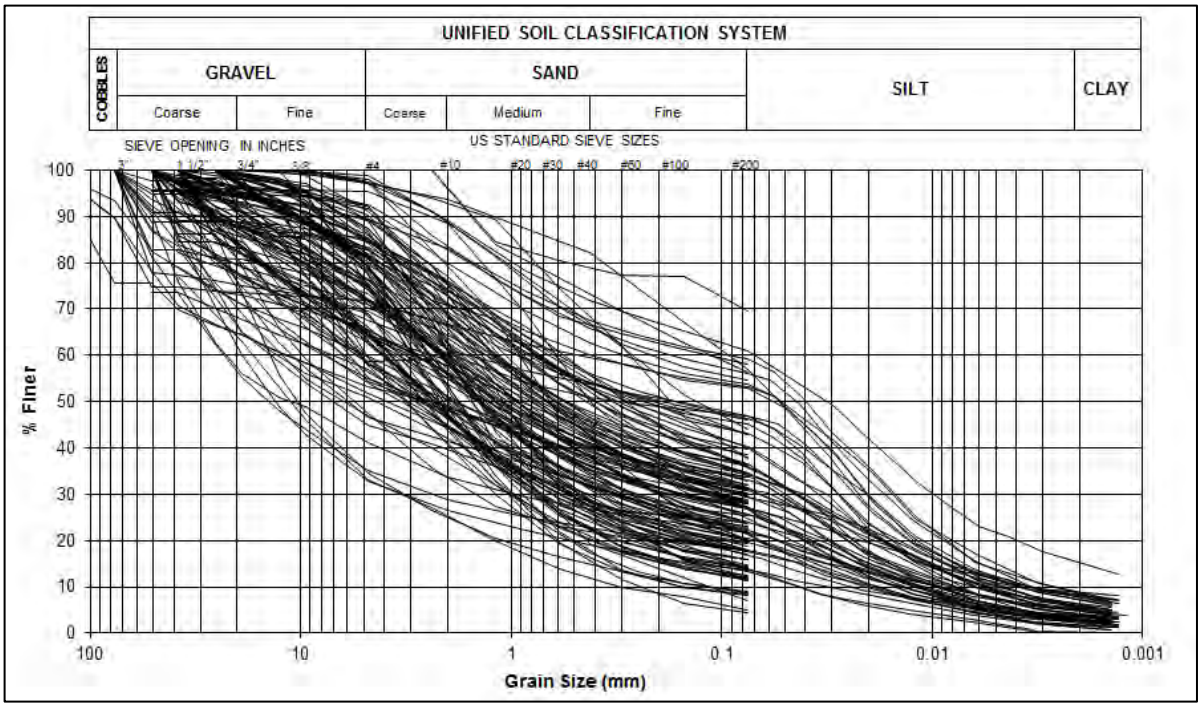
3 – GEOTECHNICAL CHARACTERIZATION

This section provides an overview of the geotechnical conditions encountered at the Mine Site. The geotechnical units are defined and their characteristics and properties are discussed, including the findings of laboratory index tests and hydraulic conductivity tests. Geotechnical units at the site include topsoil, colluvium, residual soil, alluvium and bedrock. Considerations for permafrost and frost susceptibility are also discussed.

3.1 GEOTECHNICAL UNITS

3.1.1 Topsoil

The composition of the topsoil varies throughout the Mine Site area. It is generally silty, and has a high organic content with peaty layers, roots, and plant remains. The high organic content makes topsoil unsuitable for use as a construction material. Topsoil should be carefully stripped from borrow sources and stockpiled for use in reclamation.



3.1.2 Colluvium

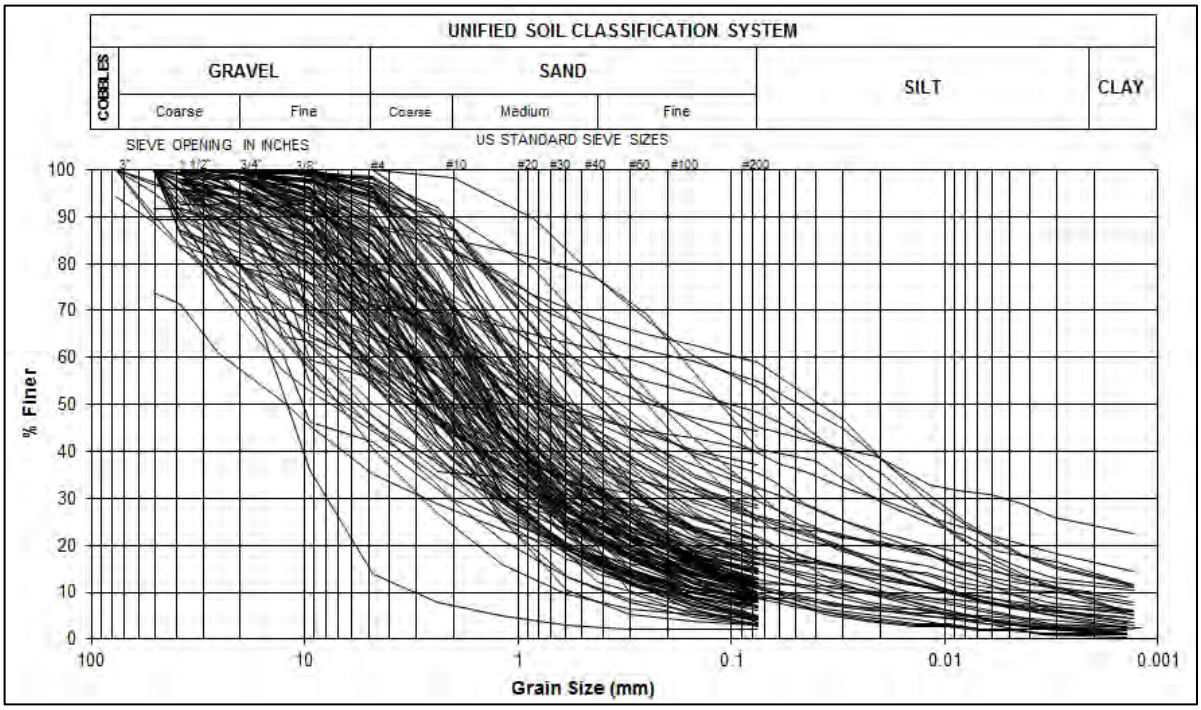
Surficial colluvium is typically found along the slopes of valleys. The colluvium is thin along the upper part of particularly south facing slopes, and generally absent on ridges where residual soils predominate.

The colluvium veneer along the slopes of Casino Creek valley comprises a fine to medium grained sand with some silt supporting coarse gravel and cobble sized broken rock fragments. The thickness generally increases down-slope. On North facing slopes, the colluvial veneer is mostly frozen and ice-rich, and not considered to be a suitable borrow source. Some of the colluvial veneer on south facing slopes may be suitable for use as borrow material. However, the nature of colluvium, i.e. material that has been transported down slopes, causes local variations in the composition. The downslope migration also causes organic material to be included at some locations. The organic content generally increases down-slope. Colluvial veneer is not considered as a potential borrow material in this assessment, due to its inherent variability and organic inclusions.

The colluvial material located towards the valley bottom, where the slope is gentler, is classified as colluvial apron. In the Casino Creek valley the colluvial apron is organic-rich, saturated and frozen, and is not suitable for use as borrow material. The colluvium at the base of the slopes in the Open Pit area consists of coarse blocky talus (scree).

The gradations of colluvium samples collected during previous site investigations are presented in Figure 3.1.

NOTES:



1. Cobbles and boulders are excluded from samples.

Figure 3.1 Gradations of Colluvium

3.1.3 Residual Soil

Residual soils typically comprise heavily weathered, iron oxidized and decomposed sand with some fine gravel and silt. The material is derived from in-situ weathering of host granodiorite bedrock. Weathering is dominated by frost action rather than chemical weathering, and as a result little clay is present. The residual soils coarsen with depth to broken rock as the weathering processes decrease. The material is locally silt rich due to windblown loess enrichment. Residual soils are mainly present along ridges at higher elevations and along the upper parts of some slopes, with thicknesses of less than five meters. Residual soils are locally thicker in the Open Pit area, due to the presence of alteration zones and preferential weathering along shear and fault structures. Residual soils are considered to be a potentially suitable borrow source.

The gradations of residual soil samples collected during previous site investigations are presented in Figure 3.2.

NOTES:

1. Cobbles and boulders are excluded from samples.

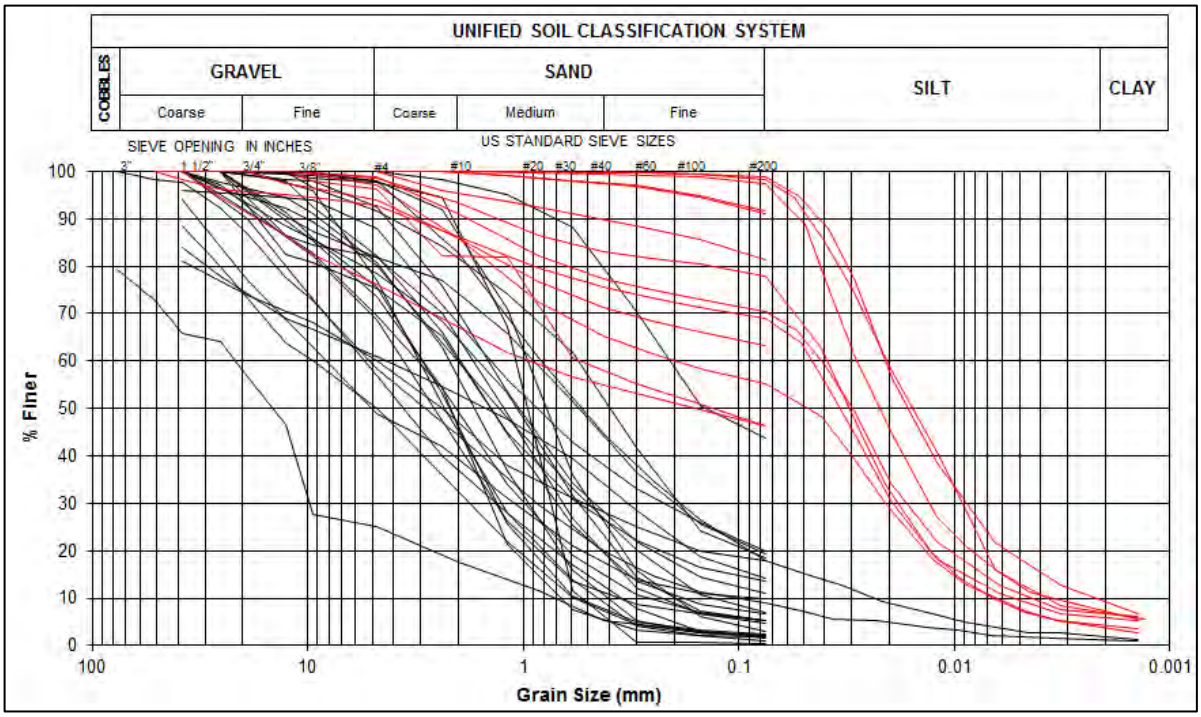


Figure 3.2 Gradations of Residual Soil

3.1.4 Alluvium

Alluvial materials in the project area are found adjacent to creeks in valley bottoms. The alluvium near Casino Creek is coarse grained and comprises interbedded sands and gravelly sands with cobbles and small boulders, and is classified as an alluvial channel deposit. These coarse materials are typically overlain by alluvial flood deposits comprising interbedded ice-rich silts, peats and sandy gravels. In tributary valleys the alluvium is generally present at surface and consists of stratified fine grained sands and silts that are ice-rich or saturated.

The alluvial flood deposits are considered unsuitable for use as construction materials due to interbedded organic layers, and thaw unstable behaviour due to a high ice content. The channel deposits are typically frozen or saturated but the free draining nature of this material makes it a potentially suitable borrow material. Organic matter has occasionally been observed in the channel deposits as a result of historical meandering of the stream; any material containing organic matter should be discarded. The alluvial channel deposits are typically over five metres thick in the vicinity of Casino Creek.

The gradations of alluvial flood deposits and channel deposits sampled during previous site investigations are presented in Figure 3.3.

NOTES:

1. Cobbles and boulders are excluded from samples.
2. Alluvial channel deposits indicated in black.
3. Alluvial floodplain deposits indicated in red.

Figure 3.3 Gradations of Alluvium

3.1.5 Bedrock

Bedrock in and surrounding Casino Creek valley comprises primarily Dawson Range Granodiorite, with minor quartz Diorite. Some quartzite and gneiss of the older Yukon Metamorphic complex were encountered as well. The depth to bedrock is typically between 1 to 4 m along slopes and ridges of the valley, where it is overlain by residual soils and colluvium. Depths to bedrock of over 20m are present in the valley bottom.

Bedrock in the deposit area comprises Granodiorite, Quartz Monzonite, Patton Porphyry (dacite) and latite breccias. Depth to bedrock varies considerably due to local variations in preferential weathering along shear, alteration and fault zones.

3.2 INDEX PROPERTIES

The database with lab test results for each geotechnical overburden unit is included in Appendix B. A summary of the index properties is presented in Table 3.1. The median values are used to characterize the geotechnical units, as certain conditions may skew the properties' average. For example, ice-rich frozen soils have very high moisture contents (over 100%), leading to unrepresentative average values.

