Parameters for Specimen No. 2

Specimen Parameter	Initial	Saturated	Consolidated	Final
Moisture content: Moist soil+tare, gms.	906.600			822.700
Moisture content: Dry soil+tare, gms.	797.000			690.300
Moisture content: Tare, gms.	131.300			131.600
Moisture, %	16.5	31.6	23.7	23.7
Moist specimen weight, gms.	647.2			
Diameter, in.	2.41	2.41	2.28	
Area, in.²	4.57	4.57	4.08	
Height, in.	5.00	5.00	4.95	
Net decrease in height, in.		0.00	0.05	
Net decrease in water volume, cc.			43.95	
Wet density, pcf	107.9	122.0	129.9	
Dry density, pcf	92.7	92.7	105.0	
Void ratio	0.8843	0.8843	0.6631	
Saturation, %	52.1	100.0	100.0	

Test Readings for Specimen No. 2

Membrane modulus = 0.124105 kN/cm²
Membrane thickness = 0.064 cm
Consolidation cell pressure = 140.02 psi (20163 psf)
Consolidation back pressure = 40.00 psi (5760 psf)
Consolidation effective confining stress = 14403 psf
Strain rate, %/min. = 0.03
Fail. Stress = 26580 psf **at reading no.** 139

Parameters for Specimen No. 3

Specimen Parameter	Initial	Saturated	Consolidated	Final
Moisture content: Moist soil+tare, gms.	906.600			793.800
Moisture content: Dry soil+tare, gms.	797.000			670.200
Moisture content: Tare, gms.	131.300			120.800
Moisture, %	16.5	32.0	22.5	22.5
Moist specimen weight, gms.	645.6			
Diameter, in.	2.42	2.42	2.26	
Area, in.²	4.58	4.58	4.02	
Height, in.	5.00	5.00	4.90	
Net decrease in height, in.		0.00	0.10	
Net decrease in water volume, cc.			52.40	
Wet density, pcf	107.4	121.7	131.3	
Dry density, pcf	92.2	92.2	107.2	
Void ratio	0.8937	0.8937	0.6293	
Saturation, %	51.5	100.0	100.0	

Test Readings for Specimen No. 3

Membrane modulus = 0.124105 kN/cm²
Membrane thickness = 0.064 cm
Consolidation cell pressure = 239.44 psi (34479 psf)
Consolidation back pressure = 0.00 psi (0 psf)
Strain rate, %/min. = 0.03
Fail. Stress = 35484 psf **at reading no.** 138

Parameters for Specimen No. 4

Specimen Parameter	Initial	Saturated	Consolidated	Final
Moisture content: Moist soil+tare, gms.	906.600			824.200
Moisture content: Dry soil+tare, gms.	797.000			701.100
Moisture content: Tare, gms.	131.300			144.500
Moisture, %	16.5	31.5	22.1	22.1
Moist specimen weight, gms.	649.1			
Diameter, in.	2.41	2.41	2.27	
Area, in.²	4.57	4.57	4.05	
Height, in.	5.00	5.00	4.87	
Net decrease in height, in.		0.00	0.14	
Net decrease in water volume, cc.			52.30	
Wet density, pcf	108.1	122.1	131.8	
Dry density, pcf	92.8	92.8	107.9	
Void ratio	0.8809	0.8809	0.6184	
Saturation, %	52.3	100.0	100.0	

Test Readings for Specimen No. 4

Membrane modulus = 0.124105 kN/cm²
Membrane thickness = 0.064 cm
Consolidation cell pressure = 440.00 psi (63360 psf)
Consolidation back pressure = 40.00 psi (5760 psf)
Consolidation effective confining stress = 57600 psf
Strain rate, %/min. = 0.03
Fail. Stress = 46543 psf **at reading no.** 51

Vancouver, British Columbia
Canada, V6C 3P1

Dear Mary,

Re: Casino Project –YESAB Water Balance to Include Climate Variability

1 – INTRODUCTION

The water balance submitted to the Yukon Environmental and Socio-Economic Assessment Board (YESAB) for the Casino Project (the project) has been updated to determine the potential impact of climate variability on modelled results. The objective of the water balance modelling exercise was to evaluate the quantity of flow of water in the ground, in the streams, and in various mine facilities under a variety of climate conditions. The water balance model also provided the platform on which the water quality model was developed.

The purpose of this letter is to outline the climate inputs and water management assumptions that were used for climate variability water balance modelling, and to present the results of the study. Only the water quantity model and results are discussed in this letter. The water quality model has been prepared by Source Environmental Associates Inc. (SEA) and will be documented separately.

2 – BACKGROUND AND MODELLING PHILOSOPHY

The water balance model submitted as part of the YESAB Proposal (the Proposal) was a deterministic model created using the GoldSim© software package based on mean monthly climate inputs. The deterministic water balance was based on the water management plan developed for the Proposal, as presented in the Knight Piésold (KP) report “Water Management Plan” (2013a). The deterministic water balance integrated the results of various models created to define the groundwater and surface water management plan for the site and these models included a watershed model, a numerical groundwater model, and the feasibility level operational mine site water balance model. The modelling methodology, assumptions and input parameters used to develop the deterministic water balance are presented in the KP report “YESAB Water Balance Model Report” (2013b), along with the results of the modelling. The water balance model presented in this letter involves variable climate inputs, but also includes modifications to the Proposal water management plan that were made in response to updated water quality predictions resulting from assessing the effects of the variable inputs.

Climate variability was modelled by systematically varying climatic inputs based on a 52 year historical climate record (precipitation and temperature) developed for the project site. The historical climate record was based on correlating available project site data with the measured data from the regional climate station at Pelly Ranch (ID 2100880), which is operated by Environment Canada (EC). Details of the development of the precipitation and temperature record for the project site are included in the KP Report “Casino Project – Baseline Climate Report” (2013c).

The water balance timeline included four years of baseline conditions (Year -8 to Year -5), four years of pre-production (Year -4 to Year -1), 22 years of operations (Year 1 to Year 22), 91 years of closure (Year 23 to Year 113), and 87 years of post-closure (Year 114 to Year 200). The 52 year net precipitation

sequence therefore had to be repeated four times to produce a time series long enough for the 208 year simulation timeline. This approach maintained the inherent cyclical nature of the climate record. The climate variability model was run with 52 iterations for each year of simulated mine life, enabling a large number of combinations of resulting wet, dry, and median months and years of precipitation to be considered. The climate inputs were essentially cycled through the model, such that the monthly climate inputs for year 2 in the first run became the inputs for year 1 in the second run, and the inputs for year 3 in the first run became the inputs for year 2 in the second run, and so on. Each year of monthly climate values that was displaced was then tacked onto the end of the 208 year (4 x 52 years) time series. Model outputs, and in particular flow volumes, were then compiled as distributions for each month in each year, from which probabilities of occurrence could be determined. The probabilities of occurrence presented for the water balance results represent the following conditions:

- Median scenario – 50% chance of being equaled or exceeded in any given month or year;
- 95th percentile scenario – 95% chance of the water volume or flow rate not being equaled or exceeded in any given month or year (5% chance that it will be); also referred to as the 95th percentile wet; and
- 5th percentile scenario – 5% chance of a water volume or flow rate not being equaled or exceeded in any given month or year (95% chance that it will be); also referred to as the 95th percentile dry.

The climate variability water balance model was used to assess the effects of the variable climatic inputs on the project, and provided a range of water quantity predictions over the operations, closure and post-closure phases. The flow outputs from the climate variability water balance were used as the inputs to the corresponding water quality model prepared by SEA. The general arrangement for the maximum footprint of the project used for the water balance is shown on Figure 1.