Table 3.1 Summary of Index Tests

Sample ID	Moisture Content	Specific Gravity	Organic Content	Atterberg Limits			Particle Size Distribution				Modified Proctor Compaction	
				LL	PL	PI	% Gravel	% Sand	% Silt	% Clay	Maximum Dry Density (tonne/m^3)	Optimum Moisture Content (%)
Colluvium	12.4	2.70	6.3	23.0	19.0	4.0	25	46	25	4	2.13	7.0
Residual Soil	9.2	2.69	2.2	24.0	18.0	6.0	24	62	11	3	2.03	9.7
Alluvium – Channel Deposits	13.3	-	4.8	NP	NP	NP	23	68	8	1	-	-
Alluvium – Floodplain Deposits	34.8	2.71	4.4	25.0	22.0	3.0	3	22	69	6	-	-

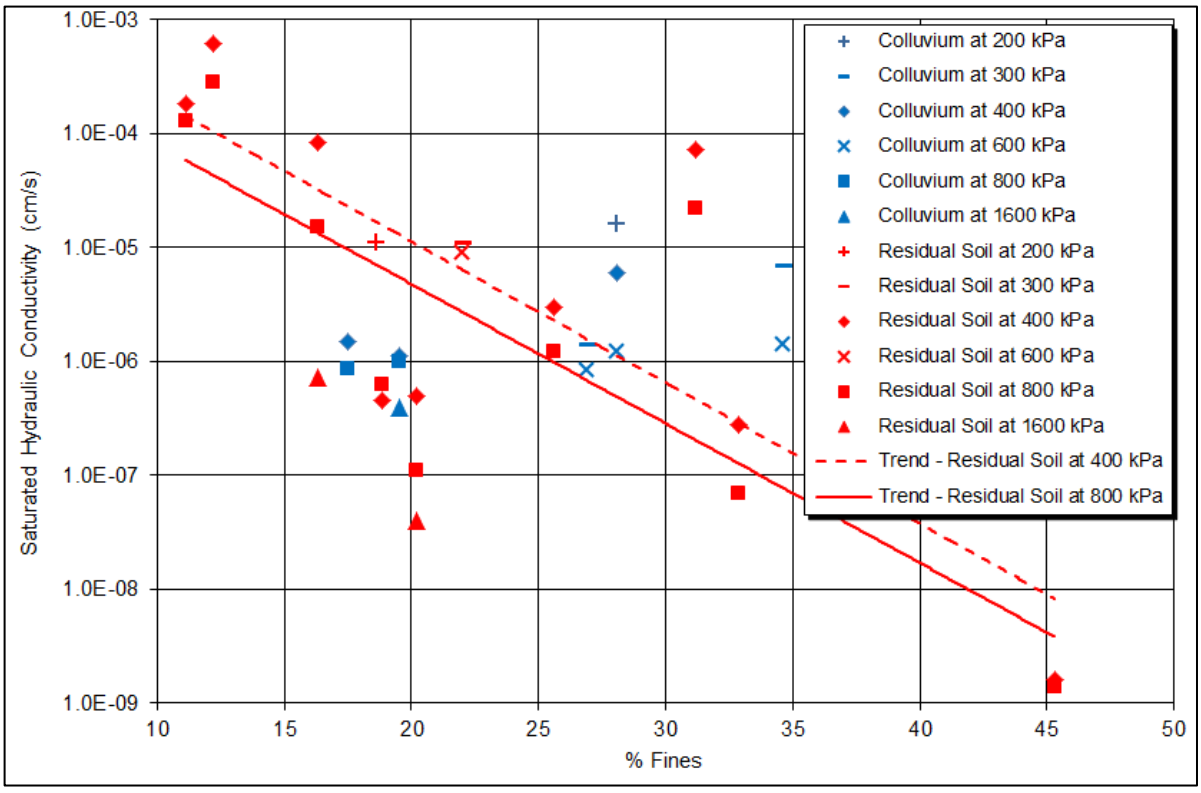
NOTES:

1. Median values reported.
2. Particle Size Distribution by percent of sample weight. Cobbles and boulders removed from samples.
3. NP = Non Plastic, LL= Liquid Limit, PL = Plastic Limit, PI = Plasticity Index.
4. Modified proctor includes an oversize correction as per ASTM D4718.

The values in Table 3.1 confirm that residual soils contain little organic matter. Colluvium has the highest organic content due to intermixing of the topsoil layer. All soil types are non-plastic to low plasticity, and contain only trace clay. The residual soils have a natural moisture content that is typically slightly below optimum, which indicates favorable conditions to achieve compaction. Colluvium has a natural moisture content several percent above the optimum moisture content, which is less favorable.

3.3 HYDRAULIC CONDUCTIVITY

Saturated hydraulic conductivity testing was completed between 2010 and 2013 on selected samples in the Knight Piésold soil laboratory in Denver, Colorado. The tests were conducted on colluvial and residual soils using a flexible wall permeameter. The results are presented on Figure 3.4.



Residual soil samples compacted to 95% Standard Proctor Maximum Dry Density (SPMDD) have saturated hydraulic conductivity values ranging from approximately 1×10^{-3} cm/s (low fines content) to 1×10^{-9} cm/s (high fines content), depending on material gradation and confining pressure. The saturated hydraulic conductivity of the colluvium ranges from 5×10^{-5} cm/s to 5×10^{-7} cm/s for 95% SPMDD.

The saturated hydraulic conductivity of residual soil generally decreases with increasing fines content. This trend is not observed for the colluvial samples.

Tests in which the same sample was subjected to various levels of confining stress indicate a reduction in hydraulic conductivity for higher stress levels. The trend line in Figure 3.4 indicates that residual soils with 20% fines have a saturated hydraulic conductivity of approximately 1×10^{-5} cm/s at 400 kPa, reducing by about half an order of magnitude at 800 kPa.

A common specification for embankment core zone and soil liner materials is compaction to 95% SPMDD. Laboratory tests indicate that increasing the compaction to 98% SPMDD leads to a

small reduction in permeability (less than half an order of magnitude). Proctor tests conducted on residual soils in 1993 indicate that compaction may result in particle crushing. It is recommended that the effects of compaction and high confining stress on the gradation and strength of the residual soils be investigated in more detail.

NOTES:

1. Fines are defined as material passing the #200 sieve (0.075 mm).
2. All samples are compacted to 95% Standard Proctor Maximum Dry Density.

Figure 3.4 Saturated Hydraulic Conductivity for Colluvium and Residual Soil

The findings from the hydraulic conductivity tests indicate that residual soil with a fines content of at least 20% is suitable for use as low permeability borrow material (1 x 10^{-5} cm/s or less). Applications of low permeability materials at low confining stresses may require residual soil with a higher fines content. Alternatively, the residual soil may be enriched with bentonite to reduce the permeability. This has been done for the Charlot River Dam, where the addition of 3% bentonite by weight to the silty sand core material decreased the permeability by one order of magnitude (Solymar and Nunn, 1983). Controlled mixing of the bentonite and silty sand proved difficult during construction, and additional studies will be required if admixing bentonite is pursued.

3.4 PERMAFROST AND FROST SUSCEPTIBILITY

Frost susceptible soils can display frost heaving and thaw weakening behaviour. Frost heaving is the result of ice segregation during the freezing process and the formation of alternating bands of soil and ice. Thaw weakening occurs when these ice bands melt, providing an excess of water. When

this water cannot escape due to remaining frozen layers or low permeability soil, excess pore pressures build up causing a reduction in soil strength. Frost heave and thaw weakening can cause differential settlements, instability, increase in void ratio, and preferential seepage paths.

The frost susceptibility classification is based on the guidelines by the U.S. Army Corps of Engineers (Johnson et al., 1986). Gravels with less than 1.5% finer than 0.02mm and sands with less than 3% finer than 0.02mm are classified to have negligible to low frost susceptibility. All other soils have a wide range of possible frost susceptibility, with a tendency to be more frost susceptible for higher fines content. A frost heave laboratory test can be performed when precise information on soil frost susceptibility is required. As a first approximation, soils having more than 10% of material passing the #200 sieve (0.075mm) can be assumed frost susceptible (Barker and Thomas, 2013).

Most natural soils present on site are frost susceptible, based on the above criteria. Soils that contain sufficient moisture are likely to accumulate excess ice when they freeze, and may become thaw unstable. Excess ice has been observed in all geotechnical units present on site. Thaw unstable soils are unsuitable for use as borrow material as they lose strength when they are allowed to thaw before placement, which may result in instability. Areas with permafrost are therefore less likely to provide suitable borrow material.

Permafrost is extensive yet discontinuous in the Casino mine site area. In Casino Creek valley, it is primarily present in the valley bottom and along North facing slopes. Permafrost is also prevalent in the Plant Site and Open Pit areas. The most suitable locations for borrow materials are typically permafrost-free areas located on south facing slopes and hilltops.

Frost heaving and thaw weakening may occur in frost susceptible borrow materials after final placement as a construction material. Measures to mitigate or prevent frost heave effects include:

- Apply a cover of insulation or non-frost susceptible material to the depth of frost penetration,
- Limit the supply of water to the freezing front using drainage measures,
- Apply a surcharge pressure to prevent or reduce frost heave to tolerable levels, and
- Limit the construction season to select months in order to reduce the effects of seasonal frost.

Care should be taken in handling and stockpiling frost susceptible materials to avoid saturation and freezing of these materials. A comprehensive strategy to mitigate frost heave effects will be developed as part of detailed design.

4 – LOW PERMEABILITY SOIL

4.1 CRITERIA

The following criteria have been used to determine suitability for use as low permeability borrow material, in addition to the general criteria presented in Section 2:

- Material shall have at least 15% fines. Laboratory tests have indicated that residual soil is required to have at least 20% fines to have a sufficiently low permeability. However, the fines content can be increased by removing the coarse fraction of the borrow material. The coarse material may be suitable for use as filter material or general fill.
- Material shall be close to or dry of optimum moisture content. Limited moisture conditioning of soils containing fines is possible, however, it is problematic and impractical to drain and dry the soil due to its low permeability. Wet and saturated soil is considered unsuitable as a low permeability material, as well as thaw unstable (ice-rich) frozen soils.

4.2 POTENTIAL BORROW AREAS

A common borrow source for low permeability soils in Canada is glacial till. However, the Casino mine site was not glaciated during the Wisconsin advance and consequently no till is present in the area. Residual soil was identified as an alternative source for low permeability borrow material, provided sufficient fines are present. Colluvium is not considered to be suitable due to its inherent variability and organic inclusions. Alluvial channel deposits are also not considered for this purpose as these primarily comprise coarse grained soils. Alluvial floodplain deposits are fine grained but contain organics and are ice-rich or saturated.

Areas with fine grained residual soils that meet the criteria were identified as potential sources for low permeability borrow material, and are presented on Figure A.2 in Appendix A.

4.3 QUANTITIES

The estimated quantity of low permeability material that is required for construction of the proposed mine site facilities is summarized in Table 4.1. The material is mainly required for the core zone of the proposed tailings dam. Low permeability borrow is also required for the soil liner of the proposed Heap Leach Facility, although in much smaller quantities. The total amount required for construction of the proposed mine site facilities is approximately 11.2 Mm^3.

Table 4.1 Required Quantity of Low Permeability Material

Line Item	Volume (m^3)
Tailings Management Facility – Starter Dam	3,400,000
Tailings Management Facility – Final Dam (excluding Starter Dam)	6,800,000
Heap Leach Facility	530,000
Miscellaneous (allowance for small ponds and other structures)	500,000
Total Required	**11,230,000**

NOTES:
1. Includes 10% overbuild.

The borrow material assessment indicates that approximately 4,600,000 m^3 of suitable low permeability material is present in the mine site area. Processing is required for some of this material to increase the fines content from 15% to 20%. This may be achieved by removing gravel and cobbles from the soil, i.e. any material greater than the #4 sieve (4.75mm). Removing the coarse fraction leads to a reduction of the available quantity of borrow material by approximately 20% to 3,700,000 m^3.

The available quantity of low permeability material is presented in Table 4.2. This table also includes the amount of unsuitable material that is overlying the intended borrow source, including topsoil and colluvium. The amount of unsuitable material that needs to be removed is relatively large compared to the quantity of borrow material. This is due to the relatively thin layer of fine grained residual soil (average between 1.5 and 2 meter thick), leading to a large disturbance area.

Table 4.2 Available Quantity of Low Permeability Material

Line Item	Volume (m^3)
Suitable Low Permeability Material – Fine Grained Residual Soil	3,700,000
Total Available	**3,700,000**
Overlying Unsuitable Material - to be removed	1,700,000

NOTES:
1. Assumes removal of coarse material (20% by weight) to produce suitable low permeability material

The borrow sources contain insufficient low permeability material for construction of the proposed project facilities at the Mine Site. The available quantities are slightly less than the amount required to construct the proposed Stage 1 (starter) dam of the Tailings Management Facility and the soil liner for the Heap Leach Facility.

4.4 METHODS TO MITIGATE SHORTAGE OF LOW PERMEABILITY MATERIAL

The site investigations completed to date have covered most of the mine site, as illustrated in Figure A.1 in Appendix A. Additional borrow areas may be explored outside the mine site area, but these will have longer hauling distances. Alternative methods to mitigate the shortage of low permeability material may be more cost-effective or have other benefits (for example, the alternative may use non-frost susceptible materials). These alternatives include:

- Addition of bentonite to the low permeability material, as described in Section 3.3, thereby lowering the required fines content and increasing the amount of suitable material.
- Use Glacial Till from other locations as low permeability material. Bond and Lipovsky (2011) indicate localized glacial deposits near Mount Cockfield, approximately 20km straight line distance from the mine site area. These are likely the glacial deposits that are closest to the mine site. The suitability of these glacial deposits has not been assessed to date.
- Optimise the tailings dam design to reduce the size of the low permeability core zone.
- Redesign the tailings dam using seepage control measures other than an earthfill core, such as:
  - Geosynthetic liners
  - Asphalt core

5 – FILTER AND TRANSITION ZONE MATERIAL

5.1 CRITERIA

One or more filter and transition zones are required to avoid migration of fines from low permeability material to adjacent coarse material (such as the shell zone in the embankment dam). The primary requirement for this material is to provide a filter relationship between the low permeability soil and the coarse material, in addition to general borrow material requirements.

The filter and transition zone materials will comprise sand and gravel with little fines and no cobbles or boulders, in order to satisfy the filter relationship. Grading limits have not been specified at this stage and will be established during detailed design.

5.2 POTENTIAL BORROW AREAS

The borrow sources for the filter and transition zones are expected to be coarse residual soils and highly weathered bedrock, or alluvial channel deposits comprising sands, gravels and cobbles in valley bottoms. These materials will require screening in order to comply with the grading limits. Rejected material that is too fine may be suitable for use as low permeability material, and particles that are too coarse may be used as general fill.

Historical laboratory test work indicates that compaction of residual soils may result in particle crushing. It is recommended that the effects of compaction and high confining stress on the gradation and strength of residual soils are investigated, to confirm suitability for use as filter material.

The primary source of coarse alluvial channel deposits is located in Casino Creek valley. The presence of shallow permafrost in the valley bottom necessitates extensive stripping, melting and stockpiling to provide access to and facilitate drainage of the coarse grained alluvial materials. These unfavorable conditions make alluvial channel deposits an unattractive borrow source for the majority of Casino Creek valley. The coarse alluvium underlying the embankment may be used despite these unfavorable conditions, as all overburden in this area must be excavated to provide a competent dam foundation.

The residual soils that are present on site are generally coarsening with depth, as the degree of weathering decreases. Coarse residual soils and highly weathered bedrock that are suitable for use as filter and transition zone materials are therefore present below the low permeability material borrow sources. Locations with surficial residual soils that are too coarse for use as low permeability material may also be suitable filter and transition zone borrow areas.

The locations of filter and transition zone borrow areas are presented on Figure A.3 in Appendix A. Materials in the proposed Open Pit area have not been considered due to their ML/ARD potential.

5.3 QUANTITIES

An estimate of filter and transition zone material that is required for the construction of the mine is provided in Table 5.1. The material is mainly used for the filter and transition zone of the tailings dam, and overliner material for the Heap Leach Facility. The total amount required for construction of the mine is approximately 3.6 Mm^3.