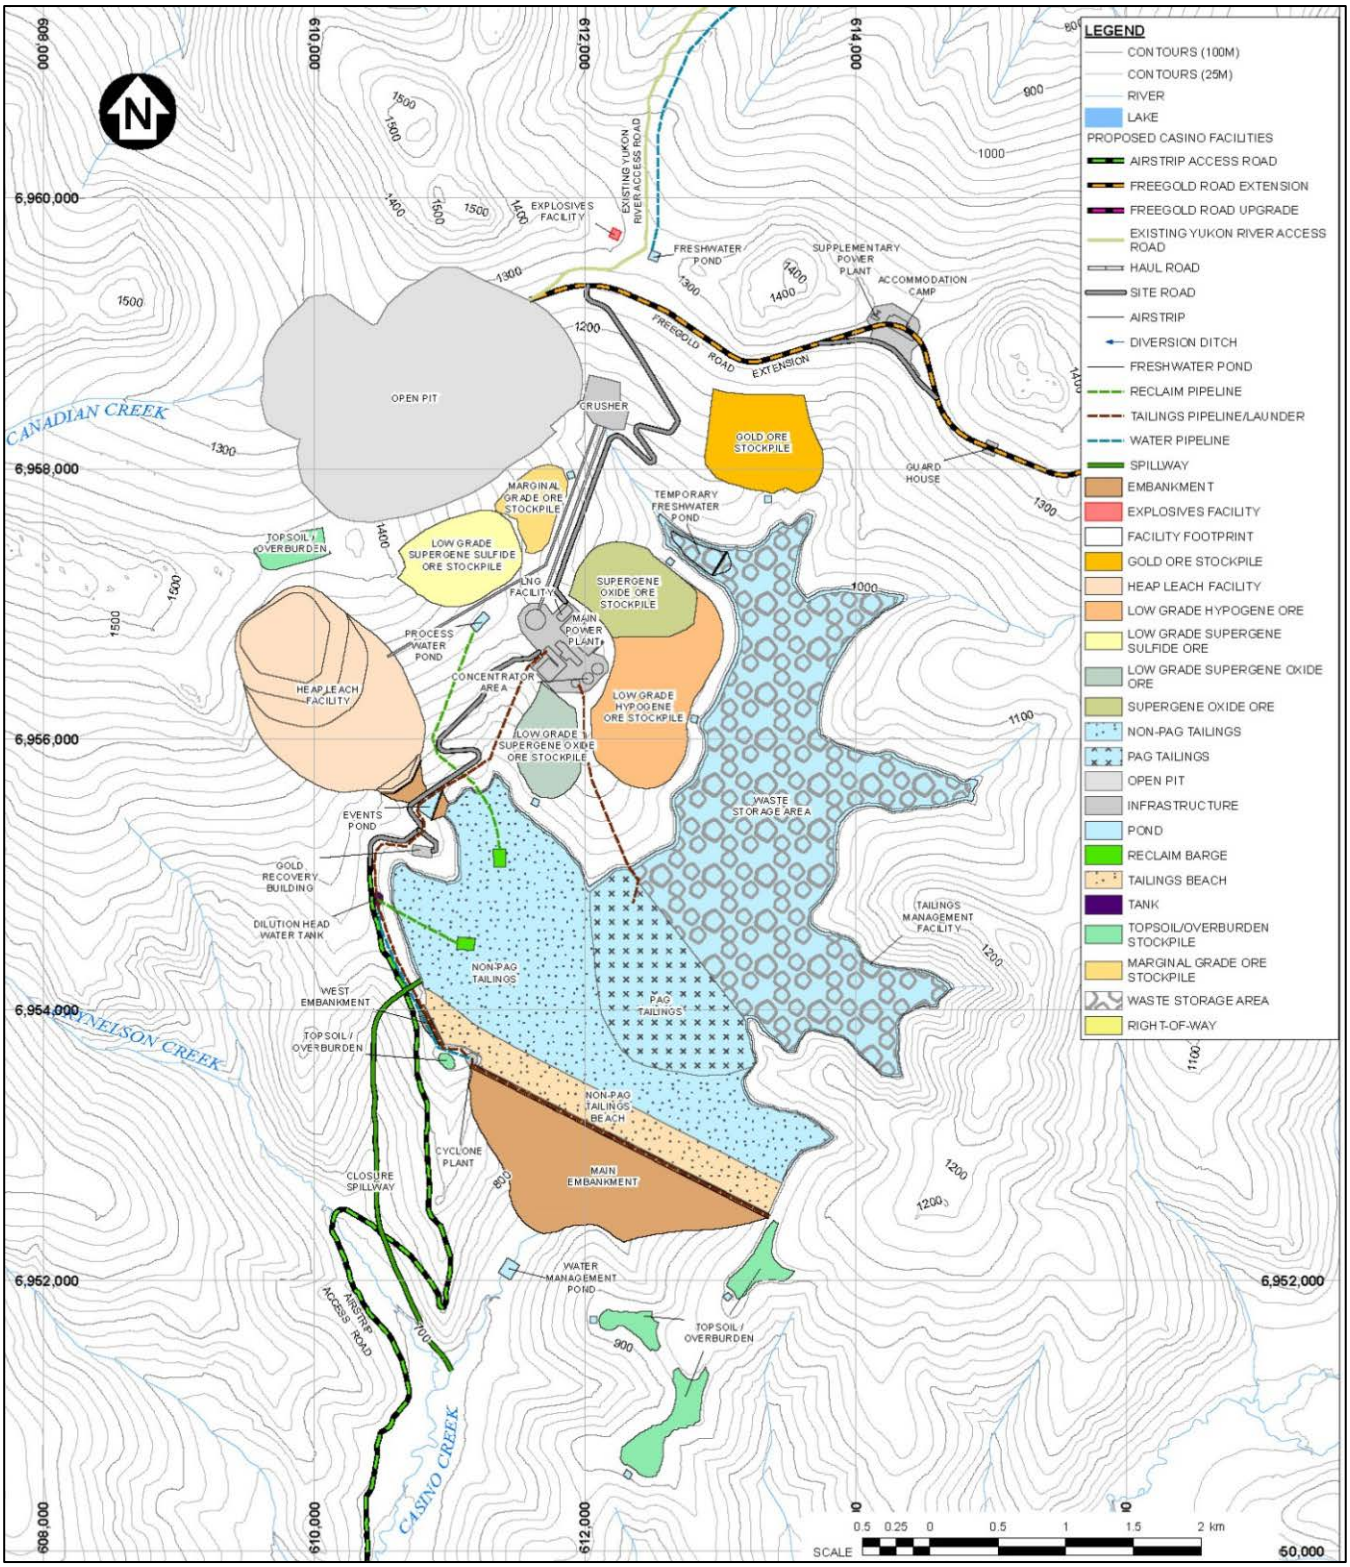

Figure 1 General Arrangement for the Maximum Footprint

3 – WATER MANAGEMENT ASSUMPTION UPDATES

The basic components of the water balance remain unchanged from those in the Proposal, but the water management plan was modified to address potential water quality issues identified by climate variability water quality modelling. The water management plan was modified as follows:

3.1 TAILINGS MANAGEMENT FACILITY AND OPEN PIT

Operations (Years 1 to 22):

- The water management pond (WMP) to be constructed downstream of the TMF embankment will include a seepage cut-off wall keyed into bedrock. The purpose of the cut-off wall will be to intercept all seepage from the TMF and force it to surface where it will collect in the storage pond. Previously, this seepage cut-off was to be implemented only at closure but now it will be constructed prior to operations in order to improve the capture of seepage from the TMF.

Closure Water Management Phase I (Years 23 to 34):

- During the first 5 years of closure (Year 23 to 27), while the TMF pond water is being pumped to the Open Pit, the seepage and runoff collected in the WMP will also be pumped directly to the Open Pit. Pumping of the WMP water directly to the Open Pit will help to facilitate ongoing improvement of water quality in the TMF pond.
- Following the 5 years of pumping TMF pond water to the Open Pit, the TMF pond will be allowed to fill naturally to the closure spillway elevation and then discharge to Casino Creek. Pumping of seepage from the WMP to the Open Pit will continue until the TMF pond reaches the approximate spillway elevation, which is predicted to occur in approximately Year 34 (under median conditions). The TMF filling time predicted in the climate variability water balance is similar to that predicted in the Proposal water balance; that is, approximately 10 to 15 years after the end of operations.
- The WMP will be expanded in closure to 600,000 m^3 (unchanged from the Proposal) in order to accommodate runoff and seepage water collected from the TMF and store it during the winter months. In the Proposal, this pond was referred to as the “winter seepage mitigation pond” in closure. For simplicity, in the climate variability model this pond will be referred to as the “water management pond” in closure, since the pond features largely remain the same as in operations (i.e. seepage cut-off wall), with the exception of the increase in volume.
- The closure cover on the Heap Leach Facility (HLF) was assumed to be 80% effective at reducing infiltration for the climate variability water balance, as opposed to an assumption of 50% in the deterministic water balance. This increase in effectiveness is based on re-contouring of the heap surface slopes and the placement of a low permeability material on top of the heap, as described in the “Conceptual Closure and Reclamation Plan” (Brodie, 2013) submitted with the Proposal.

Closure Water Management Phase II (Years 35 to 109):

- Seasonal discharge from the WMP will commence once the TMF is spilling and when natural flows in Brynelson Creek are sufficient to provide substantial dilution. This constraint was implemented as a mitigation measure in order to prevent the discharge of seepage from the project at times when there is little to no dilution available from surface runoff. The seasonal timing and associated discharge rates from the WMP will be as follows:
  - In April, the WMP will be allowed to discharge naturally as required.
  - In May, once Brynelson Creek is flowing at a rate of 20 L/s or more, the WMP will discharge at a ratio of 0.8 times the Brynelson Creek flow.
  - From June to November the WMP will discharge at a ratio of 0.8 times the Brynelson Creek flow or 200 L/s, whichever is greater. This condition will ensure that the pond will be emptied by the end of November each year.

- An additional mitigation measure adopted in the climate variability model included the discharge of surface water from the TMF to Casino Creek at the onset of freshet and through April and May to supplement the dilution of the seepage discharge from the WMP. A low-level outlet was incorporated into the TMF spillway and was assumed to discharge water at a ratio of 2.0 times the WMP seepage discharge in April and May, and then at a ratio of 1.2 until November, while still maintaining adequate water cover over the wetlands, tailings and waste rock stored in the TMF, under all climatic conditions.
- The TMF will continue to discharge excess water via the closure spillway under wet conditions, as necessary.

Closure Water Management Phase III (Year 109+):

- The Open Pit is predicted to be full as of Year 109 (under median conditions), approximately 87 years after the end of operations. This filling time is approximately 5 years less than the 92 years (Year 114) that was predicted with the deterministic water balance.
- Once the Open pit is completely flooded and discharging to the TMF, the TMF seasonal discharge (April through to November) ratio was assumed to increase to 2.5 times the WMP discharge.

4 – VARIABLE CLIMATE INPUTS AND ASSUMPTIONS

4.1 NET PRECIPITATION INPUTS

Climate variability was modelled using the net precipitation values from the calibrated watershed model described in Appendix A of the *Casino Project – YESAB Water Balance Model Report* (KP, 2013b). Net precipitation is the water available for groundwater recharge and runoff, determined as the total amount of precipitation (rainfall and snowmelt) less losses to the environment (e.g. evapotranspiration and soil moisture losses). The watershed model produced a 52 year time series of net precipitation values for baseline and mine development conditions, as presented in Appendices A and B (attached), respectively.

4.2 LAKE EVAPORATION

The deterministic water balance used an annual lake evaporation value of 300 mm for the project site, based on mean monthly values calculated using the Thornthwaite equation (without latitude correction), as presented in the baseline climate report (KP, 2013c). A subsequent review of lake evaporation for the project suggested that the annual value should be greater, and more in the range of 350 mm to 400 mm. Therefore the lake evaporation values in the climate variability water balance were revised to equate to an average annual value of approximately 390 mm, which was achieved by applying a latitude adjustment factor to the monthly values calculated using the Thornthwaite equation. The revised lake evaporation estimates are considered appropriate based on regional evaporation information currently available from the Yukon and Alaska. The estimated monthly lake evaporation values for the TMF pond and the Pit Lake, at an assumed elevation of 1400 m, are shown in Table C.1 in Appendix C.

4.3 DOWNSTREAM WATER QUALITY COMPLIANCE NODE

Flows at an additional node (W16) located downstream of the water balance model footprint were calculated for water quality purposes. Flows at this node were simulated by prorating flows from the upstream water balance model on the basis of drainage area.

5 – WATER BALANCE RESULTS

5.1 OVERVIEW

Using the climate variability approach, 52 different simulated flow values were generated for each node in the model. The water balance flow schematics, as previously developed for the deterministic water balance (KP, 2013b), were updated and are included in Appendix D. The annual flow volumes that correspond to the

nodes presented in the flow schematics for each water management phase have also been summarized in Table D.1, based on the median case results.

The following sections present discussions of detailed water balance results for the TMF, Open Pit, Water Management Pond (WMP), and Heap Leach Facility (HLF). The results are presented as monthly and annual probabilistic values (median, 95th percentile wet and 5th percentile dry), as well as mean, maximum and minimum values derived from the 52 model iterations.

5.2 TAILINGS MANAGEMENT FACILITY

The water balance was used to determine the likelihood of having a surplus or a deficit water condition for mill operations. A deficit condition pertains to when the TMF pond volume is insufficient to maintain mill operations. The minimum required TMF pond volume during operations was assumed to be 15 Mm^3, which is equal to approximately three months of mill requirements. Makeup water from the Yukon River was used to supplement the mill process water when deficit conditions occurred during years of mill operations (Years 1 to 22). The annual makeup flow requirements for the mill during operations are summarized in Table 1.

Prior to mill start up in Year 1, water from the Yukon River will be required to supplement the TMF pond to establish the minimum starting pond volume of 15 Mm^3. The start-up water requirements from the Yukon River are summarized in Table 2. The Yukon River freshwater pipeline will be adequately sized to convey the makeup water requirements for all phases of the Project. Figure 2 presents the possible range of pond volumes in the TMF, for both pre-production and operations of the mine, under variable climate conditions.

The TMF makeup water requirements at start-up and during operations that are predicted by the climate variability water balance are consistent with but slightly lower than those predicted by the deterministic water balance. There is no makeup water required under all scenarios for Year 22 because the TMF is in a surplus condition and can supply all the required process water required by the mill.

Table 1 Annual Process Water Makeup Requirements

Mine Year	Process Water Makeup Requirements (m^3/yr)					
	Mean	Maximum	5th Percentile Dry	Median	95th Percentile Wet	Minimum

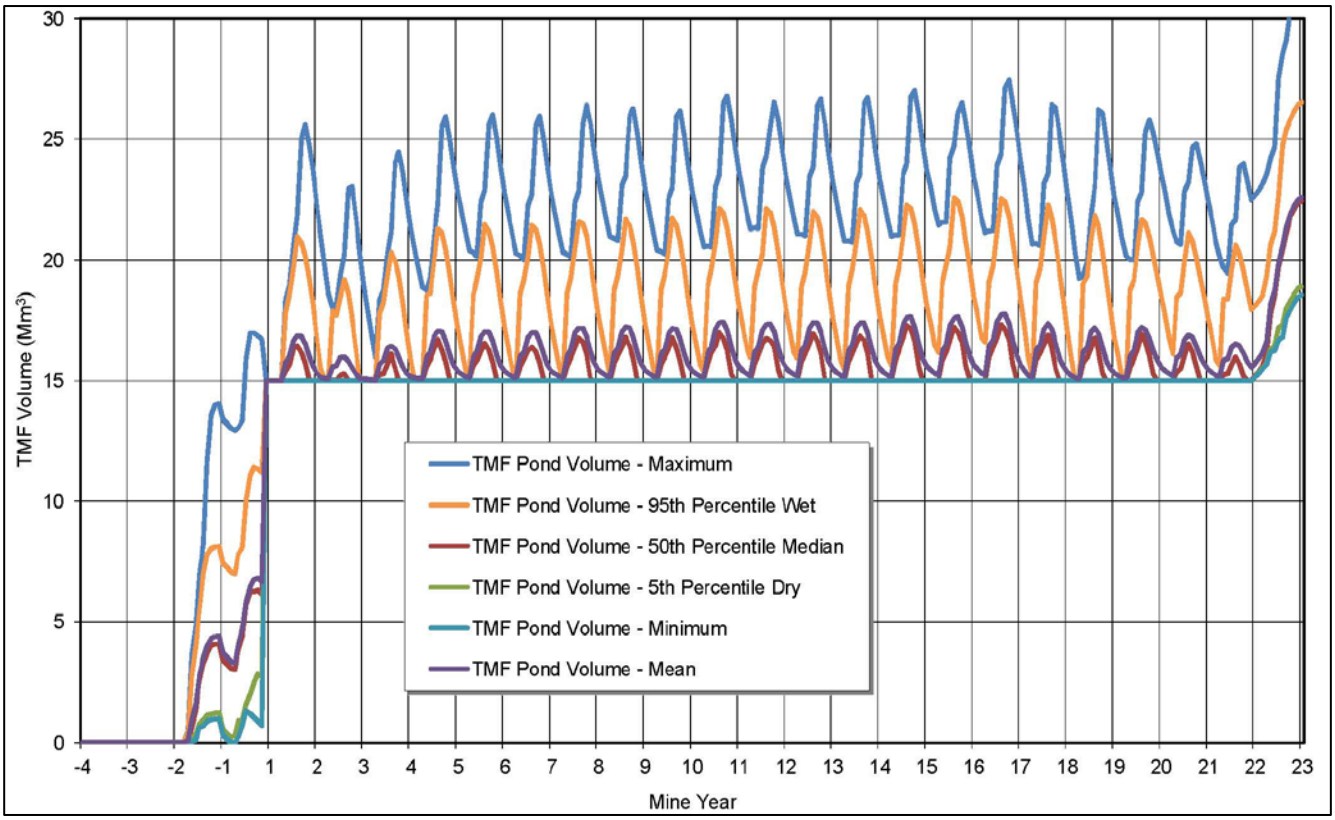

Figure 2 Tailings Management Facility Simulated Pond Volumes for Operations

Following the cessation of milling activities, water in the TMF pond will be pumped to the Open Pit to allow for the construction of the North and South TMF wetlands. The range of possible TMF pond water depths resulting from pumping under various climate scenarios are summarized in Table 3. Following the wetland establishment, the TMF pond will then fill at its natural inflow rate, and will take between 10 and 15 years to completely fill and begin spilling, depending on climate conditions.

Table 3 TMF Water Depth as a Result of Pumping to the Open Pit

	TMF Pond Depth (m)

Median	1.0
95th Percentile	1.8
Maximum	2.0

Discharge from the TMF pond in closure will be via the constructed TMF spillway to Casino Creek downstream of the WMP. The discharge from the TMF pond will be a combination of the water released through the low-level outlet in the spillway and the excess flow through the main spillway during wet periods. The predicted total combined monthly and annual discharges through the TMF spillway (low-level + main spillway) are summarized in Table 6 for the varying climate conditions. The monthly and annual flow rates for Years 60 and 120 are shown, which represent the periods prior to the Open Pit spilling and after the Open Pit spilling.

5.3 OPEN PIT

During closure, the Open Pit will be allowed to fill and become a pit lake. The annual Pit Lake discharge volume will be released to the North TMF Wetland at a controlled rate through a gravity controlled discharge system during the warmest months of the year (June through September). The climate variability water balance was used to determine the Pit Lake filling time under variable climatic conditions. The climate variability water balance simulation shows that the Pit Lake will take approximately 87 years (Year 109) to fill after the end of operations for the median case, and 83 to 88 years to fill based on 95th percentile wet and 5th percentile dry scenarios, respectively.

Once pit filling is achieved, a controlled release flow averaging 180 L/s (June through September) will be required to maintain lake levels in the Pit at or below an elevation of 1095 masl, based on average climate conditions. Flows in excess of the controlled flow rate will be allowed to spill to the North TMF Wetland. Table 5 summarizes the release rates from the Pit Lake to the North TMF Wetland for Year 110. The climate variability water balance results show that the assumed release rate from the deterministic water balance of 180 L/s will still able to maintain the maximum Pit water level elevation of 1095 masl in closure, for the median and dry scenarios. For the 95th percentile wet scenario, the climate variability model predicts excess release rates to occur in the first 11 years (Years 109 to 119) following the commencement of the Pit Lake release. The surplus flows will be discharged downstream to the North TMF Wetland.

5.4 WATER MANAGEMENT POND

The Water Management Pond (WMP) that will be constructed prior to operations, downstream of the TMF main embankment, includes a groundwater seepage cut-off wall keyed into bedrock, which will function to collect seepage and embankment runoff. In closure, the WMP will be expanded to a volume of 600,000 m^3 to allow for

the collection and storage of all runoff and seepage over the winter. Initially in closure, the water collected will be pumped directly to the Open Pit for the duration of Closure Water Management Phase I. Once the TMF begins spilling (Closure Water Management Phase II), flows collected in the WMP will be stored during the low flow months (December through March) and discharged during the spring to coincide with periods of flows in Brynelson Creek and and/or discharge from TMF spillway (April through November). Discharge from the WMP will continue in Closure Water Management Phase III, once the Open Pit is full and spilling to the TMF pond. The flow releases from the WMP are summarized in Table 6 for Years 60 and 120, which represent the periods prior to and after the Open Pit is spilling to the TMF pond.

The water management pond flow release rates for the closure period predicted by both the climate variability and deterministic water balances are consistent on an annual basis, for the median scenario. However, the monthly distributions of the flow releases differ, as those for the climate variability water balance were modified to match the timing of higher flows in Brynelson Creek in order to achieve better dilution of the winter seepage releases. This modification results in higher discharges from the pond in May, compared to the deterministic water balance, with minimal releases in April and November. Overall, the water management pond in closure is still predicted to empty by the end of each year and provide adequate storage for the winter seepage and runoff.

Table 6 Water Management Pond Flow Releases in Closure

5.5 HEAP LEACH FACILITY

The results of the climate variability water balance indicate that the Heap Leach Facility (HLF) will operate in a water deficit condition during all months of operations when ore stacking is active (Years -3 to 15). Table 7 summarizes the annual makeup water requirements during operations when ore is being actively irrigated with cyanide solution. As shown in Table 7, the makeup water requirements will decrease each year as water released from inactive areas becomes available and the environmental contributions will increase due to the increasing heap footprint. The makeup requirements predicted by the climate variability water balance are slightly lower than those predicted by the deterministic water balance; however, this also results in more

discharge from the heap to the TMF pond and/or Open Pit in the active closure phases of heap operations, as shown on Figure 3.

Figure 3 presents estimates of the surplus water generated from the heap as well as the accumulated water stored in the heap, for the median and 95th percentile wet cases. The heap will be in a surplus condition from July to September, in Years 15 to 23 (median case), because the environmental inputs will exceed the leaching water requirements during these months. The surplus water from Years 15 to 18 (blue line) is assumed to be recycled to inactive areas of the heap, therefore adding to the water inventory in the heap. During the rinsing phase (Years 19 to 23) no additional water will accumulate in the heap because the surplus water (orange line) will be pumped to the Open Pit to aid in pit filling. Once the heap draindown commences in Year 24, the stacked ore is assumed to drain to the long-term residual moisture content of 5% (by mass) over 5 years until Year 29. During the heap draindown phase, the draindown water will be discharged from the heap at a constant rate of 52,535 m^3/mon (1726 m^3/day) plus whatever environmental inputs occur (rain plus snowmelt), which will result in the seasonal discharge pattern illustrated by the red line on Figure 3. The surplus water during this phase is assumed to be pumped to the Open Pit. Once the draindown flow reaches manageable levels, as of Year 29, the closure cover on the heap is assumed to become effective by reducing the infiltration through the heap by 80% of net precipitation, and accordingly the water discharged from the heap will be reduced, as shown by the green line. From this time onwards, in perpetuity, the heap discharge as well as the runoff from the closure cover will be routed naturally downstream to the TMF pond.

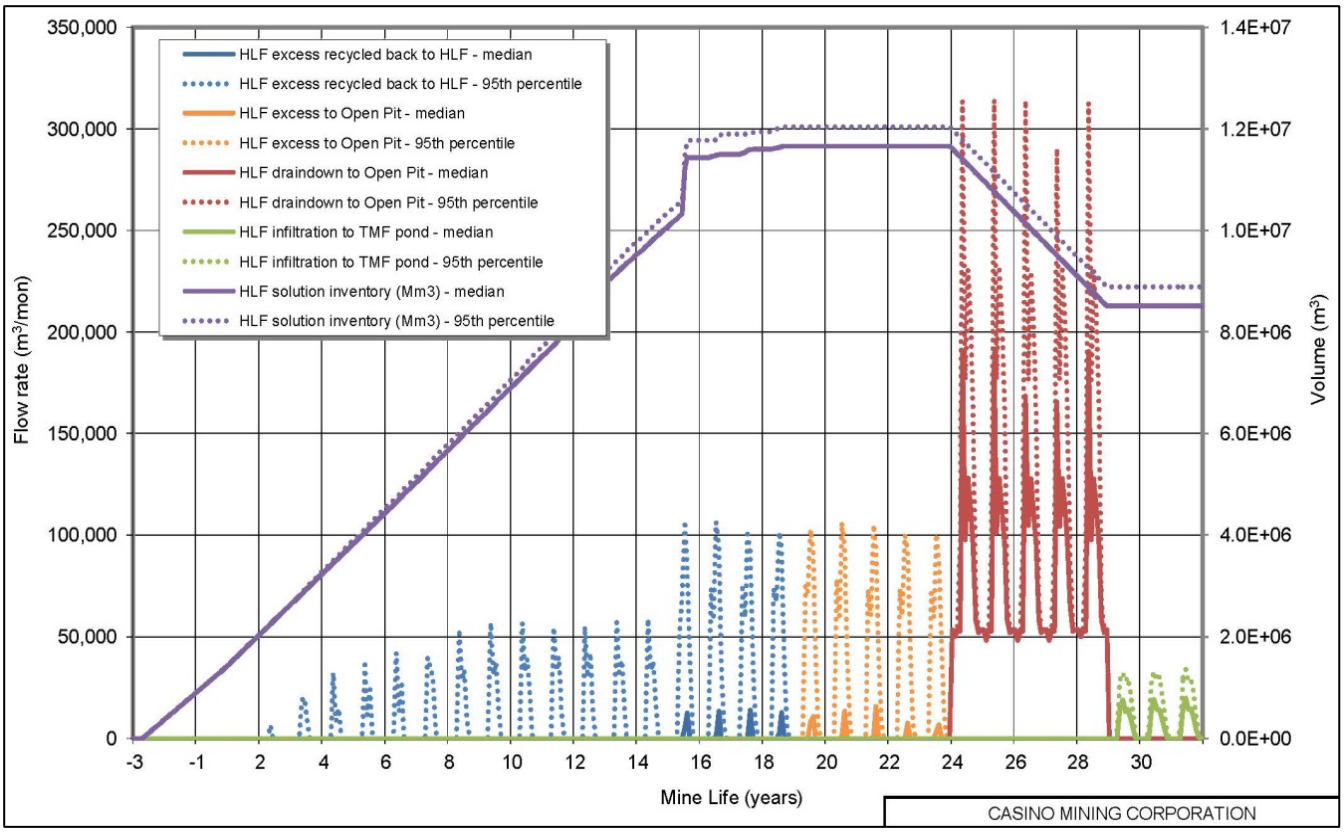

Figure 3 Heap Leach Facility – Accumulated Water and Monthly Surplus

6 – SUMMARY

The deterministic (Proposal) water balance was updated to include climate variability. The purpose of the climate variability model was to evaluate the quantities and rates of flow of water in the ground, in the streams, and in various mine facilities under a variety of climate conditions. The climate variability water balance results were also used by SEA to develop a water quality model for the project. The key results of the water balance for varying climate conditions are as follows:

- The project mine will be in a water deficit condition during operations; therefore, makeup water from the Yukon River freshwater pipeline will be required to supplement the mill process. Makeup water requirements for dry conditions (5^{th} percentile) will range from 12.6 Mm^3/yr at the start of operations to 8.3 Mm^3/yr at the end of operations, while for wet conditions (95^{th} percentile) they will range from 5.3 Mm^3/yr at the start of operations to 1.8 Mm^3/yr at the end of operations.
- Prior to mill start up in Year 1, water from the Yukon River will be required to supplement the TMF pond to establish the minimum starting pond volume of 15 Mm^3. The start-up water requirements from the Yukon River range from 12.6 Mm^3 (5^{th} percentile dry) to 4.0 Mm^3 (95^{th} percentile wet).
- Water in the TMF pond will be pumped to the Open Pit for five years following the end of operations, which will draw down the TMF pond level by approximately 0.5 m to 1.8 m, depending on the climate variability.
- The TMF will take approximately 10 to 15 years after the end of operations to begin spilling through the constructed spillway.
- Annual discharges from the TMF spillway will range from approximately 69 to 232 L/s (5^{th} and 95^{th} percentiles) following the TMF reaching its maximum capacity in closure, and range from approximately 118 to 303 L/s (5^{th} and 95^{th} percentiles) once the Pit Lake begins discharging.
- It will take approximately 83 to 88 years after the end of operations to establish the Pit Lake in the Open Pit, with an outlet elevation of 1095 masl.
- The release from the Pit Lake to the North TMF Wetland will have an average outflow of 180 L/s during June through September in order to maintain the Pit Lake elevation. For the 95^{th} percentile wet scenario, additional water will be need to be released in the first 11 years after the Pit is full to maintain the Pit Lake elevation at 1095 m. Releases are not required under the median and dry scenarios.
- The water management pond (WMP) constructed downstream of the TMF will begin releasing flows when the TMF has reached its maximum capacity and begins spilling. The WMP will release flow from April to November, with the flow rates varying per month to match the flow in Brynelson Creek in order to provide the necessary dilution to maintain water quality standards. There will be no flow releases from December through March and the pond has been sized to collect and store seepage and runoff during the winter months.
- The heap leach facility will be in a water deficit condition during operations, with makeup water consistently required from the Yukon River. Makeup water requirements for dry conditions (5^{th} percentile) will range from 0.08 Mm^3/yr to 0.6 Mm^3/yr, while for wet conditions (95^{th} percentile) they will range from 0.1 Mm^3/yr to 0.4 M m^3/yr. After operations, the heap leach facility will be in a surplus condition and water will be discharged to the Open Pit until draindown is complete, after which it will be discharged to the TMF.

ENVIRONMENTAL ASSOCIATES INC.

February 2015

Executive Summary

Introduction

A site-wide water quality model was developed for the proposed Casino Project. The model simulates water quality in the mine discharge and receiving environment. The model was used as a planning tool to help select water quality mitigation systems.

The site-wide water quality model is organized by the following six model components:

- Open Pit Lake
- Ore Stockpile Drainage
- Heap Leach Facility
- TMF Pond and Treatment Wetlands
- Seepage Management Pond
- Receiving Environment

The water quality model was developed within the GoldSim modelling platform, and includes 27 water quality parameters (i.e. potential contaminants). The model was run with a monthly time step for a time period beginning a few years prior to Construction, and continued for 200 years following the beginning of Operations.

A site-wide water balance was developed by Knight Piésold Limited (KPL) and was used as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim.

A water balance model was initially developed by KPL in 2013 and is described in KP (2013c). The 2013 water balance was representative of average annual hydrologic conditions at the site. Water quality modelling for the average annual water balance was carried out by SEA. Modelling methodology and results were reported in SEA (2013).

In 2014, a climate variability water balance model was developed by KPL (KPL, 2015) to account for the expected variability in hydrological conditions (i.e. wet and dry periods) from year to year. SEA used the climate variability water balance as the basis for the water quality model that is described herein. This report contains all information relevant to the water quality model, and repeats the pertinent information previously provided in the December 2013 report (SEA, 2013).

Input to the climate variability water balance model was developed by correlating existing site hydrology data with regional data to derive a long-term synthetic dataset of monthly site conditions. A dataset of monthly hydrological conditions (e.g. streamflow, temperature, precipitation) was developed from 52 years of continuous regional data. A

correlation was established between the regional data and data collected at the Project site. The correlation was used to convert the regional dataset to a 52-year synthetic dataset of weather conditions at the Project site. Because the model was run over a simulation period of ~200 years, the 52-year input dataset repeats approximately four times during a given simulation.

Geochemical source terms for the water quality model were developed by Lorax Environmental Services Ltd. (Lorax) and were incorporated into the GoldSim model as the basis for mass loading calculations. The source terms for the climate variability water quality model are consistent with the source terms used in the model presented in the 2013 water quality modelling report.

Geochemical modelling was integrated into the site-wide water quality model by use of dynamic links between GoldSim and PHREEQC software. The model nodes with geochemical solubility controls include the following:

- Pit Lake;
- TMF pond; and
- TMF Seepage Water Management Pond.

These nodes are locations where mixing of water streams would occur and solubility controls are expected to affect the concentrations of some water quality parameters (such as aluminum, copper and iron).

Mine drainage will enter Casino Creek (to the south) and will not enter Canadian Creek (to the north). Because there will be no mine derived sources of contaminants entering the Canadian Creek drainage basin, model predictions were limited to the Casino and Dip Creek basins.

Water Quality Mitigations

The water quality model results were used as a rationale for the selection of a number of water quality mitigation systems. Initially, copper was used as the contaminant of concern (CoC) for mitigation planning because copper was predicted to potentially exceed water quality targets by orders of magnitude based on the source terms. Once desired copper concentrations were achieved in model results, mitigations were considered for other CoCs including sulphate, fluoride, cyanide, cadmium, molybdenum, selenium, uranium, and iron.

Key Project mitigation plans for the Open Pit are as follows:

- The North TMF wetland was designed to passively treat the Pit Lake discharge. The Pit Lake water quality model results indicated that the discharge will be at

acceptable concentrations and pH for successful treatment in the North TMF wetland.

Key project mitigations included in the water quality modeling for the HLF are as follows:

- Following HLF operations, surplus water will be treated and pumped to the Open Pit until the HLF cover is in place by year 29. Treatment will include cyanide destruction and removal of selenium and mercury. Further cyanide degradation of the HLF discharge will occur as the Open Pit is filled.

- Surplus water will be directed to the Pit Lake following cyanide destruction and selenium and mercury treatment. Following drain-down, the HLF will be re-contoured and covered to promote runoff and minimize infiltration. The soil cover placed over the HLF is expected to reduce seepage from the toe of the HLF to 20% of the total net surplus water.

Key Project mitigation plans for the TMF are as follows:

- The upward migration of groundwater through the submerged waste rock in the TMF is expected to impact the water quality of the TMF Pond water. The South TMF wetland will be in place to passively treat TMF Pond water prior to discharge to Casino Creek.

- TMF pumping to the Pit Lake at closure will lower the water level in the TMF and will create suitable working conditions for the construction of the TMF wetlands.

- The placement of waste rock in the upstream (northern) end of the TMF where there will be minimal loading contribution to the foundation seepage.

The wetland passive treatment systems were designed by Clear Coast Consulting Inc. Passive treatment by the North and South wetlands was modelled as follows:

- The wetlands treat Cd, Cu, Mo, Hg, Ag, Zn to the CCME guideline;

- The wetlands treat SO_4 to 85% of the inflow concentration (i.e., 15% removal).

Key Project mitigation plans for seepage water quality management:

- Source control for one of the six ore stockpiles was identified as an appropriate Project mitigation. The groundwater seepage pathway from the southern-most ore pile was estimated to have the greatest potential influence on Casino Creek water quality. As a result, the Project proposal incorporates mitigation (e.g., groundwater seepage collection) to intercept 90% of potentially contaminated stockpile seepage. The collected discharge will be directed to the TMF pond.

- Water collected in the TMF seepage Water Management Pond (WMP) will be pumped back into the TMF Pond until the end of operations. Following

Operations, the WMP will be temporarily pumped to the Open Pit until discharge of the TMF Pond commences.

- Following mine closure, the WMP will store winter seepage and release it during the open water season when it will be mixed with the TMF Pond discharge prior to release to Casino Creek. Mixing the discharges will allow for dilution of the WMP release, especially when there is little-to-no flow expected in Brynelson Creek, a tributary to Casino Creek.

Model Results

The water quality model results for Casino Creek and Dip Creek are summarized by CoC and compared to CCME water quality guidelines. As there is no CCME water quality guideline for sulphate, the BC Water Quality Guideline (BCWQG) was adopted. Water quality guidelines are presented in this report as a point of reference and do not represent the water quality objectives adopted for the Project.

The model results are presented in two ways in this report:

1) Single Model Realization
   Results generated when one realization of the input hydrology dataset was run with the model. Single realization results provide a time-series of model output which shows a representation of water quality that would result from a realistic range in hydrological conditions at the site. The output provides an indication of how high (or low) water quality concentrations may get, and how often those results are expected to occur. Time-series plots and summary tables of water quality results for a single realization are presented throughout this report.

2) Monte-Carlo Summary (52 Realizations)
   The model was run 52 times. Each model run used a unique input hydrology dataset. The combined output from the 52 model runs (i.e., realizations) represents the range in all possible model outputs resulting from all the possible permutations of the input hydrology dataset. A statistical summary of the model output for the 52 realizations was generated to be used as the basis for the aquatic impact assesment.

The water quality results in this report do not represent an impact assessment. Palmer Environmental Consulting Group (PECG) completed the aquatic impact assessment of the Casino Project including the effects of the Project on the receiving environment downstream of the Project. EDI Consulting Services completed the wildlife impact assessment of the Casino Project including the effects of the Project resulting from the two long-term wetlands and two water bodies (Open Pit and TMF Pond) following mine closure, as presented in the Project Proposal (CMC, 2014).