Table 5.1 Required Quantity of Filter and Transition Zone Material

Line Item	Volume (m^3)
Tailings Management Facility – Starter Dam	250,000
Tailings Management Facility – Final Dam (excluding Starter Dam)	1,350,000
Heap Leach Facility	1,840,000
Miscellaneous (allowance for small ponds and other structures)	200,000
Total Required	**3,640,000**

NOTES:
1. Includes 10% overbuild.

The available quantity of filter and transition zone material is presented in Table 5.2. It is estimated that on average at least one meter of suitable filter and transition material is present in the identified borrow areas with residual soils and highly weathered bedrock. The coarse grained alluvium in the valley bottom is also estimated to comprise on average at least one meter of suitable filter and transition zone material.

Table 5.2 also includes the amount of unsuitable material in the borrow areas. Unsuitable material that was already listed as part of the low permeability material has been excluded from Table 5.2.

The identified borrow sources contain sufficient filter and transition zone material for construction of the mine.

Table 5.2 Available Quantity of Filter and Transition Zone Material

Line Item	Volume (m^3)
Suitable Filter and Transition Zone Material – Coarse Grained Residual Soil	6,440,000
Suitable Filter and Transition Zone Material – Coarse Grained Alluvial Soil below Tailings Dam	60,000
Total Available	**6,500,000**
Overlying Unsuitable Material - to be removed (1)	3,000,000

NOTES:
1. Excluding unsuitable materials that are to be removed from low permeability borrow areas (Table 4.2).

6 – GENERAL FILL

6.1 CRITERIA

General fill has to be free draining, in addition to the general requirements presented in Section 2. This is achieved by limiting the fines content to a maximum of 10% by weight.

6.2 POTENTIAL BORROW AREAS

General fill is expected to be sourced primarily from bedrock on site, as well as residual soils and alluvial channel deposits that are too coarse for use as core or filter zone materials. Waste rock from the proposed Open Pit may also be used, provided that this material is geochemically innocuous.

The general fill is sourced from the same borrow areas as the filter and transition zone material, as presented on Figure A.3 in Appendix A. A small amount of general fill is expected to be obtained from the alluvial channel deposits underlying the tailings dam. The main sources of general fill are the coarse residual soils and fractured bedrock underlying the filter borrow material. Large boulders will have to be removed from general fill to allow for proper compaction. Competent bedrock with few joints and fractures may be suitable, but would require costly methods such as drilling and blasting to remove the rock and to reduce it to an acceptable size. The general fill borrow source is therefore limited to the upper layer of bedrock where the rock can be excavated with modest effort. Unaltered Granodiorite and Quartzite are expected to be suitable rock types for use as general fill. Highly altered Granodiorite and other types of bedrock are not considered for use as general fill, due to the presence of clay minerals and the potential for acid rock drainage and metal leaching.

6.3 QUANTITIES

The required quantity of general fill is provided in Table 6.1. General fill is mainly required for construction of the shell zone of the starter dam. The shell zone of the final dam is made of cyclone sand. A contingency of 1,000,000 m^3 of general fill is included to compensate any shortfall of cyclone sand. A substantial amount of general fill is required for embankments, ponds and grading at the Heap Leach Facility. The total amount required for construction of the proposed mine site facilities is approximately 11.1 Mm^3.

Table 6.1 Required Quantity of General Fill Material

Line Item	Volume (m^3)
Tailings Management Facility – Starter Dam	7,300,000
Tailings Management Facility – Contingency for Shortfall of Cyclone Sand	1,000,000
Heap Leach Facility	2,290,000
Miscellaneous (allowance for small ponds and other structures)	500,000
Total Required	**11,090,000**

NOTES:
1. Includes 10% overbuild.

The available quantity of general fill borrow material is presented in Table 6.2. The quantity is determined using an estimated five meters of suitable residual soils and bedrock. The coarse grained alluvium in the valley bottom is estimated to comprise at least three meters of suitable general fill.

The quantities were determined assuming no general fill would be sourced from the proposed Open Pit area, as this material has potential for ML/ARD.

Unsuitable material overlying the targeted borrow materials are already included as part of the low permeability and filter borrow materials presented in Table 4.2 and Table 5.2.

The identified borrow sources contain sufficient general fill for construction of the proposed mine site facilities.

Table 6.2 Available Quantity of General Fill Material

Line Item	Volume (m^3)
Suitable General Fill Material – Coarse Grained Residual Soil	32,190,000
Suitable General Fill Material – Coarse Grained Alluvial Soil below Tailings Dam	180,000
Total Available	**32,370,000**

NOTES:

1. For unsuitable materials that are to be removed, refer to Table 4.2 and Table 5.2.

7 – AGGREGATE

7.1 CRITERIA

Aggregates are required for the production of concrete and for use as bedding material in foundations. Canadian Standard Association (CSA) standard A23.1/2-09 provides criteria for concrete aggregate, and standard test methods to determine the aggregate properties. The standard includes specific requirements for fine and coarse aggregates. Materials are tested to determine properties including the particle size distribution, density, organic impurities, durability, and petrographic examination for deleterious substances. Coarse aggregates that are suitable for concrete production are also suitable for bedding material (structural fill) in foundations. Similarly, fine concrete aggregate can also be used as bedding sand. The concrete aggregate criteria and corresponding laboratory test results are presented in Section 7.3.

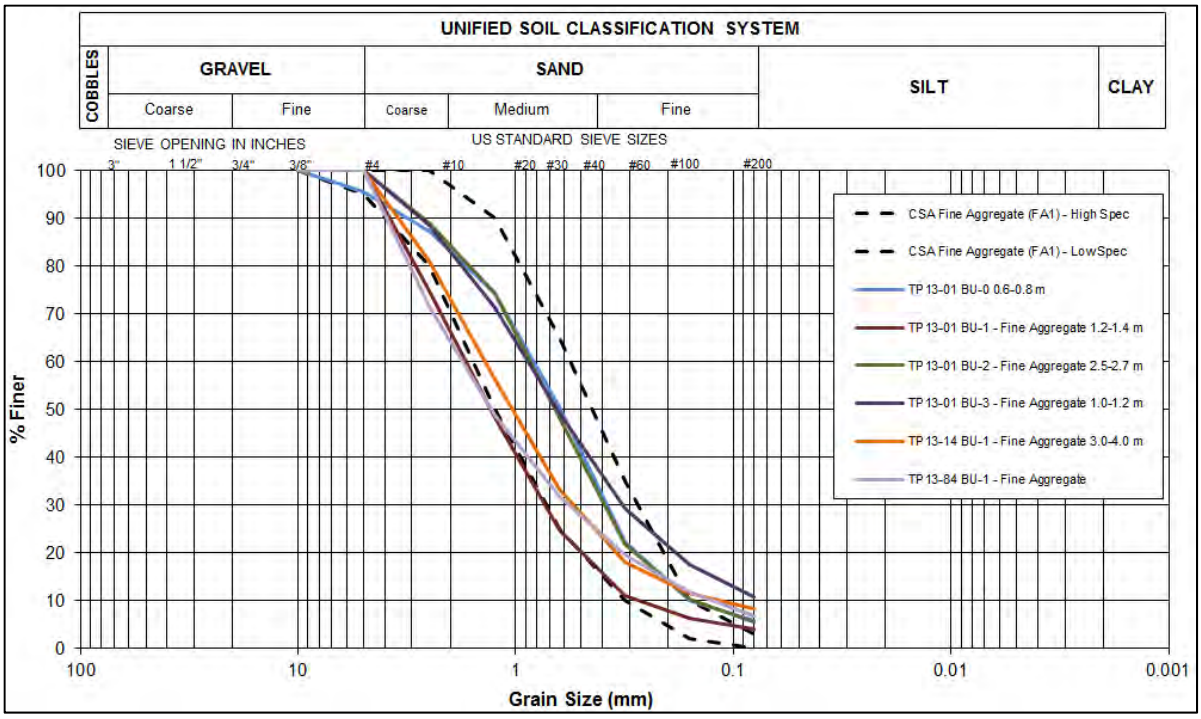
7.2 POTENTIAL BORROW AREAS

Alluvium and rock sources with fresh unaltered bedrock have been investigated for use as potential sources of aggregate.

One alluvial source was identified on a ridge along the Britannia Creek Access Road (TP13-01). This material comprised subrounded sand and gravel, with some to many cobbles, and trace silt. The material was sampled from a trench that was originally frozen but thawed out after being exposed several years ago. Other alluvial sources were found along Casino Creek (e.g. TP13-14 and TP13-19). These materials are similar to the soils in Test Pit TP13-01 but typically frozen or saturated. Traces of roots and plant remains were occasionally observed in the alluvium along Casino Creek.

Two types of bedrock were considered potentially suitable for use as aggregate based on field observations: Granodiorite and Quartzite. The fresh Quartzite was strong and fractured along pre-existing planes of weakness. Fresh Granodiorite was very strong and less prone to breaking.

The locations of aggregate borrow areas are presented on Figure A.4 in Appendix A.



7.3 CONCRETE AGGREGATE LABORATORY TESTING

Alluvial test pit samples from TP13-01 and TP13-14, and fresh Grandiorite samples from TP13-84 were sent to the Levelton Consultants laboratory in Richmond, B.C., for concrete aggregate suitability testing as per CSA standard A23.1/2-09. The Granodiorite (TP13-84) was crushed using a jaw crusher with a 28mm opening and tested for suitability as coarse aggregate. Samples were collected from various horizons in the alluvium along Britannia Creek Access road (TP13-01). The gradation was determined for each of the samples, before combining them into a representative bulk sample. The bulk sample was then split into a coarse and a fine fraction. The fine fraction was subjected to a full suite of tests, and select tests were conducted on the coarse fraction. A sample was also collected from the alluvium along Casino Creek (TP13-14). The fine fraction of this sample was subjected to select tests for fine aggregate suitability.

The gradations of the test pit samples for fine and coarse aggregate are presented in Figure 7.1 and Figure 7.2, respectively. The aggregate testing results are summarized in Table 7.1 and Table 7.2, and detailed test results are provided in Appendix C.

7.3.1 Fine Aggregate

The particle size distributions presented in Figure 7.1 indicate that the alluvial samples from TP13-01 and TP13-14 mostly satisfy the CSA gradation criteria for fine aggregate after removing material greater than 5 mm. However, the samples contain too many fines (silt and clay) to be acceptable.

NOTES:

1. No processing was required for TP13-01 BU-1 to satisfy the CSA specification for fine aggregate (FA1).
2. All other fine aggregate samples were produced by removing material greater than 5mm.
3. TP13-01 and TP13-14 comprise alluvium.
4. TP13-84 comprises Granodiorite.

Figure 7.1 Fine Aggregate Gradations

The petrographic examination indicates that the alluvial samples from TP13-01 are made up of quartz, feldspar, quartz-feldspar intergrowths, amphibole, clay, biotite, white mica, epidote, iron oxides, metamorphic schist, quartz breccia, carbonate, magnetite and chlorite.

The alluvial sample from TP13-14 is made up of feldspar, feldspar and quartz intergrowths, quartz, clay, biotite, iron oxides, amphibole, brecciated feldspar and quartz, white mica, titanite, magnetite, epidote, pyrite, carbonate and chlorite.

The two samples show different mineral compositions, which can be summarised as more abundant quartz in sample TP13-01 and more abundant feldspar in sample TP13-14. Sample TP13-01 Composite hosts more abundant amphibole, and subordinate fragments of metamorphic schists. The source rocks of this aggregate are quartzo-feldspathic plutonic rocks (Granodiorite) and schists.

Some of the minerals identified in the two samples, namely clay, feldspar and strained quartz have the potential for alkali-aggregate reactivity with Portland cement. The test CSA A23.2-25A

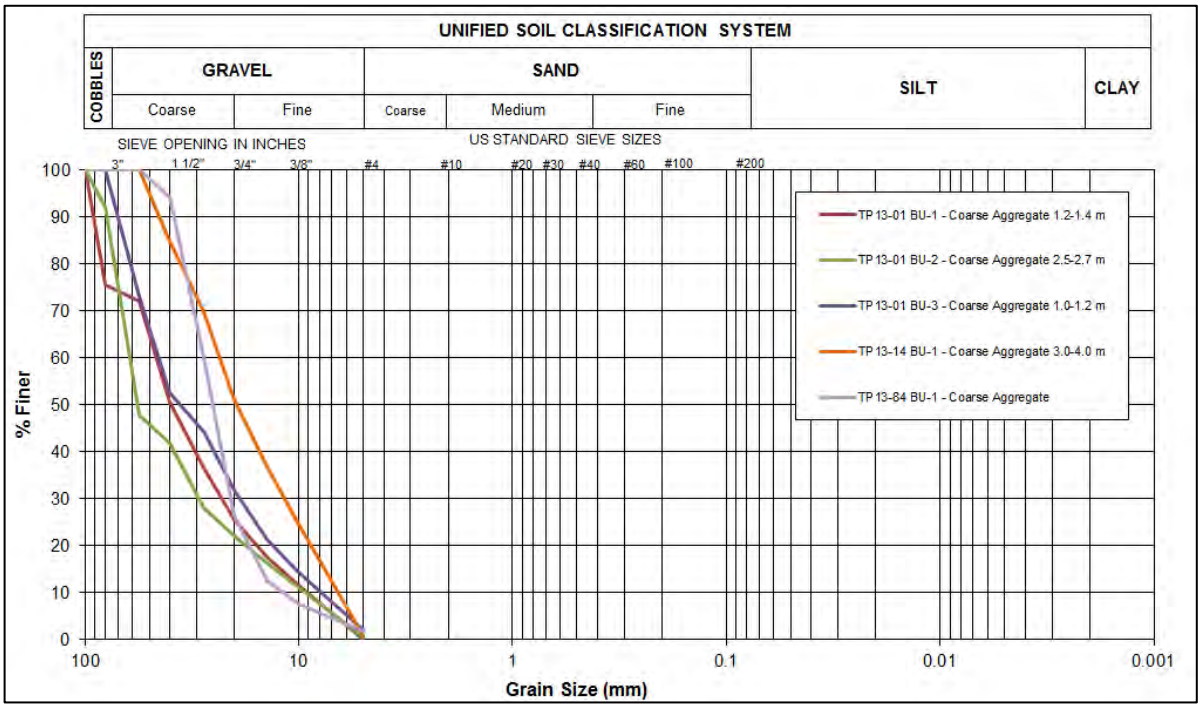
"Detection of alkali-silica reactive aggregate by accelerated expansion of mortar bars" indicated a reactivity that is below the specified maximum for TP13-01. The material in TP13-14 is not tested for alkali-reactivity.