The results showed that the water bodies on site (Pit Lake, TMF Pond, and WMP) will be able to produce more or less consistent inter-annual water quality in the receiving environment by balancing mine derived water between wet and dry years such that it can be released to the receiving environment when sufficient assimilative capacity is available.

The largest factor driving variation in Casino Creek water quality is the flow in Brynelson Creek because it will make up the majority of background flow in Casino Creek immediately downstream from the Project site. In low-flow years, higher concentrations can be expected in Casino Creek. The model results showed some exceedances of water quality guidelines in Casino Creek. This list includes sulphate, fluoride, cadmium, copper, iron, molybdenum, selenium, and uranium.

Site discharge water was calculated (using PHREEQC) to be pH neutral. Similarly, the resulting streamflow in Casino and Dip Creeks were calculated to be pH neutral. The model results showed some exceedances of generic water quality guidelines in Dip Creek. This list includes fluoride, cadmium, and copper. Molybdenum and sulphate guidelines were exceeded infrequently (i.e. about 3 times over the 200 year simulation). Exceedances of the water quality parameters are discussed in the impact assessment.

1 Introduction

The Casino Project (the Project) is a proposed open pit copper-gold-molybdenum mine in the Yukon Territory owned by Casino Mining Corporation (CMC). The Project is located at 62.74°N and 138.82°W, approximately 300 km northwest of Whitehorse, Yukon. A location map is provided in Figure 1-1. The deposit will be mined by open pit methods and processed on-site using conventional flotation cell milling methods, with an estimated nominal mill throughput of 120,000 tonnes/day of ore, over a 22 year operating life. The Project also includes a heap leach facility for cyanide leaching of gold ore.

A water quality model was developed to predict mine drainage water quality and the potential for effects on the receiving environment of the proposed Casino Mine. A site-wide water balance was developed by Knight Piésold Limited (KPL) and was used by Source Environmental Associates Inc. (SEA) as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim.

A water balance model was initially developed by KPL in 2013 and is described in KP (2013c). The 2013 water balance was run using average annual estimates for hydrologic conditions at the site. Water quality modelling for the average annual water balance was carried out by SEA. Modelling methodology and results were reported in SEA (2013).

In 2014, a climate variability water balance model was developed by KPL (and is described in KPL, 2015) to account for the expected variability in hydrological conditions (i.e. wet and dry periods) from year to year. SEA used the climate variability water balance as the basis for the water quality model that is described herein.

A comparison between the SEA (2013) water quality modelling report and this report is provided in Table 1-1.

Mine drainage and naturally occurring sources of potential contaminants within the hydrologic system of the Project site were characterized, and the rate of mass transport (mass loading) from each source was estimated. Flow rate (hydrologic) estimates were combined with mass loading rates to predict water quality concentrations of potential contaminants in the Project receiving waters.

This report presents the methodology and results of the water quality predictions. The main body of this report presents a summary of the water quality predictions in the mine drainage and in the receiving environment. Additional information related to modelling methodology and results are presented in Appendices to this report. This report contains all information relevant to the water quality model, and repeats the pertinent information previously provided in the December 2013 report (SEA, 2013).

Figure 1-1. Location Map

Table 1-1 Comparison between 2013 and 2015 Modelling Reports

Concept	SEA (2013) Report	Applies to this Report
Water Balance Input Dataset	Average monthly hydrologic conditions (e.g. precipitation, temperature, streamflow, etc.) were used as input for every year of the model simulation.	Inter-annual variation in hydrologic conditions was applied throughout the model simulation. Water balance output flows were calculated from a synthetic, long-term (52 year) input dataset of monthly hydrologic conditions. The synthetic dataset was derived from regional and site data. **Rationale:** Using the range of monthly flows is more conservative (compared to using average annual flows) because realistic wet and dry periods can be simulated.
Estimation of Wet and Dry Years	n/a - wet and dry years were not simulated.	1-in-10 year wet and dry years were identified in the water quality output time-series plots. **Rationale:** To illustrate how the water quality management system will perform as a results of infrequent wet/dry periods.
Monte-Carlo Analysis (Stochastic Modelling)	Stochastic modelling was not carried out.	Model simulations included 52 unique input hydrology datasets. A statistical summary was generated from the water quality model output for the 52 realizations. **Rationale:** To account for all possible water balance flow scenarios that could result from the input hydrology dataset.
Project Phase Start Dates for TMF Discharge Phase and Pit Discharge Phase	Project dates were based on KPL (2013) water balance model output.	Project dates were based on KPL (2015) water balance model results.
TMF Seepage Cut-Off System	The TMF seepage cut-off system was to be constructed after Operations. As a result, during Operations, the WMP was assumed to have a 90% capture efficiency with 10% seepage by-pass to Casino Creek. Following Operations, the seepage cut-off system was to be constructed, resulting in 100% seepage capture efficiency (i.e. 0% by-pass).	The seepage cut-off system will be constructed prior to Operations. The seepage collection system was assumed to have 100% capture efficiency during Operations and for all subsequent mine phases. **Rationale**: Reduce the potential for seepage water to enter Casino Creek during Operations.

Concept	SEA (2013) Report	Applies to this Report
Water Management Pond (WMP) / Winter Seepage Mitigation Pond (WSMP)	WMP was to be online for seepage collection during Operations. Following operations, the WSMP was to be used for seepage collection in winter and release during summer. Both facilities were essentially situated in the same location.	For all phases, the seepage collection pond(s) will be referred to as the WMP. **Rationale**: Simplification of terminology.
WMP Pumping to the Open Pit (Wetland Construction Phase)	During the Wetland Construction Phase, the WMP was assumed to be pumped to the TMF Pond.	During the wetland construction phase, the WMP will be pumped to the Open Pit. **Rationale:** Mass load from the WMP by-passes the TMF Pond by pumping directly to the Open Pit.
WMP Release to Casino Creek	Release from the seepage pond was set at a constant rate of 130 L/s from May to August with flows gradually reduced to 50 L/s by November.	Release of WMP was set to 0.8 times flow in Brynelson for typical conditions. To ensure sufficient seepage storage capacity for the following winter an increased release rate (above 0.8 times Brynelson flow) will be used during exceptionally dry periods, to drain-down the WMP. **Rationale:** The available dilution in Brynelson will be utilized by proportioning the release of WMP to the natural hydrograph.
TMF Pond Release to Casino Creek	TMF Pond was allowed to naturally overflow seasonally with no control of the flow rate.	The TMF pond will be released in a controlled manner. The ratio of TMF pond release to WMP release will be set between 1.2 to 2.5, depending on the Project Phase and the month. The ratio increases when there is little flow in Brynelson to provide dilution of the seepage released. **Rationale**: The available dilution in Brynelson is utilized by tying the release of WMP to the natural hydrograph.

Concept	SEA (2013) Report	Applies to this Report
Location of GoldSim-PHREEQC modelling nodes Embedded in the Water Quality Model	Solubility limits were calculated (using PHREEQC) for the following nodes: • Open Pit • TMF Pond • "Mixing Point" (upstream from H18 – where TMF Pond and WMP water mix)	Solubility limits were calculated (using PHREEQC) for the following nodes: • Open Pit • TMF Pond • WMP **Rationale:** Contact of WMP seepage with atmospheric conditions will occur in the WMP and chemical precipitation is more likely to occur in the WMP, rather than at the mixing point.
Pit Water Quality PHREEQC Input Assumptions	Assumption was that all available NP in the pit walls was released during submergence and fully mixed in the pit. This results in neutral pH and low copper concentration (~0.4 mg/L).	Assumption is that the available NP in the pit walls will be a source of buffering. Only the NP required for buffering is released. This change in the assumptions resulted in a predicted Pit Lake pH of about pH 6.2 and higher copper concentrations (about 5 mg/L rather than 0.4 mg/L). **Rationale:** The updated assumption used in 2015 is more conservative because not all the NP in the wall rock will be released and mixed with the pit lake during initial submergence of wall rock.
pH Prediction	pH was calculated for mine contact water (TMF Pond, WMP, Open Pit) using PHREEQC. pH was not calculated for Casino and Dip Creeks.	pH was calculated (using PHREEQC) for mine contact water, Casino Creek and Dip Creek modelling points.
CoC List	7 CoCs were reported. The CoC list did not include fluoride.	Fluoride was added as a CoC, so 8 CoCs are reported. **Rationale**: Fluoride was added as it exceeded a generic water quality guideline

2 Overview of the Proposed Mine Facilities

The following section provides a discussion of the proposed mine components and activities as they are relevant to water quality modelling. Additional information related to design and operation of the facility is provided in the Project Proposal (CMC, 2014), as well as updated information provided in the Supplementary Information Report (SIR) (CMC, 2015).

2.1 Mine System Components

The following Project facilities are proposed for the Casino Project and are described in the following sub-sections:

- Open Pit;
- Ore Stockpiles;
- Heap Leach Facility (HLF); and
- Processing Facility (mill);
- Tailings Management Facility (TMF).

2.1.1 Open Pit

Mining will be carried out by conventional open pit methods. The Open Pit will be situated between the headwaters of Casino Creek and Canadian Creek and will be up to 600 m deep and up to 2400 m wide, with an ultimate footprint area of approximately 3 km^2. The four main mineralization types found in the Open Pit are summarized in Table 2-1.

Table 2-1. Mineralization Types in the Open Pit

Mineralization Type	Acronym	Characteristics
Leached Cap (oxide gold zone)	CAP	Gold-enriched and copper-depleted. Forms the top layer (average 70 m thick) of the mineralization types in the Open Pit.
Supergene Oxide	SOX	Copper-enriched, with trace molybdenite. Generally occurs as a thin layer (10 m) above the Supergene Sulphide zone.
Supergene Sulphide	SUS	Copper mineralization occurs in an up to 200 m deep weathered zone below the leached cap and above the hypogene. Average thickness of 60 m.
Hypogene	HYP	Below the other mineralization types, also occurs throughout the various alteration zones as mineralized stock-work veins and breccias.

2.1.2 Ore Stockpiles

Temporary storage of ore will be required to provide a steady input to the mill and to the HLF throughout Operations. Ore types will be separated and placed into six stockpiles based on ore grade and mineralization type (Table 2-2).

Mitigation measures to reduce groundwater seepage will be installed for the Low Grade Supergene Oxide pile to reduce loading to the environment. The seepage reduction mitigation was assumed to have 90% load reduction efficiency in the water quality model.

Table 2-2. Casino Ore Stockpiles

Ore Stockpile Name	Project Years [1]	
	Stockpiling	Processing
Supergene Oxide Ore	-3 to 1	4 to 12
Gold[2]	-2 to 3 & 8 to 10	4 to 7 & 11 to 15
Low Grade Supergene Oxide	-1 to 15	19 to 22
Low Grade Hypogene	2 to 17	19 to 22
Low Grade Supergene Sulphide	-1 to 16	19 to 22
Marginal Grade	-2 to 4	Backfilled to Open Pit

1. Project Years are relative to the first year of ore processing in the Mill, described in Section 2.2.
2. Leached Cap (CAP) rock to be processed in the HLF.

2.1.3 Ore Processing Facility (Mill)

Ore processing consists of primary crushing followed by a mill circuit and conventional copper/molybdenum flotation to produce molybdenum and copper concentrates. Process water will be supplied by reclaim from the TMF Pond with makeup water supplied from the Yukon River. The process will produce two tailings slurry streams: Non-Acid Generating (NAG) and Potentially Acid Generating (PAG). M3 Engineering and Technology (2013) estimated that 80% (by mass) of the total tailings will be NAG, and the remaining 20% will be PAG.

2.1.4 Heap Leach Facility (HLF)

The HLF will process crushed gold ore using a cyanide leach system. The HLF will be constructed in a small valley upslope from Casino Creek, 1 km south of the Open Pit. An earthen embankment at the eastern end of the pad will provide structural support. A composite liner system will be constructed below the HLF to minimize seepage into groundwater. A spill and runoff control collection system (Events Pond) will be constructed immediately down slope from the heap leach pad. The completed HLF and associated infrastructure will encompass approximately 1.3 km^2 (KPL, 2013a).

2.1.5 Tailings Management Facility (TMF)

Tailings and waste rock will be stored in the TMF, located in the Casino Creek valley southeast of the open pit. Two embankments, the Main Embankment, and the West Saddle Embankment will be constructed across the Casino Creek valley to create the storage impoundment. The finished TMF will have a footprint area of approximately 11 km^2, and a final water surface elevation of approximately 990 m.

Waste rock and PAG tailings will be stored subaqueously to maintain a saturated state and inhibit oxidation and potential reactivity. A portion of the NAG tailings will be processed in the cyclone sand plant to produce material for construction of the TMF embankments. The remainder of the NAG tailings will be stored in the TMF.

The TMF Water Management Pond (WMP) will be constructed downstream from the embankments to recover seepage and runoff from the embankments. The recovered seepage will be pumped back into the TMF Pond during mine Operations, and to the Open Pit for a few years following Operations, and will discharge to Casino Creek following Closure.

2.2 Project Water Management Phases

The Casino Project life was sub-divided into five water management phases (Table 2-3) in this document. Project years are described relative to the beginning of milling Operations. For example, Year -2 refers to the second year before Operations begins, and Year 2 refers to the second year of Operations. Relevant information related to water quality modeling is provided in the following sub-sections.

Project phases are based on the best estimate years provided by KPL in the climate variability water balance model report (KPL, 2015). Water balance model results indicated that the pit will most likely fill to its storage capacity and discharge to the North Wetland between Year 105 and Year 110, however, KPL has established Year 109 as the best estimate for the beginning of the Pit Discharge Phase. Therefore, Year 109 is used in Table 2-3.

Table 2-3 shows the project years that were presented in the 2013 report (SEA, 2013), for comparison. Mine years for the beginning of the TMF Discharge Phase and the Open Pit Discharge Phase differ slightly from those reported in the SEA (2013) report. The reason for this difference comes from a revision to WMP pump-out during the Wetland Construction Phase. In the 2013 version, the WMP was assumed to be pumped to the TMF Pond. In the 2015 revision, the WMP was assumed to be pumped to the Open Pit. As a result, reduced inflow to the TMF Pond led to a slightly longer time until initial discharge of the TMF Pond. Conversely, the increased inflow to the Open Pit led to a slightly shorter time to pit filling, and initial discharge, compared to the 2013 model results.

Table 2-3. Water Management Phases

Water Management Phase	Abbreviation	Project Year	
		SEA (2013) Report	Applies to this Report
Construction Water Management	Construction	-4 to -1	-4 to -1
Operations Water Management	Operations	1 to 22	1 to 22
Wetland Construction Phase (zero discharge from the mine site to Casino Creek continues during this phase)	Wetland Construction	23 to 30	23 to 34
TMF Discharge Phase (the TMF Pond and WMP will discharge to Casino Creek during this phase)	TMF Discharge	31 to 112	35 to 109
Open Pit Discharge Phase (the Pit Lake will have filled and discharges to the TMF Pond during this phase)	Pit Discharge	>113	> 109

2.2.1 Construction (Year -4 to Year -1)

Project construction is expected to take four years to complete. Activities relevant to water quality modelling include:

- Open Pit stripping of overburden and mining the top layer of ore;
- ore stockpile development;
- construction and operation of a fresh water supply pond (for interim use);
- construction of the fresh water supply pipeline from the Yukon River;
- construction of the Mill;
- construction and operation of the WMP downstream from the TMF footprint;
- construction of the cyclone sand plant;
- TMF embankment development; and
- construction and operation of the HLF.

Open Pit construction will begin by overburden stripping and stockpiling, followed by mining of the CAP rock from the Open Pit. The gold ore (from the CAP rock) that is removed from the Open Pit during the construction phase will be placed in a temporary stockpile (Gold Ore Stockpile), and processing by heap leaching will begin in Year -3.

The fresh water supply pipeline from the Yukon River will be constructed and operational by the end of the Construction Phase. While the water supply pipeline is under construction, a fresh

water supply pond will be constructed on Casino Creek (at the north end of the TMF area) to provide an interim source of fresh water for use by the HLF.

Local borrow material and suitable waste rock from Open Pit stripping will be used for initial construction of the TMF starter Main Embankment and the West Saddle Embankment. A reclaim water pond upstream from the Main Embankment will collect surface runoff and precipitation to provide mill start-up water for initial ore processing.

2.2.2 Operations (Year 1 to Year 22)

Milling Operations will commence in Year 1 and will continue to the end of Year 22. A portion of the NAG tailings produced in the milling process will be cycloned in the Cyclone Sand Plant for construction of the TMF embankments. During Operations, unused NAG tailings (including overflow from the Cyclone Sand Plant), PAG tailings, and waste rock will be disposed of in the TMF. Waste rock will be placed at the north end of the TMF at an elevation above the level of the supernatant pond to provide a dry, stable placement surface for machine access and waste rock deposition. Seepage water losses from the TMF will be collected in the WMP (downstream of the embankments) and pumped back to the TMF throughout Operations.

Mining of the Open Pit will be carried out from Year 1 until the end of Year 19. The pit will be dewatered by pump and pipeline systems and the water will be used as make-up water in the Mill.

The low grade ore stockpiles will be processed during the final four years of Operations (Year 19 to Year 22). The waste rock area will be covered by a layer (approximately 3 m thick) of NAG tailings produced by the processing of the low grade ore.

Ore stacked in the HLF will be processed until the end of Year 14. Crushed oxide gold ore sequentially piled in the HLF will be leached with an aqueous cyanide solution and the pregnant solution extracted for gold and copper using a SART facility, until the end of Year 18. Surplus barren solution will be treated in a cyanide destruction facility. Supplementary water will be supplied from the fresh water pipeline.

A general layout of the Project is provided in Figure 2-1 to illustrate the site conditions during Operations.

2.2.3 Wetland Construction Phase (Year 23 to Year 34)

The primary objective of the mine closure and reclamation initiative will be to achieve long-term physical and geochemical stability of the reclaimed mine components to ensure acceptable water quality in the receiving environment. The proposed closure plan is to flood waste rock and tailings stored in the TMF and to allow the Open Pit to flood to create a Pit Lake. Additional information related to mine closure activities are provided in the *Casino Project Conceptual Reclamation and Closure Plan* (BCL, 2013), included as part of the Project Proposal.

The Wetland Construction Phase is presented in this document as the period of time immediately following ore processing, when water will be actively managed at some locations and the site will remain a zero discharge facility.

Closure of the Open Pit will begin prior to Year 23. Mining of the Open Pit will be completed by the end of Year 19. Dewatering will be discontinued, and the Open Pit will be allowed to fill with groundwater, overland runoff, and direct precipitation.

Water from the TMF will be pumped to the Open Pit from Year 23 to Year 27 (inclusive). Pumping to the Open Pit will stop at the beginning of Year 28, and the TMF Pond will be allowed to fill with surface runoff, precipitation and groundwater inflow to its maximum storage capacity. Filling of the TMF Pond was predicted by KPL (2015) to be complete by the end of Year 34.

Water from the WMP (mostly tailings embankment runoff and TMF seepage) will be pumped to the Open Pit until the time when TMF Pond discharges to Casino Creek.