Table 7.1 Summary of Fine Aggregate Tests Results

Test Method	Standard	CSA Specification Maximum Percentage	Alluvium TP13-01 Composite	Alluvium TP13-14 BU-1
Sieve analysis of fine aggregate	CSA A23.2-2A	See Figure 7.1		
Clay lumps in natural aggregate (%)	CSA A23.2-3A	1.0	0.0	0.0
Low-density granular material in aggregates (%)	CSA A23.2-4A	0.5	0.0	Not tested
Amount of material finer than 80 µm in aggregates (%)	CSA A23.2-5A	3.0	8.6	6.0
Relative density (saturated surface-dry basis) and absorption (%) in fine aggregate	CSA A23.2-6A	N/A	Density: 2.563 Absorption: 1.24	Not tested
Organic impurities in fine aggregates for concrete (color plate index)	CSA A23.2-7A	No. 3 or less	No. 3	No. 4
Petrographic examination of aggregates	CSA A23.2-15A	Identification of deleterious substances, discussed separately		
Resistance of fine aggregate to degradation by abrasion in the Micro-Deval apparatus (% loss)	CSA A23.2-23A	20.0	13.0	Not tested
Detection of alkali-silica reactive aggregate by accelerated expansion of mortar bars (% expansion at 14 days)	CSA A23.2-25A	0.150	0.102	Not tested

NOTES:

1. Specifications as per CSA A23.1 Table 12.



The results of the testing program indicate that alluvium is overall a good source of fine aggregate. It was determined to be a durable and sound material, with the following deficiencies:

- Amount of fines. The gradations in Figure 7.1 and the results from test CSA A23.2-4A indicate that too much fines are present in the aggregate samples. Silt coating on particles may affect the strength of the concrete by weakening the bond between the cement and the particles. It may also cause frost susceptibility of fine aggregates used as bedding sand. It is recommended to wash the alluvium to remove the silt coating prior to use as fine aggregate.
- Organic impurities. The alluvium at TP13-01 contained some organic impurities, but within the allowable range. The organic impurities at TP13-14 exceeded the CSA specifications. A fine aggregate failing the test may be used, provided that can be demonstrated that the organic impurities do not have a detrimental effect on the compressive strength of mortar produced using

this aggregate. It is recommended to conduct test CSA A23.2-8A "Measuring mortar-strength properties of fine aggregate" on alluvium from TP13-01 and TP13-14 to determine the effect of organic impurities on mortar strength.

7.3.2 Coarse Aggregate

The gradations of alluvium and crushed Granodiorite after removal of material smaller than 5mm are presented in Figure 7.2. The gradations are not within the specified limits for coarse aggregate listed in CSA A23.2-09 Table 11. Additional crushing and screening is required before these materials can be used as coarse aggregate.

NOTES:

1. Coarse aggregate samples produced by removing material smaller than 5mm.
2. TP13-01 and TP13-14 comprise alluvium.
3. TP13-84 comprises Granodiorite.

Figure 7.2 Coarse Aggregate Gradations

Table 7.2 Summary of Coarse Aggregate Tests Results

Test Method	Standard	CSA Specification Maximum Percentage	Alluvium TP13-01 Composite	Granodiorite TP13-84 BU-1
Sieve analysis of coarse aggregate	CSA A23.2-2A	See Figure 7.2		
Clay lumps in natural aggregate (%)	CSA A23.2-3A	0.3	Not tested	0.0
Low-density granular material in aggregates (%)	CSA A23.2-4A	0.5	Not tested	0.0
Amount of material finer than 80 µm in aggregates (%)	CSA A23.2-5A	1.0	Not tested	0.6
Relative density (saturated surface-dry basis) and absorption (%) of coarse aggregate	CSA A23.2-12A	N/A	Not tested	Density: 2.668 Absorption: 0.60
Flat and elongated particles in coarse aggregate - Procedure A, ratio 4:1 (% Flat, Elongated, and Flat and Elongated)	CSA A23.2-13A	20.0	8.3	2.8
Petrographic examination of aggregates	CSA A23.2-15A	Identification of deleterious substances, discussed separately		
Resistance to degradation of small-size aggregate by abrasion and impact in the Los Angeles machine (% loss)	CSA A23.2-16A	50.0	Not tested	41.9
Resistance of unconfined coarse aggregate to freezing and thawing (% total weighted loss)	CSA A23.2-24A	6.0	3.3	0.0
Detection of alkali-silica reactive aggregate by accelerated expansion of mortar bars (% expansion at 14 days)	CSA A23.2-25A	0.150	Not tested	0.030
Resistance of coarse aggregate to degradation by abrasion in the Micro-Deval apparatus (% loss)	CSA A23.2-29A	17.0	Not tested	14.2

NOTES:

1. Specifications as per CSA A23.1 Table 12.
2. CSA coarse aggregate specification listed for concrete exposed to freezing and thawing.

Coarse aggregate samples are classified on the basis of the petrographic number (PN) method as specified by CSA A23.2-15A. The crushed Granodiorite has a PN of 100 and is judged to be of "good" physical-mechanical quality for all types of aggregate use, including concrete.

The rock is made up of plagioclase, quartz, biotite, magnetite and probably hornblende. Subordinate and sub-ellipsoidal masses of fine-grained microdiorite are dispersed as inclusions within the Granodiorite. The microdiorite is made up of biotite/hornblende, plagioclase and quartz. The Granodiorite has a very high strength. Apart from the subordinate microdiorite, which is richer in mica and can be scratched and scraped with some difficulty, the aggregate cannot be scratched. The sample is fresh and does not show coatings.

The aggregate is interpreted to have a low reactivity, however, some minerals were identified that may promote an alkalicarbonate reaction in concrete. The test CSA A23.2-25A "Detection of alkali-silica reactive aggregate by accelerated expansion of mortar bars" indicated a very low reactivity that is far below the specified maximum. Therefore alkali-reactivity of the Granodiorite is not of concern.

The results of the testing program indicate that crushed granodiorite is a durable, sound material that complies with all CSA specifications for coarse aggregate.

7.4 QUANTITIES

Approximate quantities of fine and coarse aggregate required for construction of the Mine Site facilities are presented in Table 7.3 and Table 7.4. The quantities are derived from take-offs from the Feasibility study and estimates provided by the client. A total of approximately 65,000 m^3 fine aggregate and 260,000 m^3 coarse aggregate is required.

Table 7.3 Required Quantity of Fine Aggregate

Line Item	Volume (m^3)
Fine Concrete Aggregate	20,000
Bedding Sand	45,000
Total Required	**65,000**

NOTES:
1. Includes 10% overbuild.
2. Includes 5% overpour for concrete.

Table 7.4 Required Quantity of Coarse Aggregate

Line Item	Volume (m^3)
Coarse Concrete Aggregate	40,000
Structural Fill	220,000
Total Required	**260,000**

NOTES:
1. Includes 10% overbuild.
2. Includes 5% overpour for concrete.

The preferred borrow source for fine concrete aggregate is alluvium located along the Britannia Creek Access Road near TP13-01. This material is preferred over alluvium along Casino Creek due to its lower moisture and organic content. The alluvial borrow source along Britannia Creek is estimated to be approximately ten meters thick, based on nearby exposures. A relatively small borrow area would suffice to provide the required amount of fine aggregate, as indicated on Figure A.4 in Appendix A. This borrow area provides approximately 100,000 m^3 of alluvium. Assuming 30% reject of coarse material would result in sufficient fine aggregate material. The rejected material may be suitable for use as filter and transition zone material, general fill or coarse

concrete aggregate. Additional site investigations are required to determine the depth and areal extent of the proposed borrow source, and to determine variability of material. It is recommended to conduct test CSA A23.2-8A “Measuring mortar-strength properties of fine aggregate” on the alluvium to determine the effect of organic impurities on mortar strength.

Fresh Granodiorite is the most suitable borrow source for coarse aggregate. Abundant Granodiorite is present at the mine site, with varying degrees of alteration, metamorphism and weathering. The material at TP13-84 is fresh, unaltered and suitable for use as coarse aggregate. A borrow area for coarse aggregate is indicated on Figure A.4 in Appendix A. This borrow area assumes a quarry depth of ten meters, to provide approximately 300,000 m^3 of Granodiorite. Assuming 10% reject due to unsuitable size after drilling, blasting and processing, would leave sufficient coarse aggregate material. The extent of this borrow source is to be confirmed using additional site investigations. There is no need to investigate the possibility of other rock sources (such as Quartzite) for coarse aggregate, based on the excellent properties and abundance of Granodiorite.

The results of the coarse aggregate testing of Granodiorite suggest that this borrow source may also be suitable for use as fine aggregate. However, this requires additional crushing and screening that likely makes this option less cost effective than using the alluvium.

The identified borrow sources contain sufficient fine and coarse aggregate for construction of the mine site facilities. Additional site investigations are required if aggregate borrow sources closer to the mine site are to be pursued.

8 – RECOMMENDATIONS

It is recommended that the following work be undertaken:

- Develop measures to mitigate the shortage of low permeability material. These measures may include addition of bentonite to borrow materials with low fines content, import of Glacial Till from outside the project area, optimisation of the tailings dam design to reduce the size of the low permeability core zone, and redesign the tailings dam using alternative seepage control measures, such as geosynthetic liners and an asphalt core.
- Confirm that the proposed borrow sources are geochemically innocuous, by implementing a ML/ARD Management Plan prior to excavation of the borrow materials.
- Establish gradation limits for construction materials.
- Determine the effects of compaction and high confining stress on the gradation and strength of the residual soils.
- Conduct test CSA A23.2-8A “Measuring mortar-strength properties of fine aggregate” on alluvial samples from the fine aggregate borrow area to determine the effect of organic impurities on mortar strength.
- Conduct additional site investigations to confirm the depth and areal extent of the proposed aggregate borrow sources, and to determine the variability of this material.

M:\1\01\00325\16\A\Report\3 - Borrow Source Assessment\Rev 0\Appendix B\[Appendix B - Lab Tests Results_rev A.xlsm]Table B.1

NOTES:

1. Particle size distribution by percent of sample weight.
2. Organic content according to ASTM D 2974, method C.
3. Cobble content may vary in the field.
4. Standard proctor includes an oversize correction as per ASTM D 4718-87.

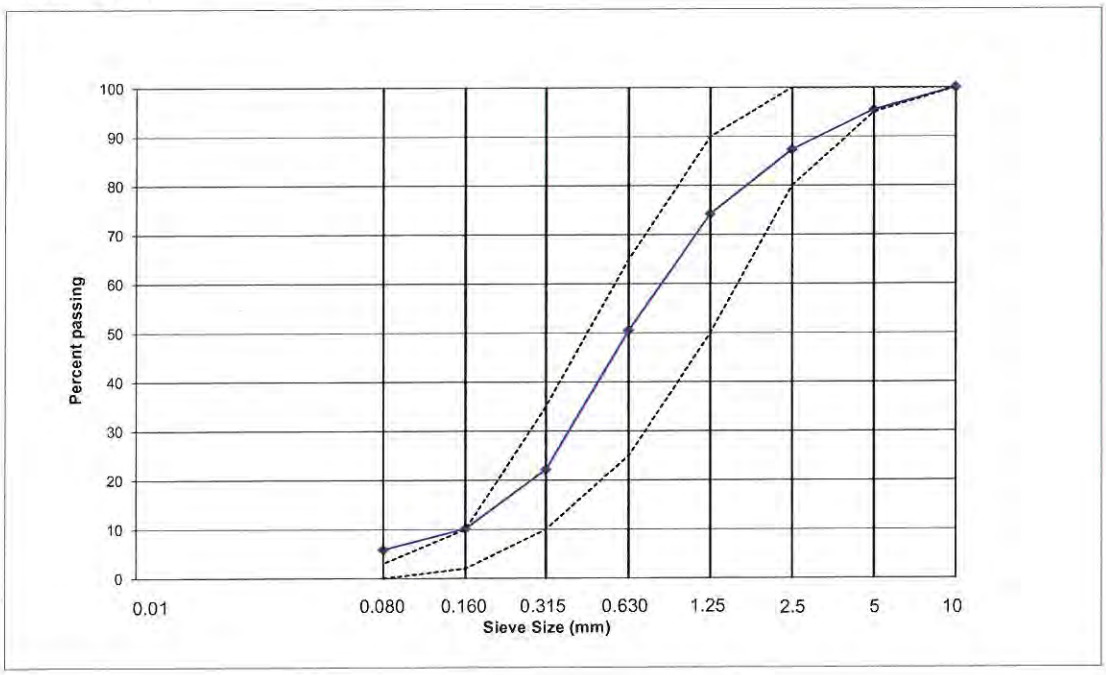
File No: R814-0178-00
Report No: 1

Attention: Mr. Sanne Brinkman, M.Sc

Project: KP - Yukon Mine Aggregate Qualification

Date Issued: February 18, 2014

SAMPLING INFORMATION



Source: TP13-01 BU - 0 (0.6-0.8 m)
Material: Fine Aggregate

Specification: CSA A23.1 Table 10 grading limits for fine aggregate

Date Sampled: August, 2013
Date Tested: January, 2014
Sample No: 1
Sampled by: Client
Tested by: NC

Material Specification			Sieve Analysis	
Sieve	HIGH SPEC	LOW SPEC	Sieve	% Passing
10	100	100	10	100.0
5	100	95	5	95.4
2.5	100	80	2.5	87.3
1.25	90	50	1.25	74.2
0.630	65	25	0.630	50.5
0.315	35	10	0.315	22.2
0.160	10	2	0.160	10.1
0.08	3	0	0.08	5.8

Fineness Modulus: **2.60**

REMARKS: Sample tested in accordance with CSA A23.2-2A and 5A.

Knight Piesold Ltd.
Suite 1400 – 750 West Pender Street
Vancouver, BC V6C 2T8

Attention: Mr. Sanne Brinkman, M.Sc.

Project: KP – Yukon Mine Aggregate Qualification
Subject: Aggregate Test Results

Dear Mr. Sanne Brinkman, MSc.;

Knight Piesold Ltd. retained Levelton Consultants Ltd. to complete testing of aggregate samples obtained by the client from Alluvium and Granodiorite test pits. Prior to further testing for aggregate qualification, samples were initially tested for sieve analysis. Based on the results from the sieve analysis, Knight Piesold has grouped and selected the following samples to be tested for aggregate qualification: *Alluvium TP13-01 Composite Fine Aggregate, Alluvium TP13-01 Composite Coarse Aggregate, Alluvium TP13-14 BU1 3.0-4.0 m Fine Aggregate, and Granodiorite TP13-84 BU-1 Coarse Aggregate*. The tests requested by Knight Piesold are as outlined in Tables 1 and 2. Test results are summarized in Tables 3 and 4 and formal test reports are appended to this letter.

Table 1: Coarse Aggregate Tests

Test Procedure
Material Finer than 80 μm (CSA A23.2-5A)
Relative Density & Absorption of Coarse Aggregate (CSA A23.2-12A)
Clay Lumps & Friable Particles in Aggregates (CSA A23.2-3A)
Flat & Elongated Particles (CSA A23.2-13A)
Resistance to Degradation of Small-Size Aggregate by Abrasion and Impact in the Los Angeles Machine (CSA A23.2-16A)
Potential Alkali Reactivity of Aggregates (Mortar-Bar Method) (CSA A23.2-25A)
Low Density Granular Materials in Aggregate (CSA A23.2-4A)
Resistance of Coarse Aggregate to Degradation by Abrasion in the Micro-Deval Apparatus (CSA A23.2-29A)
Resistance of Unconfined Coarse Aggregate to Freezing and Thawing (CSA A23.2-24A)
Petrographic (CSA A23.2-15A)

Table 2: Fine Aggregate Tests

Test Procedure
Material Finer than 80 μm (CSA A23.2-5A)
Relative Density & Absorption of Fine Aggregate (CSA A23.2-6A)
Clay Lumps & Friable Particles in Aggregates (CSA A23.2-3A)
Potential Alkali Reactivity of Aggregates (Mortar-Bar Method) (CSA A23.2-25A)
Low Density Granular Materials in Aggregate (CSA A23.2-4A)
Organic Impurities in Fine Aggregate (CSA 23.2-7A)
Resistance of Coarse Aggregate to Degradation by Abrasion in the Micro-Deval Apparatus (CSA A23.2-23A)
Petrographic (CSA A23.2-15A)

Table 3: Summary of Coarse Aggregate Test Results

Test Method	CSA Specifications A23.1 – Table 12 (See Clauses 4.2.3.2.2, .3.3.3, .3.4.3, .3.6, and .3.9.1) Maximum %	Alluvium TP13-01 Composite	Granodiorite TP13-84 BU-1 Composite
Material Finer than 80 µm (Percent Passing, %) (CSA A23.2-5A) CA	1.0	-	0.6
Relative Density (kg/m^3) and Absorption (%) of Coarse Aggregate (SSD) (CSA A23.2-12A)	N/A	-	Density:2668 Absorption: 0.60
Clay Lumps & Friable Particles in Aggregates (%) (CSA A23.2-3A)	0.3	-	0.0
Flat & Elongated Particles (Neither Flat nor Elongated, %) (CSA A23.2-13A)	N/A	91.7*	97.2
Degradation of Small-Size Aggregate by Abrasion and Impact in the Los Angeles Machine (Percent Loss, %) (CSA A23.2-16A)	50.0	-	41.9
Potential Alkali Reactivity of Aggregates (Mortar-Bar Method) (Expansion at 14 days, %) (CSA A23.2-25A)	0.150	-	0.030
Low Density Granular Materials in Aggregate, %) (CSA A23.2-4A)	0.5	-	0.0
Resistance of Coarse Aggregate to Degradation by Abrasion in the Micro-Deval Apparatus (Percent Loss, %) (CSA A23.2-29A)	17.0	-	14.2
Resistance of Unconfined Coarse Aggregate to Freezing and Thawing (Total Weighted Percent Loss, %) (CSA A23.2-24A)	6.0	3.3*	0.0
Petrographic (CSA A23.2-15A)	N/A	-	Petrographic Report is Enclosed

Note: *Knight Piesold only requested the following tests to be conducted on the Alluvium TP13-01 Composite coarse sample

Table 4: Summary of Fine Aggregate Test Results

Test Method	CSA Specifications A23.1 – Table 12 (See Clauses 4.2.3.2.2, 4.2.3.3.3, 4.2.3.4.3, 4.2.3.6, and 4.2.3.9.1)	Alluvium TP13-01 Composite	Alluvium TP13-14 BU-1 3.0-4.0 m
Material Finer than 80 µm (Percent Passing, %) (CSA A23.2-5A)	3.0	8.6	6.0*
Relative Density (kg/m^3) and Absorption (%) of Fine Aggregate (SSD) (CSA A23.2-6A)	N/A	Density: 2563 Absorption: 1.24	-
Clay Lumps & Friable Particles in Aggregates (%) (CSA A23.2-3A)	1.0	0.0	0.0*
Potential Alkali Reactivity of Aggregates (Mortar-Bar Method) (Expansion at 14 days, %) (CSA A23.2-25A)	0.150	0.102	-
Low Density Granular Materials in Aggregate (%) (CSA A23.2-4A)	0.5	0.0	-
Resistance of Fine Aggregate to Degradation by Abrasion in the Micro-Deval Apparatus (Percent Loss, %) (CSA A23.2-23A)	20.0	13.0	-
Organic Impurities in Fine Aggregates (Color Plate Index) (CSA A23.2-7A)	< No. 3	No.3	No. 4*
Petrographic (CSA A23.2-15A)	N/A	Petrographic Report is Enclosed	Petrographic Report is Enclosed*

Note: *Knight Piesold only requested the following tests to be conducted on the Alluvium TP13-14 BU-1 3.0-4.0 m fine sample.

We trust this meets your current needs. Please contact us if you require anything further. Thank you for retaining Levelton.

Yours truly,

Photomicrographs of Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand....19

1. Introduction

Mr. Norman Chang of Levelton Consultants Ltd. submitted one coarse aggregate (Granodiorite (TP13-84 BU-1) Coarse Aggregate) and two fine aggregates (Alluvium (TP13-01 Composite) Natural Sand, and Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand) to Vancouver Petrographics for petrographic examination according to the Standard CSA A23.2-15A.

2. Detailed Petrographic Examination of Coarse Aggregate "Granodiorite (TP13-84 BU-1) Coarse Aggregate"

2.1. Methodology

The sample was examined as received. It was washed and dried, then was examined with the naked eyes. In some cases a 10× lens was used. No thin section was prepared in the identification of the coarse aggregate.

2.2. Petrographic quality

In accordance with methods in use in the aggregate industry, the coarse size fractions were classified on the basis of the petrographic number (PN) method (see Table 1). Using standard petrographic quality multipliers for the various quality classifications of each rock type, a PN of 100 was calculated for the sample. The PN indicates a "good" rating. Table 1 details the rock types classified as "good", "fair", or "poor", according to the specifications of CSA 23.2-15A. The coarse aggregate sample did not present significant coating.

2.3. Results

The 5–14 mm coarse aggregate is made up of the plutonic rock "Granodiorite (TP13-84 BU-1) Coarse Aggregate", and its PN of 100 is judged to be "good" in its physical-mechanical quality for concrete production. The rock is made up of plagioclase, quartz, biotite, magnetite and probably hornblende. Subordinate and sub-ellipsoidal masses of fine-grained microdiorite are dispersed as inclusions within the granodiorite. The microdiorite is made up of biotite/hornblende, plagioclase and quartz. The granodiorite shows very high strength. Apart from the subordinate subordinate microdiorite, which is richer in mica and can be scratched and scraped with some difficulty, the aggregate cannot be scratched. The sample is fresh and does not show coatings.

Concerning chemical stability, the aggregate is interpreted to have a low reactivity (Ingham, 2012); however, feldspar, biotite, chlorite, and clay have been reported as promoting an alkali-carbonate reaction in concrete (Stark and Bhatty, 1986), therefore it is recommended that the

alkali-aggregate reactivity (AAR) potential of the aggregate be assessed. The biotite may affect the compressive strenght of the concrete (Schmitt, 1990).

Table 1: Detailed petrographic examination of Sample Granodiorite (TP13-84 BU-1) Coarse Aggregate.

Sample ID: "Granodiorite (TP13-84 BU-1) Coarse Aggregate"		**Sieve fraction: 5–14 mm**
Petrographer: Fabrizio Colombo Ph.D., P.Geo.		**Date tested: March 26, 2014**
Petrographic description and quality	**Per cent by mass**	**Petrographic number contribution**
Good (PN Multiplier: 1)		
Granodiorite	100	100
Fair (PN Multiplier: 3)		
Poor (PN Multiplier: 6)		
Total	100	100
Notes:		
1 The Petrographic Number (PN) is not related to the potential for alkali-aggregate reactivity (AAR) of this aggregate when used in Portland cement concrete. AAR potential must be separately assessed.		
2 Rock types indicated by * may have potential for alkali-aggregate reaction (AAR).		
See CSA A23.1 and CSA A23.2 for information on the assessment of AAR in new concrete construction.		

Table 2: Suggested limits of the petrographic number (PN) for aggregate quality classifications (from CSA 23.2 15A).

Product type	***PN limits***
Concrete class C1, C2, F1	*125 max*
Other concrete classes	*140 max*
Shotcrete	*125 max*
Railroad ballast	*125 max*
Granular base	*150 max*
Select granular sub base	*160 max*

3. Detailed Petrographic Examination of Fine Aggregates " Alluvium (TP13-01 Composite) Natural Sand" and "Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand"

3.1. Methodology

The fine aggregates were examined with a stereomicroscope, and 12 polished thin sections were prepared from a representative portion of each size fraction. A minimum of 300 particles were examined for each size fraction under the stereomicroscope or a petrographic microscope, and the results are summarized in Table 3a and 3b (Sample Alluvium (TP13-01 Composite) Natural Sand and Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, respectively) and Figure 1a and 1b. The petrographic features of each rock type and mineral are listed in Table 4 and are shown in the photomicrographs attached in Appendix A.

3.2. Alkali-aggregate reactivity

Some of the minerals identified in the two samples, namely clay, and feldspar (see Table 3a and 3b for their relative abundance), have a reactivity potential for AAR with the alkali compounds in Portland cement (Ingham, 2013). If the aggregate has not been previously evaluated for AAR in accordance with the test methods and criteria given in CSA A23.1, it is recommended that such assessment be carried out.

3.3. Results

3.3.1 Sample Alluvium (TP13-01 Composite) Natural Sand

This sample is made up of quartz, feldspar, quartz-feldspar intergrowths, amphibole, clay, biotite, white mica, epidote, iron oxides, metamorphic schist, quartz breccia, carbonate, magnetite and chlorite. Aggregates rich in quartz, feldspar, and amphibole are intergrown with and enclose subordinate amounts of minerals, which are listed in Table 3a and Table 4 and are documented by photomicrographs in Appendix A.

3.3.2 Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand

This sample is made up of feldspar, feldspar and quartz intergrowths, quartz, clay, biotite, iron oxides, amphibole, brecciated feldspar and quartz, white mica, titanite, magnetite, epidote, pyrite, carbonate and chlorite. The feldspar- and quartz-rich fragments are intergrown with and enclose subordinate amounts of minerals, which are listed in Table 3a and Table 4.

3.4. Discussion

The two samples show different mineral compositions, which can be summarised as more abundant quartz in Sample Alluvium (TP13-01 Composite) Natural Sand and more abundant feldspar in Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand. In both samples, the feldspar-quartz intergrowths are liberated in the size fraction 0.630–0.315 mm. Sample Alluvium (TP13-01 Composite) Natural Sand hosts more abundant amphibole, and subordinate fragments of metamorphic schists, which must be considered one of the protoliths from which this aggregate, in association with quartzo-feldspathic plutonic rocks, was generated.

Both samples contain fragments of brecciated quartz. The strained quartz contained within the brecciated fragments is reported as having a potential AAR (Ingham, 2013). Despite the small amount of these brecciated fragments, it must be considered that some of the quartz and the feldspar-quartz intergrowths show different degrees of strain, which is indicated by strong undulose extinction of the quartz under crossed Nicols in transmitted polarized light. The AAR potential must be separately assessed in these two samples.

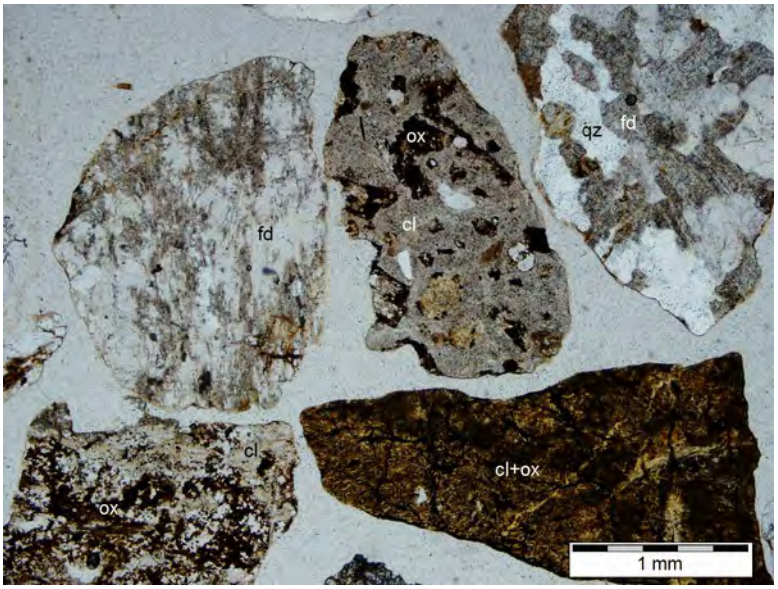
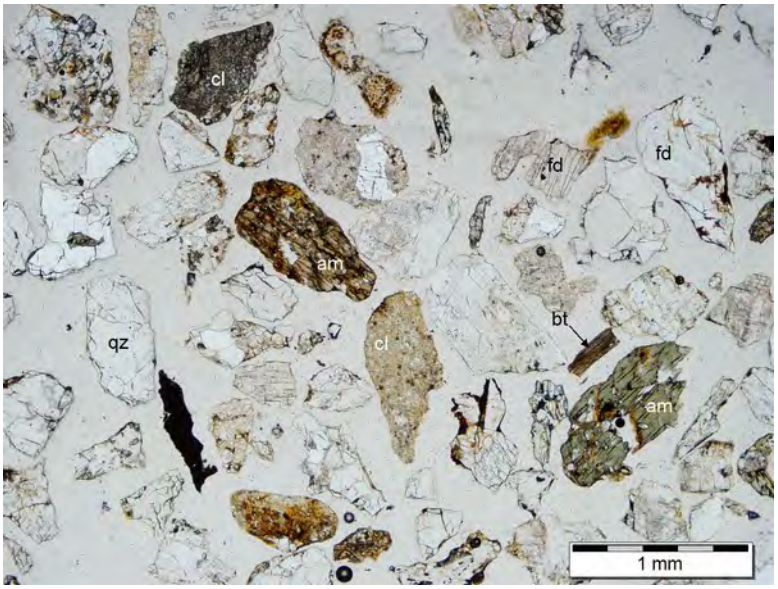
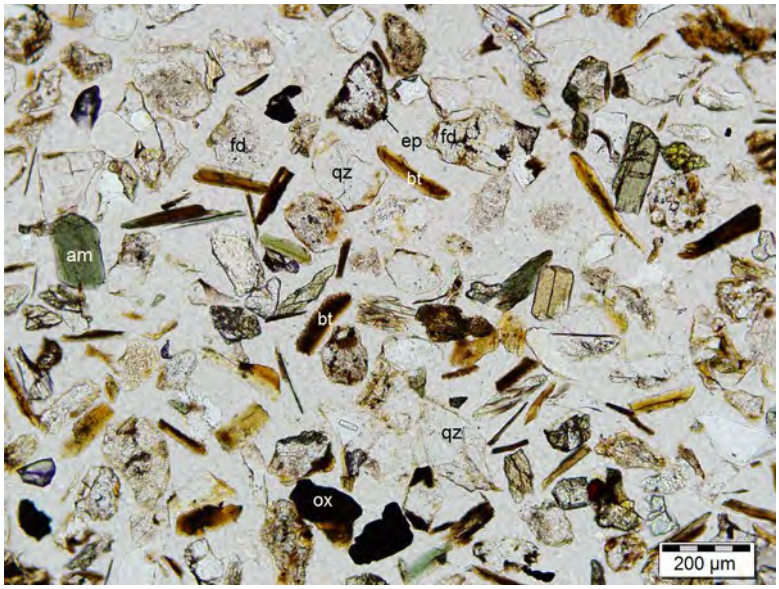
Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 5.00–2.50 mm*: Angular fragments of quartz (qz) and feldspar (fd) are intergrown and form the most abundant fragment type in this sieve fraction. The shape of the feldspar indicate this fragment is a plutonic rock (granitoid?). Crossed Nicols transmitted light.*