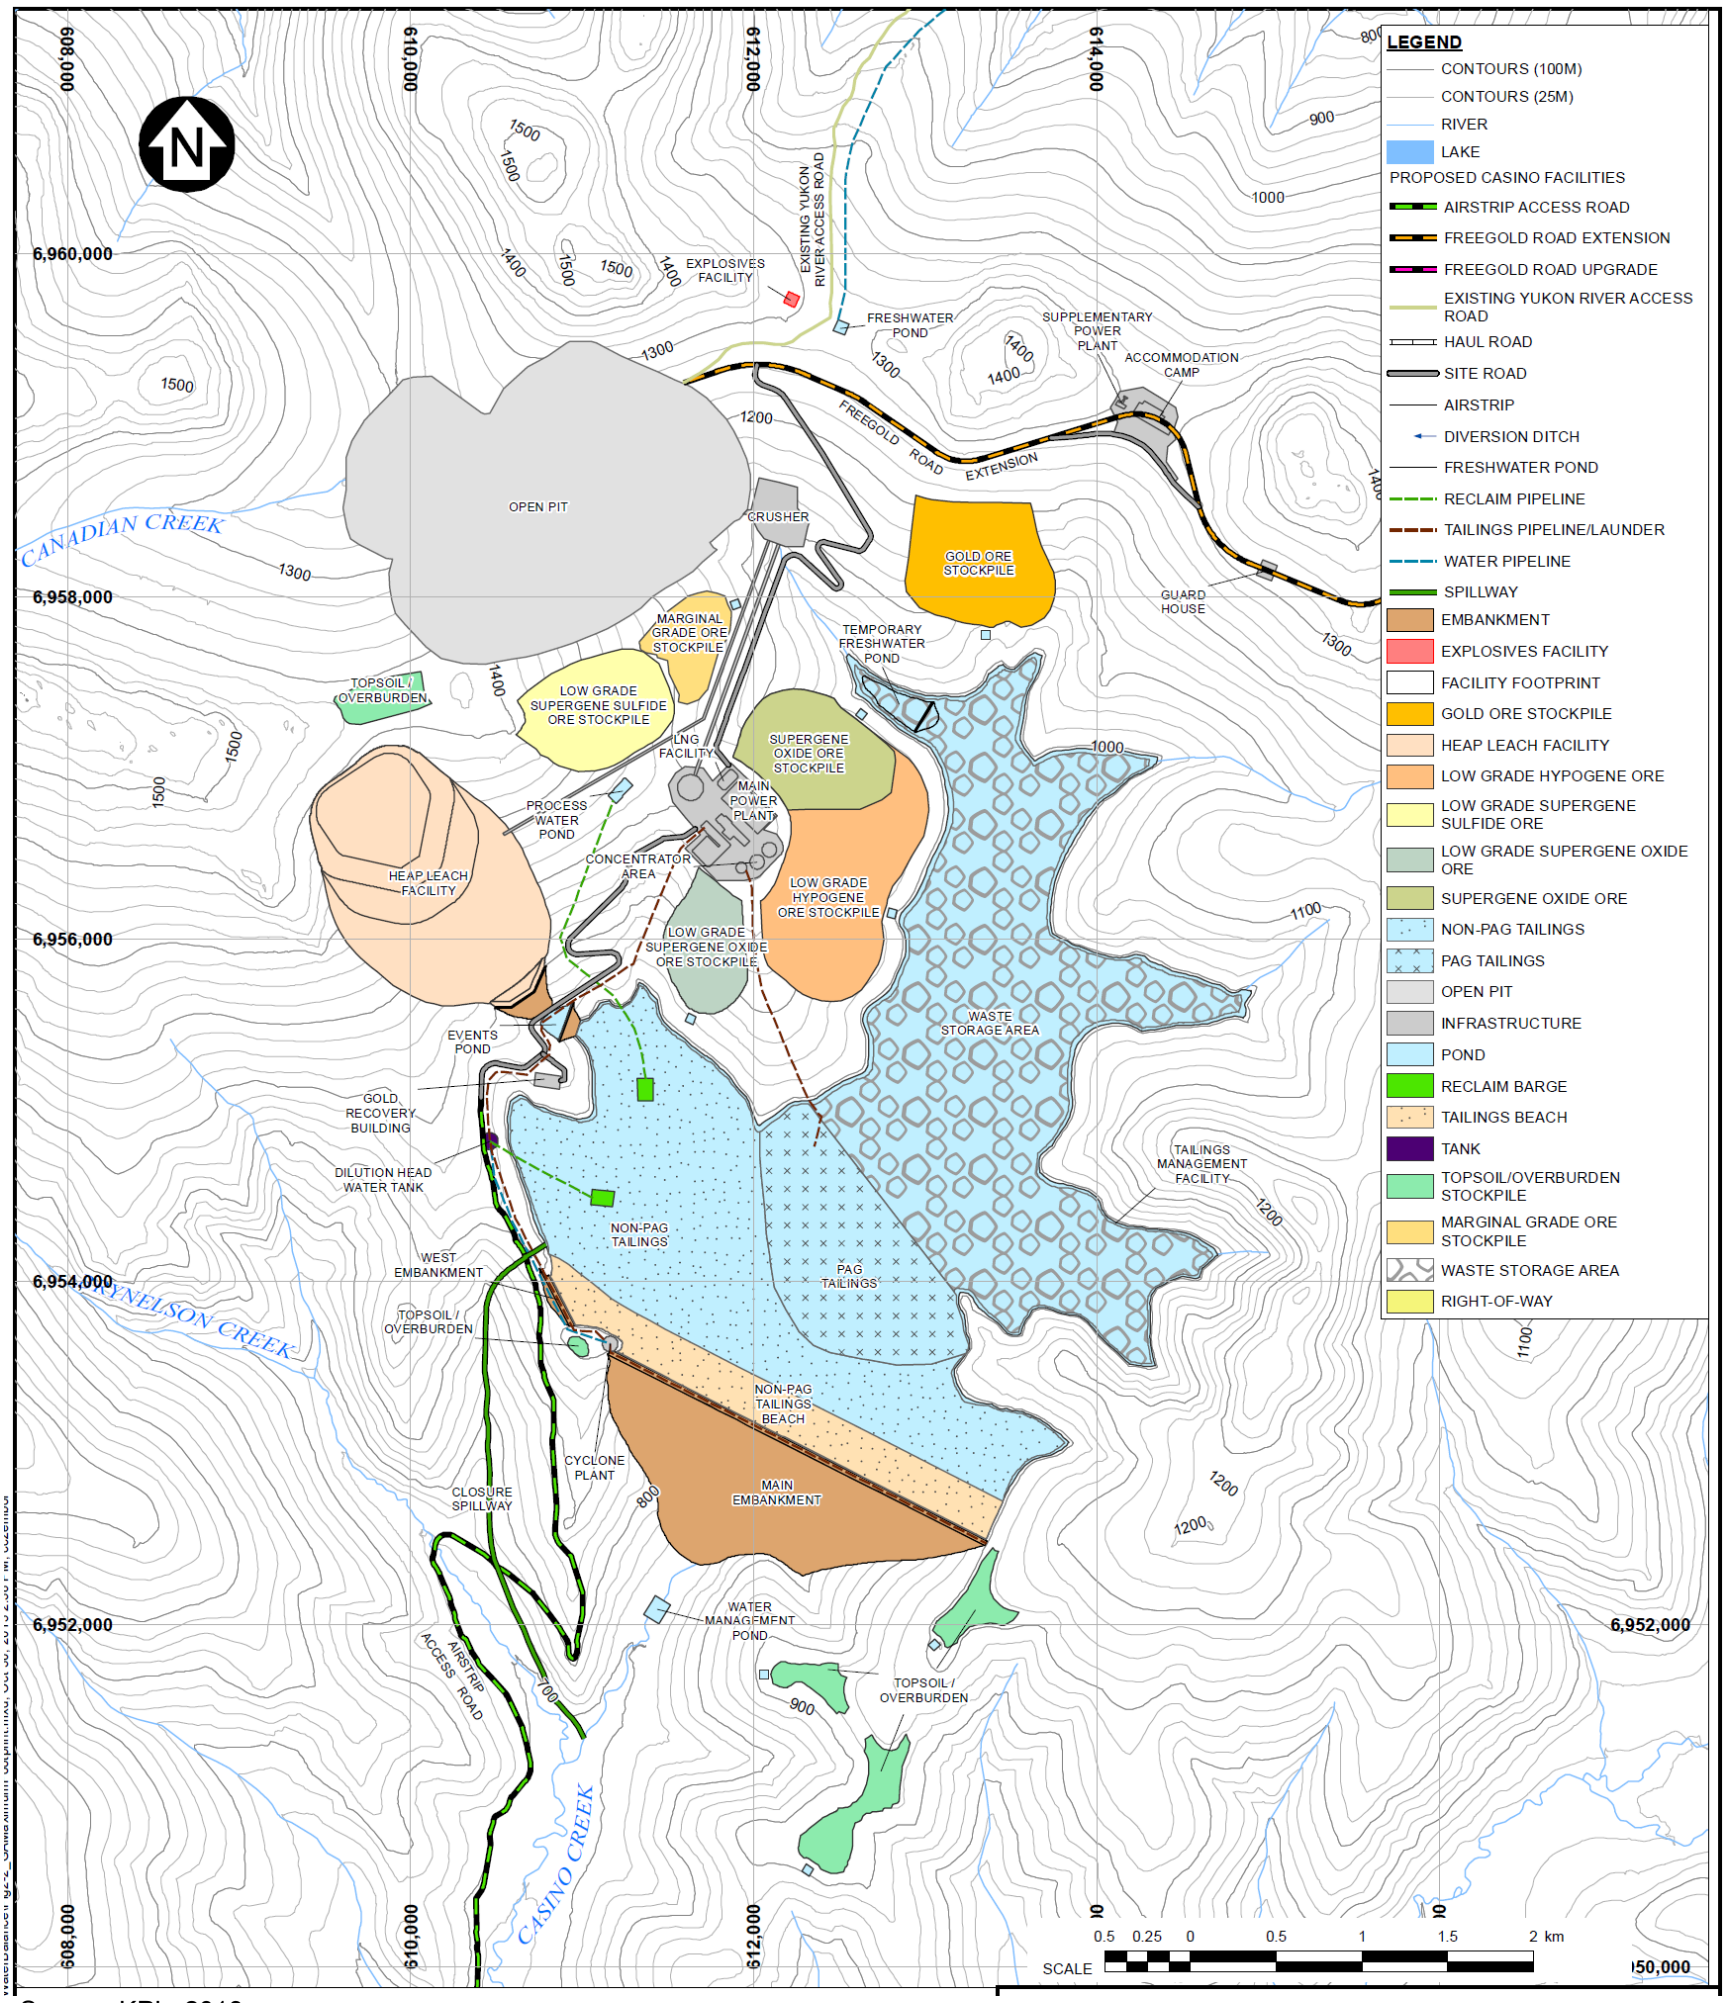
Closure of the HLF will begin before Year 23 with an ore rinsing process (Year 19 to Year 23), followed by drain down (Year 24 to Year 28). Surplus rinse water and drain down water will be treated in a cyanide destruction facility and then pumped to the Open Pit. The final slopes of the HLF ore will be graded, covered, and re-vegetated to provide adequate drainage and erosion protection from surface runoff. Surface runoff and seepage from the toe of the HLF will flow to the TMF beginning in Year 28.

Some residual ore may be present in the surface ore stockpiles following mine closure if the ore is not economical to process. Unprocessed ore will be placed in the Open Pit. For closure planning purposes, BCL (2013) assumed that the Gold Ore and Supergene Oxide Ore would be processed completely, while 5% of the low grade ores would remain at the end of mining. BCL (2013) conservatively assumed that none of the Marginal Ore will be processed. The 5% low grade ore remainder and 100% of the Marginal Grade Ore will be disposed of in the Open Pit. The reclaimed stockpile footprints will be covered with stockpiled overburden and re-vegetated.

Construction of two engineered wetlands within the TMF will begin during this phase. The wetlands are intended to perform as long-term passive water treatment systems for removal of contaminants by chemical precipitation and biological processes. The North TMF Wetland will be constructed for treatment of the discharge from the Pit Lake. The South TMF Wetland will be constructed immediately upstream of the TMF spillway for removal of contaminants from the TMF Pond prior to discharge to Casino Creek.