Photomicrograph 3. Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 5.00–2.50 mm*: The angular fragment of schist is made up of quartz (white), feldspar (earthy appearence) and shows a sub-planar foliation defined by iso-oriented white mica (lamellar crystals). Plane-polarized transmitted light.*

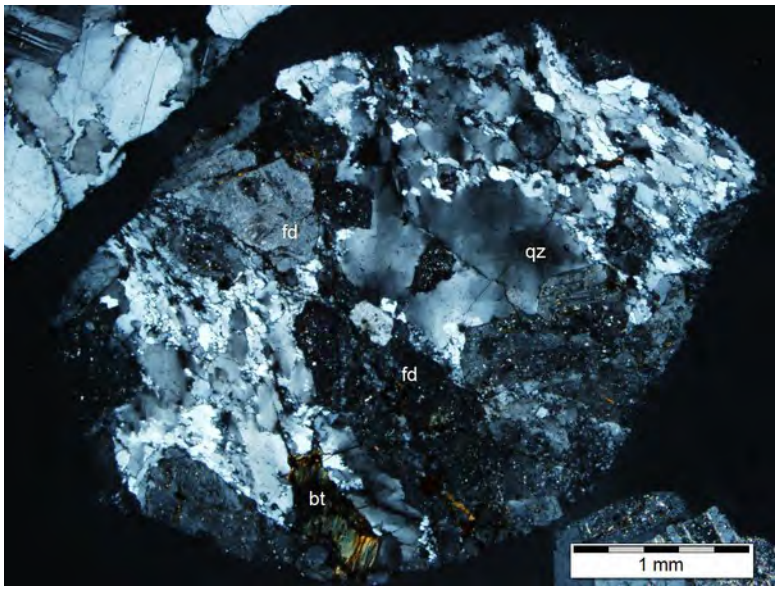


Photomicrograph 4. Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 5.00–2.50 mm*: The sub-rounded fragment of quartz (qz), epidote (ep) and amphibole was probably generated during a metamorphic event. The quartz shows undulose extinction. Crossed Nicols transmitted light.*

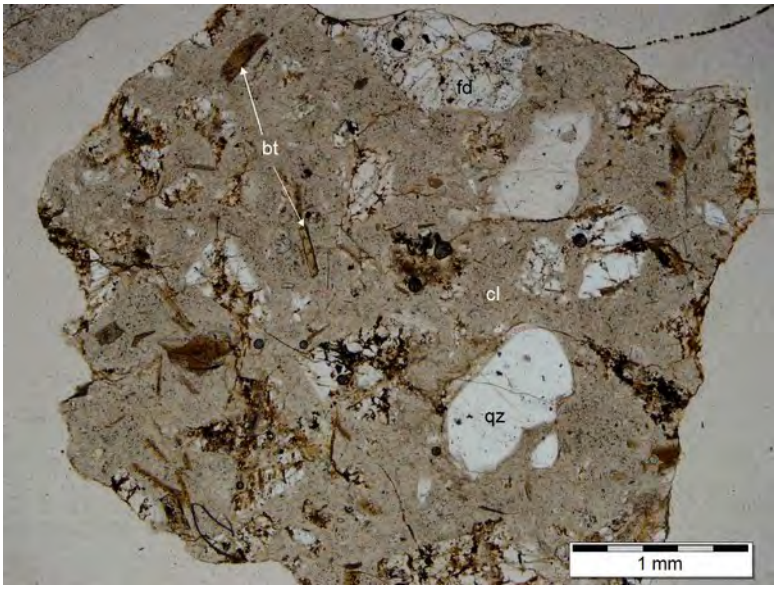


Photomicrograph 5. Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 2.50–1.25 mm*: Two of the fragments in this photomicrographs are made up of feldspar (fd), quartz (qz), amphibole (am), and are probably derived from a intrusive granitoid. In the upper left of the photomicrograph the sub-rounded fragment is made up of very fine-grained clay (cl) and iron oxides (ox). Plane-polarized transmitted light.*

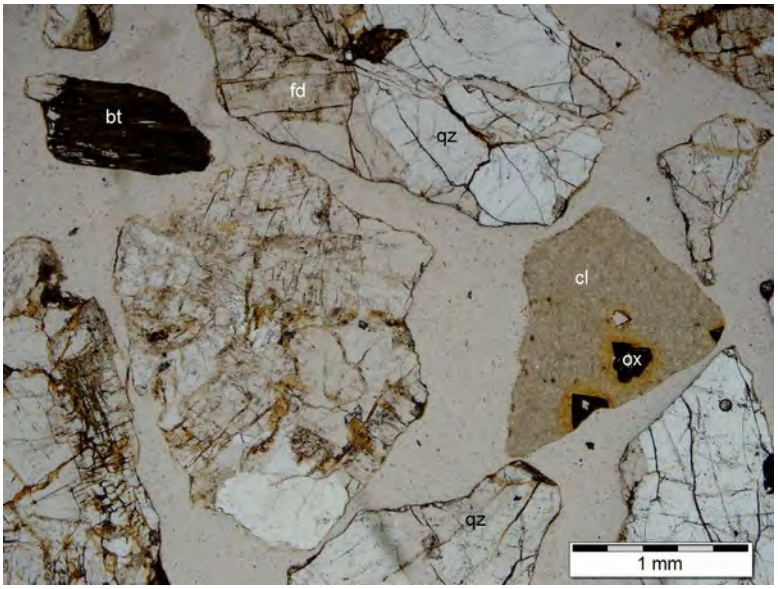
Photomicrograph 6. Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 2.50–1.25 mm*: The fragments in the lower part of this photomicrograph are made up of varying amount of clay (cl) and iron oxides (ox). A crystal fragment of feldspar (fd) is slightly altered by clay (on the left). A volcanic fragment (center-right) is replaced by clay (cl) and iron oxides (ox), and in the upper right a granitic rock is distinguished by the intergrowth of feldspar (fd) and quartz (qz). Plane-polarized transmitted light.*



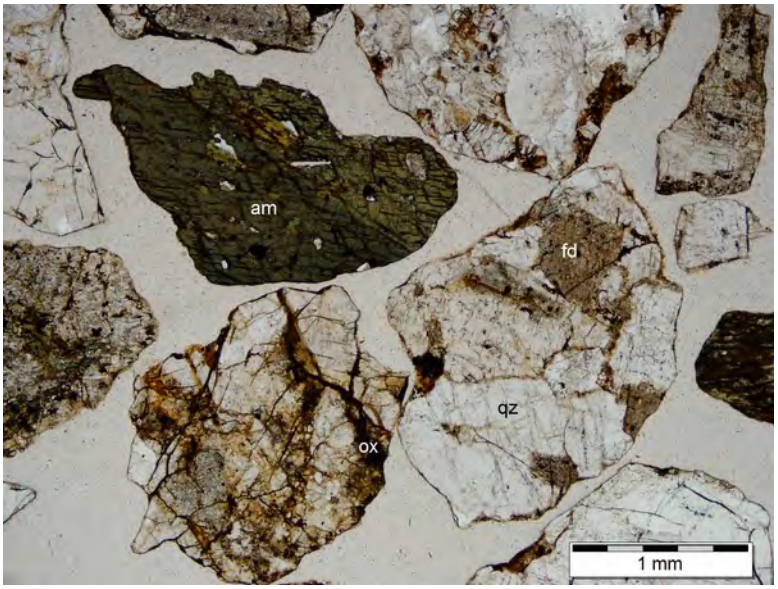
Photomicrograph 7. Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 0.630–0.315 mm*: In this sieve fraction the quartz (qz) and feldspar are mostly liberated and the percentage of clay-rich fragments (cl) and lamellar biotite (bt) increases. Plane-polarized transmitted light.*



Photomicrograph 8. Sample Alluvium (TP13-01 Composite) Natural Sand, sieve fraction 0.160–0.080 mm*: The crystal fragments of quartz (qz), feldspar (fd) and biotite (bt) prevail in the finest sieve fraction. Fragments of epidote (ep), amphibole (am) and iron oxides are also distinguished in this photomicrograph. Plane-polarized transmitted light.*

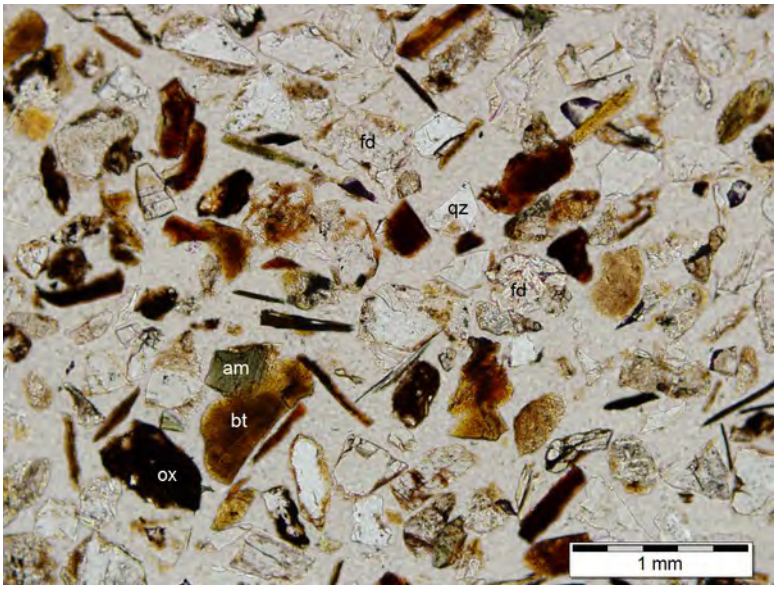


Photomicrographs of Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand



Photomicrograph 9. Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, sieve fraction 5.00–2.50 mm*: Feldspar (fd) and quartz (qz) are intergrown with subordinate biotite (bt) within this sub-rounded fragment. Crossed Nicols transmitted light.*

Photomicrograph 10. Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, sieve fraction 5.00–2.50 mm*: Quartz (qz), feldspar (fd) and biotite (bt) are immersed within a clay-rich aggregate within this altered fragment of volcanic rock. Plane-polarized transmitted light.*



Photomicrograph 11. Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, sieve fraction 2.50–1.25 mm*: Angular fragments of feldspar (fd) and quartz (qz) are associated with fragments of quartz (qz), clay (cl) and iron oxides (ox) and biotite in this photomicrograph. Plane-polarized transmitted light.*

Photomicrograph 12. Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, sieve fraction 2.50–1.25 mm*: The fragments of feldspar (fd) and quartz (qz) host varying amounts of iron oxides (ox), which are probably generated by the weathering of ferromagnesian minerals. Angular fragments of amphibole (am) and the microstructure of the feldspar and quartz aggregates indicate that most of the fragments are derived from plutonic rock. Plane-polarized transmitted light.*

Photomicrograph 13. Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, sieve fraction 0.630–0.315 mm*: Most of the quartz (qz) and the feldspar (fd) are liberated in this sieve fraction, and are associated with subordinate biotite (bt), amphibole (am), clay (cl) and iron oxides (ox). Plane-polarized transmitted light.*

Photomicrograph 14. Sample Alluvium (TP13-14 BU-1 3.0-4.0 m) Natural Sand, sieve fraction 0.160–0.080 mm*: Within this sieve fraction the feldspar (fd) is the most abundant mineral, and is associated with biotite (bt), quartz (qz), amphibole (am), and iron oxides (ox). The biotite tends to occur as lamellar crystals. Plane-polarized transmitted light.*

EXECUTIVE SUMMARY

A laboratory testing program has been conducted to determine the geotechnical characteristics of the Casino tailings materials. The tailings sample provided by Casino Mining Corporation for testing represents Non Acid Generating (NAG) Whole Tailings. This sample was used to generate representative samples of tailings Cyclone Overflow (fine tailings) and Cyclone Underflow (sand) materials. A sample of Potentially Acid Generating (PAG) tailings (with pyrite) was not available for testing at this time.

The test program included index testing to enable geotechnical classification of the materials, and slurry settling, air drying, consolidation and permeability testing to determine the characteristics of the Whole Tailings and Cyclone Overflow following deposition and for a range of conditions (representative of expected field conditions).

The Whole Tailings material can generally be described as non-plastic sand and silt with trace clay. The particle size distribution of the Whole Tailings sample comprises approximately 58% fine sand, 35% silt and 7% clay. The Cyclone Overflow sample was generated to a target particle size distribution with approximately 75% fines (silt and clay fractions). The resulting cyclone overflow material comprised approximately 23% sand, 69% silt and 8% clay (77% total fines). Similarly, the Cyclone Underflow sample was generated for a target particle size distribution with a maximum of 15% fines. The resulting cyclone underflow material comprised approximately 85% sand, 13% silt and 2% clay (15% total fines).

The specific gravity of the tailings solids was determined to be 2.70 for the Whole Tailings sample, 2.71 for the Cyclone Overflow sample, and 2.80 for the Cyclone Underflow sample.

Undrained settling, drained settling and air drying tests were carried out on slurry samples of the Whole Tailings and Cyclone Overflow. The Whole Tailings slurry was tested at a target solids content of 55%, corresponding to the current design value. The Cyclone Overflow slurry was tested at three solids contents (approximately 25%, 40% and 55%) to provide information on the effect of initial slurry solids content on the settling and permeability characteristics of the material and the effect on water recovery and achieved density. Slurry settling (sedimentation) tests provide an estimate of the density to which the tailings slurry will settle in a sub-aqueous environment, under undrained and drained conditions. These tests provide an indication of the tailings dry density achieved in a storage facility after settling and before any significant consolidation or air drying occurs. Air drying tests were carried out on the tailings samples to determine the effect of air drying after initial slurry settling and removal of supernatant water.

The undrained settled dry density of the Whole Tailings slurry is 1.0 tonnes/m^3. The drained settled dry density is 1.09 tonnes/m^3. The undrained settled dry density of the Cyclone Overflow varies from 0.8 tonnes/m^3 (initial slurry solids content of 25%) to 1.07 tonnes/m^3 (initial solids content of 55%). The drained settled dry density varies from 0.95 tonnes/m^3 to 1.2 tonnes/m^3. The dry densities achieved for drained settling are approximately 10% to 20% higher than those for undrained settling, with the larger increase occurring for Cyclone Overflow slurry with lower initial solids content.

Air drying of the tailings materials produces a significant increase in dry density over those from the undrained and drained settling tests. The highest densities are achieved for slurries with higher initial solids content (dry densities of 1.35 tonnes/m^3 for the Whole Tailings and 1.44 tonnes/m^3 for

the Cyclone Overflow sample with an initial slurry solids content of 55%). As expected, the amount of water recovered is highest for tailings slurries with lower initial solids content (higher initial water content). Supernatant water recovery from settled Cyclone Overflow with an initial slurry solids content of 25% is expected to be approximately 75%.

Laboratory tests carried out to determine the consolidation and permeability characteristics of the Whole Tailings and Cyclone Overflow included Slurry Consolidometer testing, Low Stress Slurry Consolidation tests and Falling Head Permeability tests (conducted on settled tailings after completion of drained settling tests). Relationships between coefficient of consolidation, void ratio and vertical coefficient of permeability to effective stress have been developed for both of these tailings materials. Calculated coefficients of consolidation for the Whole Tailings range from 100 m^2/year at very low stresses to over 1000 m^2/year at high stresses. Calculated coefficients of consolidation for the Cyclone Overflow range from 25 m^2/year at very low stresses to over 1000 m^2/year at high stresses.

Measured vertical permeability values for the Whole Tailings and Cyclone Overflow decrease with increasing effective stress. The permeability of the Whole Tailings ranges from approximately 1×10^{-4} cm/sec at low stresses (representing unconsolidated or fresher tailings near surface) to about 1×10^{-6} cm/sec at high stresses, corresponding to a reduction in void ratio (representing more consolidated or deeper tailings within the deposit). Similarly, the permeability of the Cyclone Overflow ranges from approximately 5×10^{-5} cm/sec at low stresses to about 1×10^{-6} cm/sec at high stresses.

Compaction, shear strength and permeability tests were carried out on the laboratory manufactured Cyclone Underflow sample. The shear strength and permeability tests were carried out over a large range of confining stresses to examine the influence of high confining stresses (corresponding to a large dam height) on the strength and permeability values. The optimum moisture content of the Cyclone Underflow sample was determined to be 16.7% and the maximum dry density was 1,559 kg/m^3. The shear strength of the cyclone sand is defined by an average effective friction angle of 36 degrees and zero cohesion. The potential strength characteristics of the cyclone sand over a large stress range have been examined by comparison of the laboratory test data to published information on the non-linear strength characteristics of similar granular materials (angular sands). This information suggests that the effective friction angle of the cyclone sand may be greater than 36 degrees at low confining stresses but potentially lower at very high stresses. However, the laboratory test results for the Cyclone Underflow sample suggest that there is no apparent loss of strength at the higher stresses, over the stress range tested.

Permeability values determined for the Cyclone Underflow show a general trend of reducing permeability with increasing confining stress. This decrease is the result of the decrease in material density and potentially from the generation of finer particles due to particle crushing. However, the results do not appear to indicate a dramatic decrease in permeability at high stresses, which would be indicative of significant particle crushing and changes to the fines content of the material. The permeability of the Cyclone Underflow ranges from approximately 2×10^{-3} cm/sec at lower stresses to about 5×10^{-4} cm/sec at high stresses (approximately 3000 kPa). Extrapolation of these results suggests that the permeability of the Cyclone Underflow will remain greater than 1×10^{-4} cm/sec at very high stresses of about 4000 to 5000 kPa.

It is recommended that laboratory testing is also carried out on a representative sample of PAG tailings for future design studies.

APPENDICES

Appendix A Detailed Results of Tailings Laboratory Tests (Provided by Knight Piesold Denver)

1 – INTRODUCTION

This report presents the details and findings of a laboratory testing program to determine the geotechnical characteristics of the Casino tailings materials. The laboratory testing was carried out at the Knight Piésold laboratory in Denver, Colorado.

A sample of the Casino tailings was provided by Casino Mining Corporation for testing. The tailings sample represents Non Acid Generating (NAG) whole tailings. This sample was used to generate representative samples of Cyclone Overflow (fine tailings) and Cyclone Underflow materials. A sample of Potentially Acid Generating (PAG) tailings (with pyrite) was not available for testing at this time.

The Cyclone Overflow sample was generated to a target particle size distribution with approximately 75% fines (silt and clay fractions). Similarly, the Cyclone Underflow sample was generated for a target particle size distribution with a maximum of 15% fines. The target particle size distributions used for generation of the cyclone overflow and underflow materials were based on the anticipated material products from cycloning of the Casino whole tailings and information provided by cyclone manufacturers.

The laboratory test program included index testing to enable geotechnical classification of the materials, and slurry settling, air drying, consolidation and permeability testing to determine the characteristics of the Whole Tailings and Cyclone Overflow following deposition and for a range of conditions (representative of expected field conditions). The following is a list of the geotechnical tests conducted on the Whole Tailings and Cyclone Overflow samples:

Index Tests

- Specific Gravity of solids
- Atterberg Limits (Plastic and Liquid Limits), and
- Particle size distribution by mechanical sieve and hydrometer.

Slurry Settling and Air Drying Tests

- Undrained Settling
- Drained Settling (with Falling Head permeability measurement), and
- Air drying.

Slurry Consolidation Tests

- Slurry Consolidometer Test (with permeability measurement), and
- Low Stress Slurry Consolidation (Burette) Test.

The slurry settling (sedimentation) tests provide an estimate of the density to which the tailings slurry will settle in a sub-aqueous environment, under undrained and drained conditions. These tests provide an estimate of expected tailings density in a storage facility after settling and before any significant consolidation or air drying occurs. The air drying test provides the geotechnical characteristics of the tailings for expected conditions on exposed beaches following deposition. The effect of air drying on moisture loss and tailings density is determined by this test.

The slurry consolidometer test is used to determine the consolidation, compressibility and permeability characteristics of the tailings over a wide range of confining pressures (typically corresponding to expected conditions in the field). These parameters can be used to determine the

amount and rate of consolidation, seepage rates, settlement and density increase for the tailings. The slurry consolidation cylinder test provides a measure of the consolidation characteristics of the tailings at very low effective stresses (representing freshly deposited tailings immediately following settling).

The following is a list of the geotechnical tests conducted on the Cyclone Underflow sample:

Index Tests

- Specific Gravity of solids, and
- Particle size distribution by mechanical sieve and hydrometer.

Strength and Permeability Tests

- Compaction (Proctor) Test
- Tri-axial Shear Strength, and
- Flexible Wall Permeability.

The compaction test provide information on the expected density of the cyclone sand following placement as compacted sand fill for embankment construction. The shear strength test provides information on the strength of the compacted sand over a range of confining stresses, and is used for embankment stability assessment. Similarly, the Flexible Wall permeability test provides information on the expected permeability of the cyclone sand fill over a range of confining stresses. The permeability characteristics of the cyclone sand are an important consideration in the design of free-draining cyclone sand embankment dams.

It is recommended that laboratory testing is also carried out on a representative sample of PAG tailings for future design studies.

2 – INDEX TESTS

2.1 GENERAL

Index testing was carried out on the tailings solids for the Whole Tailings sample and the laboratory generated Cyclone Overflow (fine tailings) and Cyclone Underflow (cyclone) samples.

The Specific Gravity, Atterberg Limits (Plastic and Liquid Limits), and particle size distribution (screen and hydrometer) of the tailings were determined. These tests provide a measure of the type and condition of the material, specifically the particle density, composition (size and distribution) and plasticity characteristics. The index properties can provide a relationship to material structural properties, including compressibility, permeability and strength.

A summary of the tailings index test results is presented in Table 2.1. Detailed results of the index tests are included in Appendix A.

2.2 PARTICLE SIZE DISTRIBUTION

Mechanical sieve and hydrometer particle size analyses were carried out on each of the tailings samples in accordance with ASTM standard D422 procedures. The hydrometer analysis is used to determine the silt and clay fraction particle sizes.

The particle size distribution of the Whole Tailings sample comprises approximately 58% fine sand, 35% silt and 7% clay. The Cyclone Overflow sample was generated to a target particle size distribution with approximately 75% fines (silt and clay fractions). The resulting cyclone overflow material comprised approximately 23% sand, 69% silt and 8% clay (77% total fines). Similarly, the Cyclone Underflow sample was generated for a target particle size distribution with a maximum of 15% fines. The resulting cyclone underflow material comprised approximately 85% sand, 13% silt and 2% clay (15% total fines).

The particle size distributions of the three tailings samples tested are presented on Figure 2.1.

2.3 SPECIFIC GRAVITY

The specific gravity of the tailings solids was determined in accordance with ASTM standard D854. The measured specific gravity is 2.70 for the Whole Tailings sample, 2.71 for the Cyclone Overflow sample, and 2.80 for the Cyclone Underflow sample.

2.4 ATTERBERG LIMITS (PLASTICITY)

The Atterberg Limits (Plastic and Liquid Limits) of the tailings samples were determined in accordance with the ASTM standard D4318 test procedure. Examination of each of the three sample indicated that the tailings materials are non-plastic. A Liquid Limit (LL) of 24% was determined for the Cyclone Overflow sample. The liquid limit is the moisture content at which a soil material starts to exhibit liquid behaviour.

2.5 MATERIAL CLASSIFICATION

The Whole Tailings material can generally be described as non-plastic Silty Sand with trace Clay, and classifies as SM (sand with non-plastic fines) under the Unified Soil Classification System.

The Cyclone Overflow material is described as Silt with Sand, and classifies as ML (inorganic silts of slight or no plasticity).

The Cyclone Underflow material is described as a non-plastic Sand with some Silt and a trace Clay, and classifies as SM (sand with non-plastic fines). The fines content of the Cyclone Sand sample (15%) is significantly lower than for the Whole Tailings (42%).

3 – SLURRY SETTLING & AIR DRYING TESTS

3.1 GENERAL

Undrained Settling, Drained Settling and Air Drying tests were carried out on the Whole Tailings and Cyclone Overflow samples.

The Whole Tailings slurry sample was prepared at an initial target solids content of approximately 55%, corresponding to the current design discharge value for the project. For the Cyclone Overflow the tests were conducted on slurry samples prepared at initial solids contents of approximately 25%, 40% and 55%. The design solids content of the cyclone overflow material was unknown at the time of testing. Testing the slurry at different solids contents provides information on the effect of slurry solids content on the settling and permeability characteristics of the material, and also the effect on water recovery and achieved density.

Slurry settling (sedimentation) tests provide an estimate of the density to which the tailings slurry will settle in a sub-aqueous environment, under undrained and drained conditions. These tests provide an indication of the tailings dry density achieved in a storage facility after settling and before any significant consolidation or air drying occurs. The actual settled density achieved in the field, prior to commencement of consolidation or air-drying, is likely to be within the range bounded by the densities obtained from the Undrained and Drained Settling tests.

Air Drying tests are carried out to determine the effect of air drying after initial slurry settling and removal of supernatant water, thereby simulating expected conditions on exposed tailings beaches following deposition.

Complete results of the slurry settling and air drying tests are included in Appendix A.

3.2 UNDRAINED SETTLING TESTS

The Undrained Settling test estimates the density to which the tailings slurry will settle in an undrained sub-aqueous environment.

Undrained Settling tests were performed by placing the slurry into a one litre graduated cylinder and recording the rate of settling and change in volume of the tailings sample as supernatant water bleeds to the surface. The final dry density of the settled solids is determined once the change in settled volume remains essentially constant.

The Whole Tailings and Cyclone Overflow slurries took one to two days to complete undrained settling. The settled dry densities increase with increasing initial slurry solids content. For the Whole Tailings sample the settled dry density is 1.0 tonnes/m^3. The undrained settled dry density of the Cyclone Overflow sample is 0.80 tonnes/m^3 for an initial slurry solids content of 25% solids, 0.99 tonnes/m^3 for 40% solids, and 1.07 tonnes/m^3 for 55% solids.

The initial and final settled dry densities achieved for the Undrained Settling tests are included in Table 3.1. Also included in Table 3.1 are the corresponding initial and final void ratios (ratio of voids volume to volume of solids) and the corresponding total water recovery from the slurry (as a percentage of total water in initial slurry) after settling is complete.

3.3 DRAINED SETTLING TESTS

The Drained Settling test provides an indication of the tailings dry density that will be achieved from settling with free drainage from the base of the sample.

The Drained Settling tests were performed by placing the tailings slurry into a one litre graduated cylinder with provision for bottom drainage and recovery of downward seepage. The rate of settling and change in volume of the sample is recorded with time, as supernatant water bleeds to the surface and drains from the base. Supernatant water is continually decanted from the surface, whenever possible, to minimize development of a vertical seepage gradient across the sample. The final dry density of the settled solids is calculated once the change in settled volume remains constant.

Similar to the Undrained Settling tests, the tailings slurries took one to two days to complete drained settling. For the Whole Tailings sample, the settled dry density is 1.09 tonnes/m^3 (initial slurry solids content of 55%). For the Cyclone Overflow sample, the settled dry densities are 0.95 tonnes/m^3 for an initial slurry solids content of 25%, 1.13 tonnes/m^3 for 40% solids, and 1.20 tonnes/m^3 for 55% solids.

The initial and final settled dry densities achieved for the Drained Settling tests are included in Table 3.1. Also included in Table 3.1 are the corresponding initial and final void ratios and the corresponding total water recovery from the slurry after settling is complete.

Permeability measurements of the tailings samples were taken after completion of the Drained Settling tests. Details and results of Falling Head permeability tests conducted on the drained settled samples are provided in Section 4.4.

3.4 AIR DRYING TESTS

The Air Drying tests were conducted by allowing the tailings slurry samples to settle and air dry under monitored conditions in order to investigate the relationship between density, moisture content, and degree of saturation in a drying environment. Partially saturated conditions are achieved as the amount of moisture loss through evaporation exceeds the reduction in volume of the sample. An absolute relationship between dry density and moisture content exists up to a point at which the degree of saturation falls below 100%. At this stage negative pore pressures (suction pressures) develop and act to further consolidate the sample (reducing the volume). Further drying below a limiting moisture content (the shrinkage limit) produces no further consolidation and the dry density at this point represents the maximum that can be achieved by air drying of the material.

The Air Drying tests are performed by introducing a sample of tailings slurry into a one litre container with no underdrainage and allowing the slurry to settle while decanting supernatant water. Routine measurements are taken of sample weight and volume. Once the slurry has completely settled and all surface water has been removed, air drying commences causing moisture loss and consolidation. An evaporation control, subjected to the same drying environment as the slurry sample, is also monitored in order to estimate the rate and amount of evaporation (from a free water surface) applied to the sample. However, in the field, greater evaporation rates and correspondingly faster consolidation rates may occur than in the laboratory due to the effects of wind, advection and solar radiation.

The Whole Tailings and Cyclone Overflow samples required approximately one to two weeks to complete air drying (achieving the shrinkage limit) under laboratory conditions. For the Whole Tailings sample the air dried dry density was 1.35 tonnes/m^3 (initial slurry solids content of 55%). For the Cyclone Overflow sample the air dried dry densities achieved were 1.29 tonnes/m^3 for an initial slurry solids content of 25%, 1.43 tonnes/m^3 for 40% solids, and 1.44 tonnes/m^3 for 55% solids.

The dry densities achieved for each of the Air Drying tests are included in Table 3.1. Also included in Table 3.1 are the corresponding initial and final void ratios after settling and air drying is complete.

Complete results of the Air Drying tests are provided in Appendix A, including plots showing the relationship between tailings dry density, volume reduction, moisture content, degree of saturation and evaporation.

3.5 SUMMARY OF SETTLING AND AIR DRYING TESTS

The settled dry density of the Whole Tailings is approximately 1.0 tonnes/m^3 for undrained settling and 1.09 tonnes/m^3 for drained settling. The dry density achieved for drained settling is approximately 10% higher than for undrained settling. Supernatant water recovery from settled Whole Tailings with an initial slurry solids content of 55% is expected to be approximately 26% for undrained conditions and about 43% for drained settling conditions.

Using the results of the Undrained and Drained Settling tests, the final dry densities and corresponding total water recovery for the Cyclone Overflow slurry are plotted as functions of initial slurry solids content on Figures 3.1 and 3.2, respectively.

Figure 3.1 illustrates the higher dry density for slurries with higher initial solids content, and the increase in dry density for drained settling compared to undrained settling. The undrained settled dry density of the Cyclone Overflow varies from approximately 0.8 to 1.07 tonnes/m^3. The drained settled dry density varies from approximately 0.95 tonnes/m^3 to 1.2 tonnes/m^3. The dry densities achieved for drained settling are approximately 10% to 20% higher than those for undrained settling, with the larger increase occurring for slurries with lower initial solids content.

The final dry densities from the Air Drying tests are also plotted on Figure 3.1. Air drying of the Cyclone Overflow material produces a significant increase in dry density over those from the Undrained and Drained Settling tests. The highest densities are achieved for slurries with higher initial solids content (up to a dry density of about 1.44 tonnes/m^3 for an initial slurry solids content of 55%).

Figure 3.2 illustrates the relationship between total water recovery (supernatant water recovered from the tailings slurry) and initial solids content of the Cyclone Overflow slurry. As expected, the amount of water recovered is highest for slurries with lower initial solids content (higher initial water content). Supernatant water recovery from settled Cyclone Overflow with an initial slurry solids content of about 25% is expected to be approximately 75% or higher, depending on actual drainage conditions during settling.

4 – SLURRY CONSOLIDATION AND PERMEABILITY TESTS

4.1 GENERAL

Laboratory tests have been carried out to determine the consolidation and permeability characteristics of the Whole Tailings and laboratory generated Cyclone Overflow. Material consolidation, compressibility and permeability (hydraulic conductivity) parameters derived from the laboratory testing can be used in design studies to determine the amount and rate of tailings consolidation, to predict seepage rates from and through the tailings, and to predict tailings settlements and density increase with time.

The consolidation and permeability parameters have been provided by Slurry Consolidometer testing, Low Stress Slurry Consolidation tests and Falling Head Permeability tests (conducted on settled tailings after completion of Drained Settling tests).

4.2 SLURRY CONSOLIDOMETER TEST

A specialized slurry consolidometer device was used to determine the consolidation, compressibility and permeability characteristics of the tailings over a range of effective confining stresses. The slurry consolidometer apparatus is designed to evaluate the consolidation characteristics of slurries that initially have high void ratios and high moisture contents at low effective stresses.

The tests were conducted by placing a slurry sample into the consolidometer and allowing the tailings to settle and consolidate under self weight. Confining stresses ranging from very low (about 14 kPa) to over 800 kPa were then applied in incremental loading stages. Routine measurements of settlement with time were recorded during each loading stage. Once settlement ceased or became negligible during loading the confining stress was increased to the next loading stage. The permeability of the tailings was measured at the end of each loading stage. Two-way drainage conditions were facilitated in the test. Detailed results of the testing are provided in Appendix A.

The results of the Slurry Consolidometer test were used to calculate the coefficient of consolidation (c_v) for each loading stage. The coefficient of consolidation is a measure of the consolidation characteristics (rate of consolidation) of a material. A high coefficient of consolidation corresponds to a high rate of consolidation while a low value indicates a slow rate of consolidation. The coefficients of consolidation and void ratios determined for the tailings are presented for each loading stage in Table 4.1 for Whole Tailings and Table 4.2 for Cyclone Overflow. Calculated tailings dry densities and measured vertical permeability (k_v) values are also included in Tables 4.1 and 4.2.

Coefficients of consolidation determined for the Whole Tailings and Cyclone Overflow are generally similar and increase with increasing effective confining stress, ranging from approximately 200 m^2/year at low stresses to over 1000 m^2/year at high stresses. Measured void ratios decrease from about 1.0 at low stresses to less than 0.7 at high stresses. Calculated values of the coefficient of consolidation and void ratio for the Whole Tailings are included on Figures 4.1 and 4.2, respectively. Calculated values of the coefficient of consolidation and void ratio for the Cyclone Overflow are included on Figures 4.3 and 4.4, respectively.

The calculated tailings dry density for each loading stage is included in Tables 4.1 and 4.2. The dry density of the tailings materials increases with increasing effective stress, with a value of about 1.6 tonne/m3 achieved at high effective stresses.

Measured vertical permeabilities for the Whole Tailings and Cyclone Overflow are included on Figures 4.5 and 4.6 respectively.

4.3 LOW STRESS SLURRY CONSOLIDATION TEST

The Low Stress Slurry Consolidation (burette) test provides a measure of the consolidation characteristics of the tailings at very low effective stresses (approximately 1 to 2 kPa), representing freshly deposited tailings immediately following initial settling. The test is used to estimate the coefficient of consolidation of the tailings at a very low effective stress (and corresponding high void ratio).

The test is carried out by introducing a pre-measured quantity of the tailings slurry sample into a one litre burette with the bottom stopcock closed. After initial settling (sedimentation) of the slurry, the bottom stopcock is opened to permit drainage and dissipation of pore pressures, causing an increase in the effective stress within the sample. Observations of the decrease in slurry volume (settlement) with time are recorded, and used to estimate the coefficient of consolidation. Estimates of initial and final sample void ratio, dry density, permeability and the corresponding effective stresses (due to the self-weight of the sample) are calculated.

Tests were conducted for both the Whole Tailings and Cyclone Overflow samples. A summary of the Low Stress Slurry Consolidation test results, including calculated values of void ratio, dry density, coefficient of vertical permeability and the coefficient of consolidation are presented in Table 4.3 for both samples. The calculated values of coefficient of consolidation are 100 m^2/year for the Whole Tailings and 25 m^2/year for the Cyclone Overflow. Calculated permeability values are approximately 2 x 10^{-4} cm/sec for the Whole Tailings and 3 x 10^{-5} cm/sec for the Cyclone Overflow.

Detailed results of the testing are included in Appendix A.

4.4 FALLING HEAD TESTS ON SETTLED TAILINGS

Falling Head permeability tests were performed on the settled tailings samples, after completion of each of the drained settling tests (see Section 3.3). This test provides an indication of the vertical permeability of the tailings material at very low effective stresses (approximately 1 kPa) and corresponding low density (high void ratio). In practice, the permeability will decrease as consolidation increases the density and reduces the void ratio.

The test is conducted by applying water to the surface of the settled tailings, imposing a vertical gradient across the sample. The drainage rate and drop in water level were recorded with time to provide a value of vertical permeability (hydraulic conductivity). The test is repeated several times to provide an average permeability value.

The average permeability values provided by the Falling Head tests for each of the drained settling test samples are included in Table 3.1. The average permeability measured for the Whole Tailings is approximately 1 x 10^{-4} cm/sec. The average permeability measured for the Cyclone Overflow ranges from approximately 3 x 10^{-5} cm/sec to 6 x 10^{-5} cm/sec.

Detailed results of the testing are included in Appendix A.

4.5 SUMMARY OF CONSOLIDATION AND PERMEABILITY TESTS

Calculated coefficients of consolidation for the Whole tailings range from about 100 m^2/year at very low stresses (representing freshly settled tailings) to over 1000 m^2/year at high stresses (representing consolidated tailings at depth within the deposit). This indicates that the rate of tailings consolidation has the potential to increase as effective stress conditions increase with depth, but will be dependent on in situ pore water pressure conditions. The relationship between coefficient of consolidation and effective stress for the Whole Tailings is shown on Figure 4.1, including calculated coefficient of consolidation values provided by the Slurry Consolidometer test and the Low Stress Slurry Consolidation test. Similarly, calculated coefficients of consolidation for the Cyclone Overflow range from about 25 m^2/year at very low stresses to over 1000 m^2/year at high stresses. The relationship between coefficient of consolidation and effective stress for the Cyclone Overflow is shown on Figure 4.2.

The relationship between tailings void ratio and effective stress is shown for the Whole Tailings and Cyclone Overflow materials on Figures 4.3 and Figure 4.4 respectively. These relationships were developed using calculated void ratios provided by the Slurry Consolidometer tests and the Low Stress Slurry Consolidation tests. The data presented on Figures 4.2 and 4.3 suggests a bilinear relationship between void ratio and effective stress for both materials. At low effective stress levels the steep line is indicative of the large volume change which occurs during the tailings sedimentation and initial consolidation process. The shallower line exhibited for higher stresses is indicative of the consolidation process, whereby smaller volume changes occur under increased loading as the structure of the tailings material becomes more compact. This bilinear relationship is typical for sedimented tailings materials.

The vertical coefficient of permeability of the Whole Tailings is shown as a function of effective stress on Figure 4.5. These relationships were developed using permeability values provided by the Slurry Consolidometer tests, Low Stress Slurry Consolidation tests and Falling Head tests performed on the drained settled samples. As expected, a general trend of decreasing permeability with increasing effective stress (decreasing void ratio) is observed. The relationship presented on Figure 4.5 indicates that the permeability of the Whole Tailings will generally range from approximately 1×10^{-4} cm/sec (representing unconsolidated or fresher tailings near surface) to about 1×10^{-6} cm/sec or less, corresponding to an increase in effective stress and reduction in void ratio (representing more consolidated or deeper tailings within the deposit).

The vertical coefficient of permeability of the Cyclone Overflow is shown as a function of effective stress on Figure 4.6. The relationship presented on Figure 4.6 indicates that the permeability of the Cyclone Overflow will generally range from approximately 5×10^{-5} cm/sec to about 1×10^{-6} cm/sec.

5 – CYCLONE SAND TESTS

5.1 GENERAL

Compaction, shear strength and permeability tests were carried out on the laboratory manufactured Cyclone Underflow (cyclone sand) sample. The test samples used for shear strength and permeability testing were prepared to target density and moisture content conditions representative of compacted cyclone sand fill material used for embankment construction.

The shear strength and permeability tests were carried out over a large range of confining stresses to examine the influence of a large dam height (and corresponding high confining stress) on the strength and permeability values.

Complete results of the compaction, shear strength and permeability tests are included in Appendix A.

5.2 COMPACTION TEST

The maximum dry density and optimum moisture content of the Cyclone Underflow sample were determined from a Standard Proctor test (ASTM D-698-07 Method A Standard). The optimum moisture content was determined to be 16.7% and the maximum (ultimate) dry density was 1,559 kg/m^3. Test samples used for shear strength and permeability testing were prepared to 95% of the maximum dry density.

5.3 SHEAR STRENGTH TEST

Consolidated Undrained triaxial compression tests were carried out on the Cyclone Underflow sample to determine the shear strength of the material over a range of confining stresses. The tests were performed at effective confining stresses of approximately 350 kPa, 700 kPa, 1650 kPa and 2760 kPa.

The effective shear strength of the cyclone sand is defined by the effective friction angle and cohesion. The test results indicate an average effective friction angle of 36 degrees with zero cohesion.

The potential strength characteristics of the cyclone sand over a large stress range has also been examined, including estimation of the shear strength (effective friction angle) at low and very high stresses. The strength of granular materials is typically higher at low stresses due to the dilatant behaviour of the material under shearing, while a lower strength may occur at high stresses due to particle crushing and reduced dilation of the material. The shear strength test results for the Cyclone Underflow have been compared to published information on the strength characteristics of granular materials (rockfill and angular sands) provided by Leps (“Review of Shearing Strength of Rockfill, Journal of the Soil Mechanics and Foundations Division, ASCE, Vol. 96, No. SM4, July 1970). Specifically, a relationship between friction angle and effective stress provided for angular sands has been used for comparison to the Cyclone Underflow test results. This relationship suggests that the effective friction angle of the cyclone sand will be greater than 36 degrees at low confining stresses (approximately 40 degrees for a normal effective stress of 100 kPa), but potentially lower at very high stresses (about 30 degrees for very high effective stresses of about 4000 to 5000 kPa). However, it

is noted that the laboratory test results for the Cyclone Underflow sample suggest that there is no apparent loss of strength at the higher stresses, over the stress range tested. This is an important consideration for stability assessment of large cyclone sand dams where confining stresses can be very high.

5.4 PERMEABILITY TEST

Flexible Wall Permeability tests were carried out at applied confining stresses of approximately 350 kPa, 700 kPa, 1650 kPa and 2760 kPa. The tests were carried out at these confining stresses to investigate the influence of increasing confining stress (and corresponding embankment height) on the permeability of the material.

The permeability values determined for the Cyclone Underflow sample are presented on Figure 5.2, which shows a general trend of reducing permeability with increasing confining stress. This decrease is the result of the increase in material density (decrease in void ratio) and potentially from the generation of finer particles due to particle crushing. However, the results do not appear to indicate a dramatic decrease in permeability at high stresses, which would be indicative of significant particle crushing and changes to the fines content of the material. The particle size distribution of the sample was determined following completion of the permeability test to investigate the potential for increased fines content due to particle crushing. The measured fines content (% passing #200 sieve) of the sample increased by only one percent, from 15% to 16%. This is not enough to suggest any significant particle crushing under the very high confining pressures imposed during the permeability testing.

The relationship presented on Figure 5.2 indicates that the permeability of the Cyclone Underflow will generally range from approximately 2×10^{-3} cm/sec at lower stresses to about 5×10^{-4} cm/sec at higher stresses (approximately 3000 kPa). Extrapolation of these results suggests that the permeability of the Cyclone Underflow will remain greater than 1×10^{-4} cm/sec at very high stresses of about 4000 to 5000 kPa.