2.2.4 TMF Discharge Phase (Year 35 to 109)

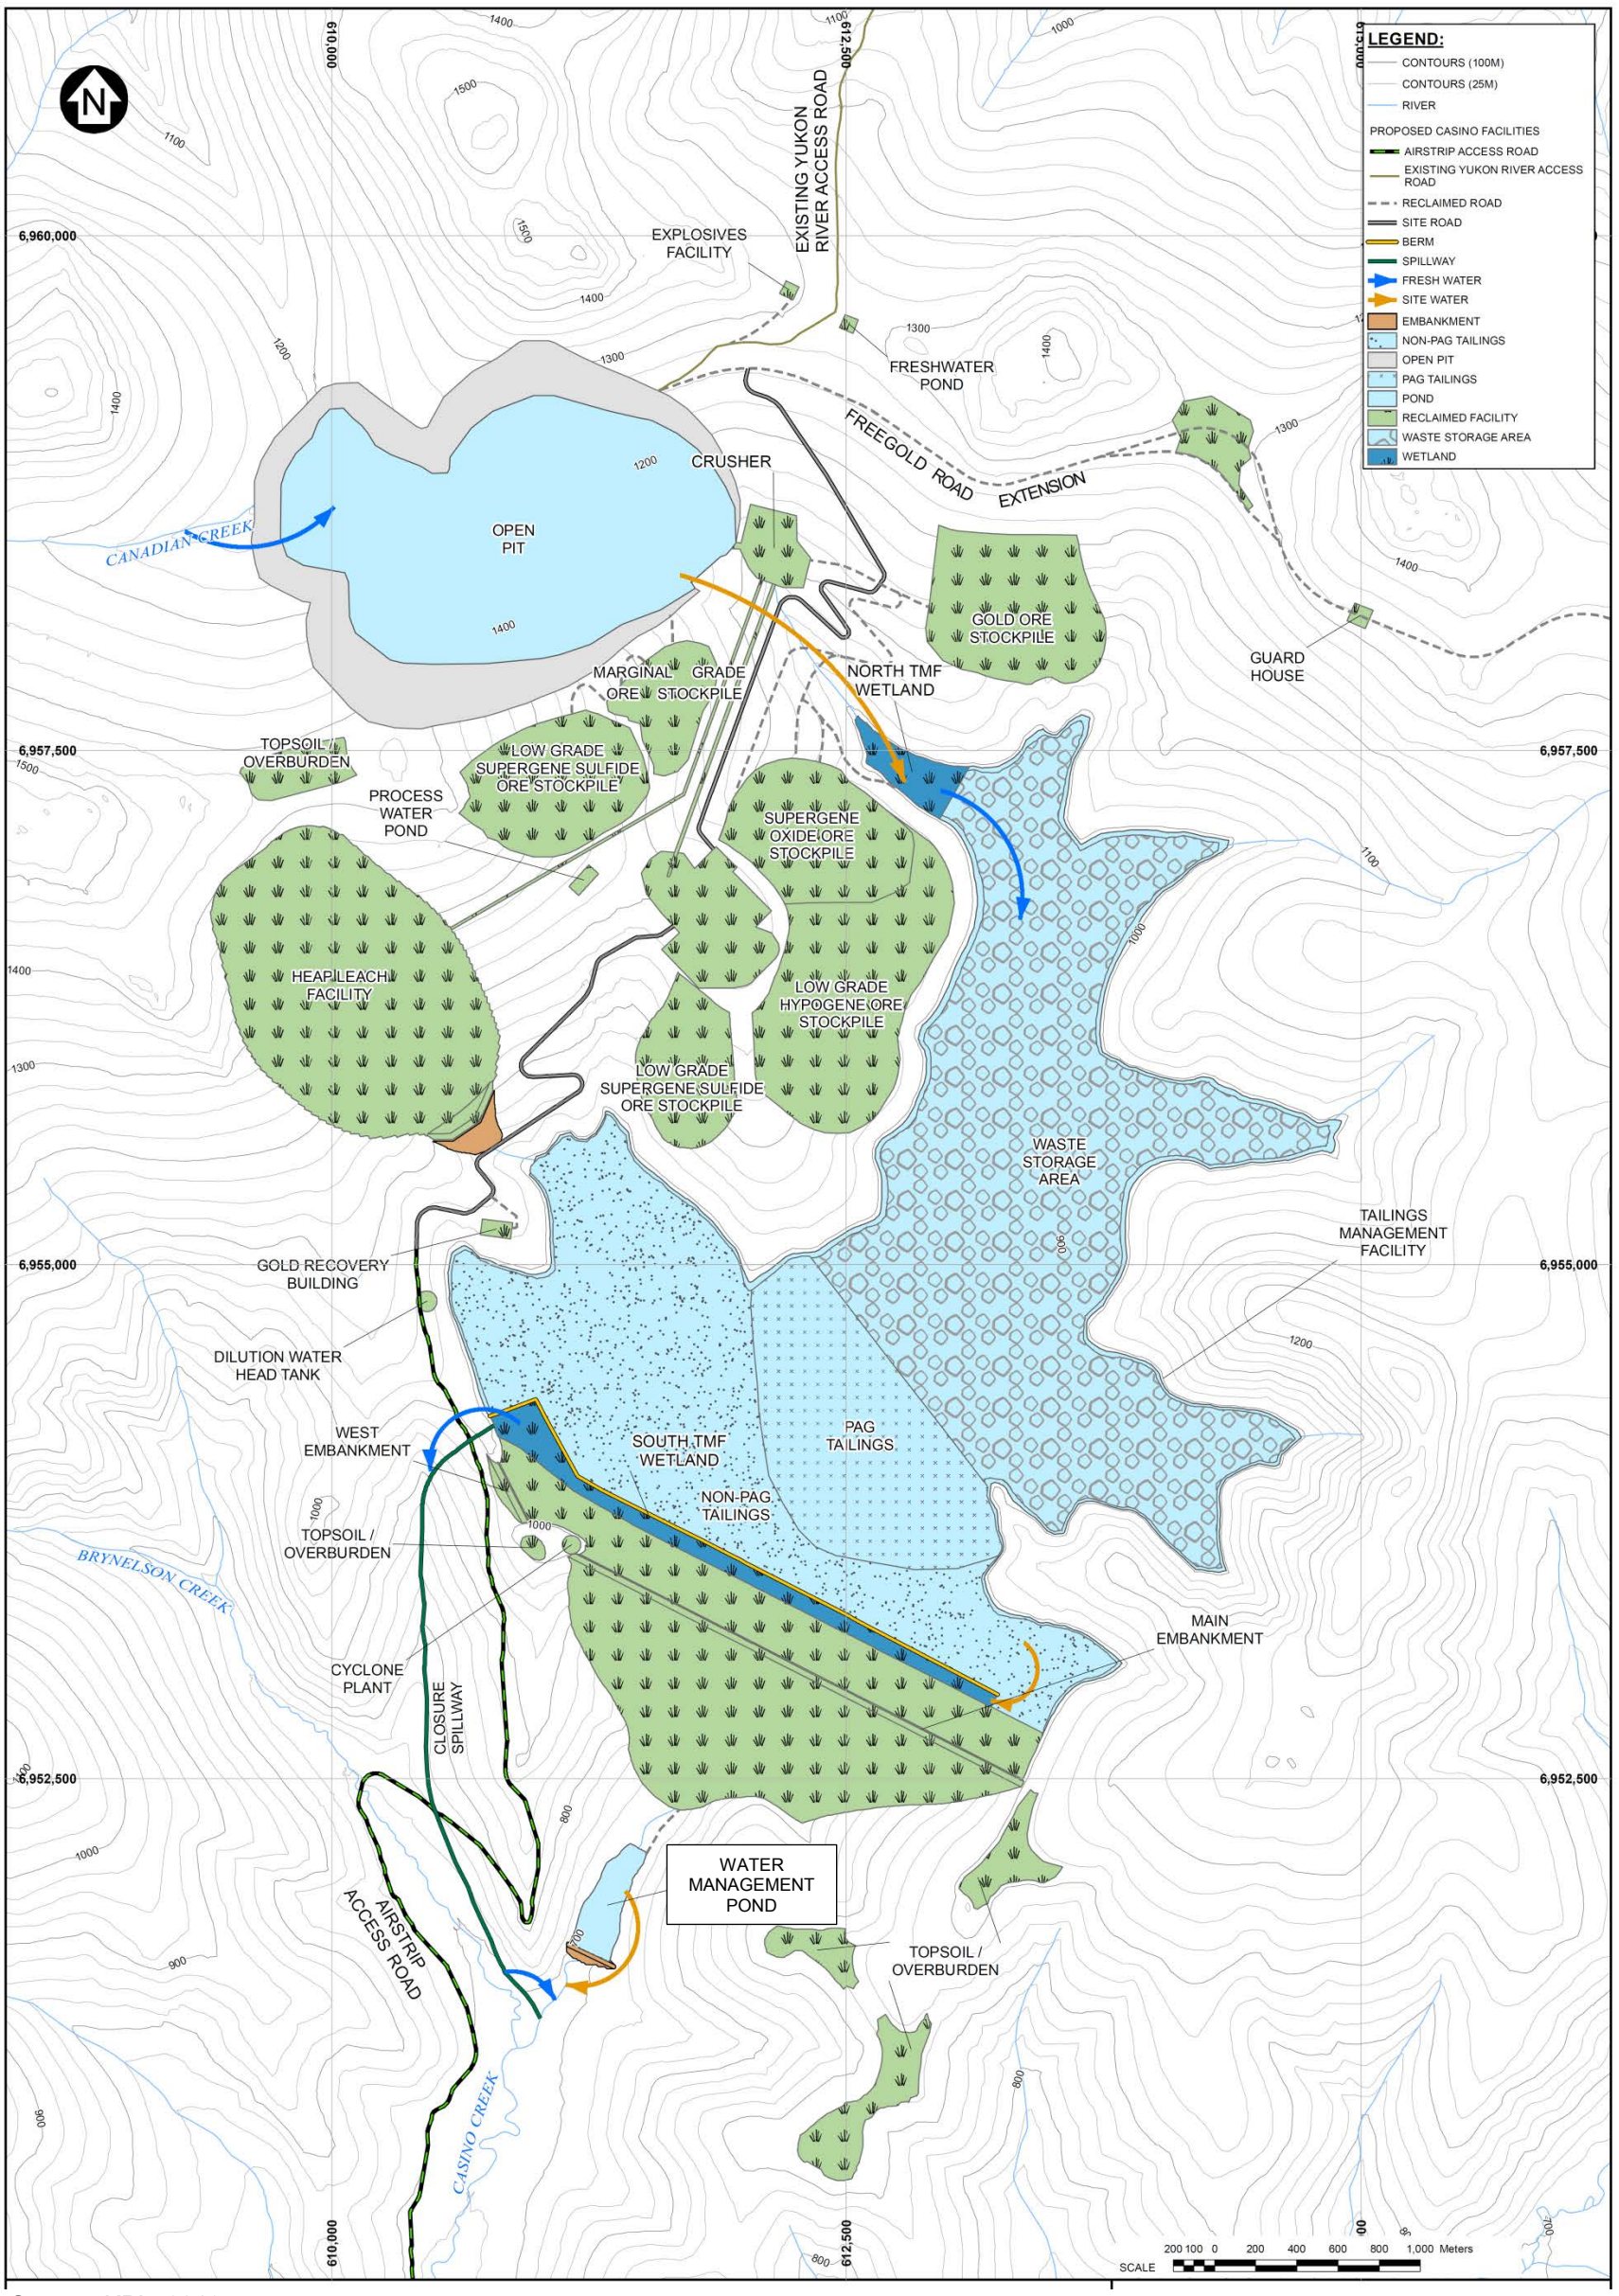
The TMF Discharge Phase will begin immediately after the TMF Pond reaches its maximum capacity and overflows to Casino Creek via the TMF Closure Spillway. KPL (2015) predicted



initial discharge of the TMF to occur during Year 35. The TMF Pond water will travel through the TMF South Wetland for passive treatment prior to release into Casino Creek.

Starting in Year 35, seepage recovered downstream from the TMF embankments will be stored in the Water Management Pond (WMP) through the low flow months of the year (winter), and released during the remaining months when the TMF Pond water discharges via the Closure Spillway, such that the seepage water quality will be less influential on the water quality in Casino Creek.

2.2.5 Pit Discharge Phase (Year 109+)



Eventually (approximately 90 years following the cessation of mining), the Pit Lake will fill to its maximum water storage capacity and will discharge to the North TMF Wetland treatment system, which will be constructed at the northern end of the TMF. Treated effluent from the wetland will discharge to the TMF Pond.

Layout of the Project site during Pit Discharge is provided in Figure 2-2 to illustrate the long-term site conditions including: the final Open Pit Lake, reclaimed HLF and stockpile areas, TMF pond, and wetland treatment systems.

Figure 2-2. Site Plan Showing Proposed Mine Components (Pit Discharge Phase)

3 Existing Site Conditions at the Casino Project

A discussion of the existing environmental conditions as they are relevant to water quality modelling is provided in the following section. This section is unchanged from Section 3 of SEA (2013).

3.1 Physiography

The Casino Project property is located in the west central Yukon, in the north-westerly trending Dawson Range Mountains. The Dawson Range forms a series of rounded ridges and hills that reach a maximum elevation of 1675 m with moderate to deeply incised valleys. Major drainage channels extend below 1000 m elevation. The Yukon River is about 16 km north of the Project site and flows to the west. Most of the Casino Project lies between the 650 m elevation at Dip Creek and an elevation of approximately 1400 m on Patton Hill near the proposed open pit (M3 Engineering, 2013).

3.2 Climate

The climate at the Casino Project area is continental and cold. Winters are long, cold and dry, with snow typically on the ground from September through June. Summers are short, mild, and wet, with the greatest monthly precipitation falling in July.

Site weather data was initially collected by KPL (previously Hallam Knight Piesold) from 1993 to 1995. A new weather station was established in 2008 at approximately the same location at an elevation of approximately 1200 m (Figure 3-1) and has been operational since that time. Monthly average climate conditions at Casino (for an elevation of 1200 m) were derived by KPL (2013d), and are presented in Table 3-1.

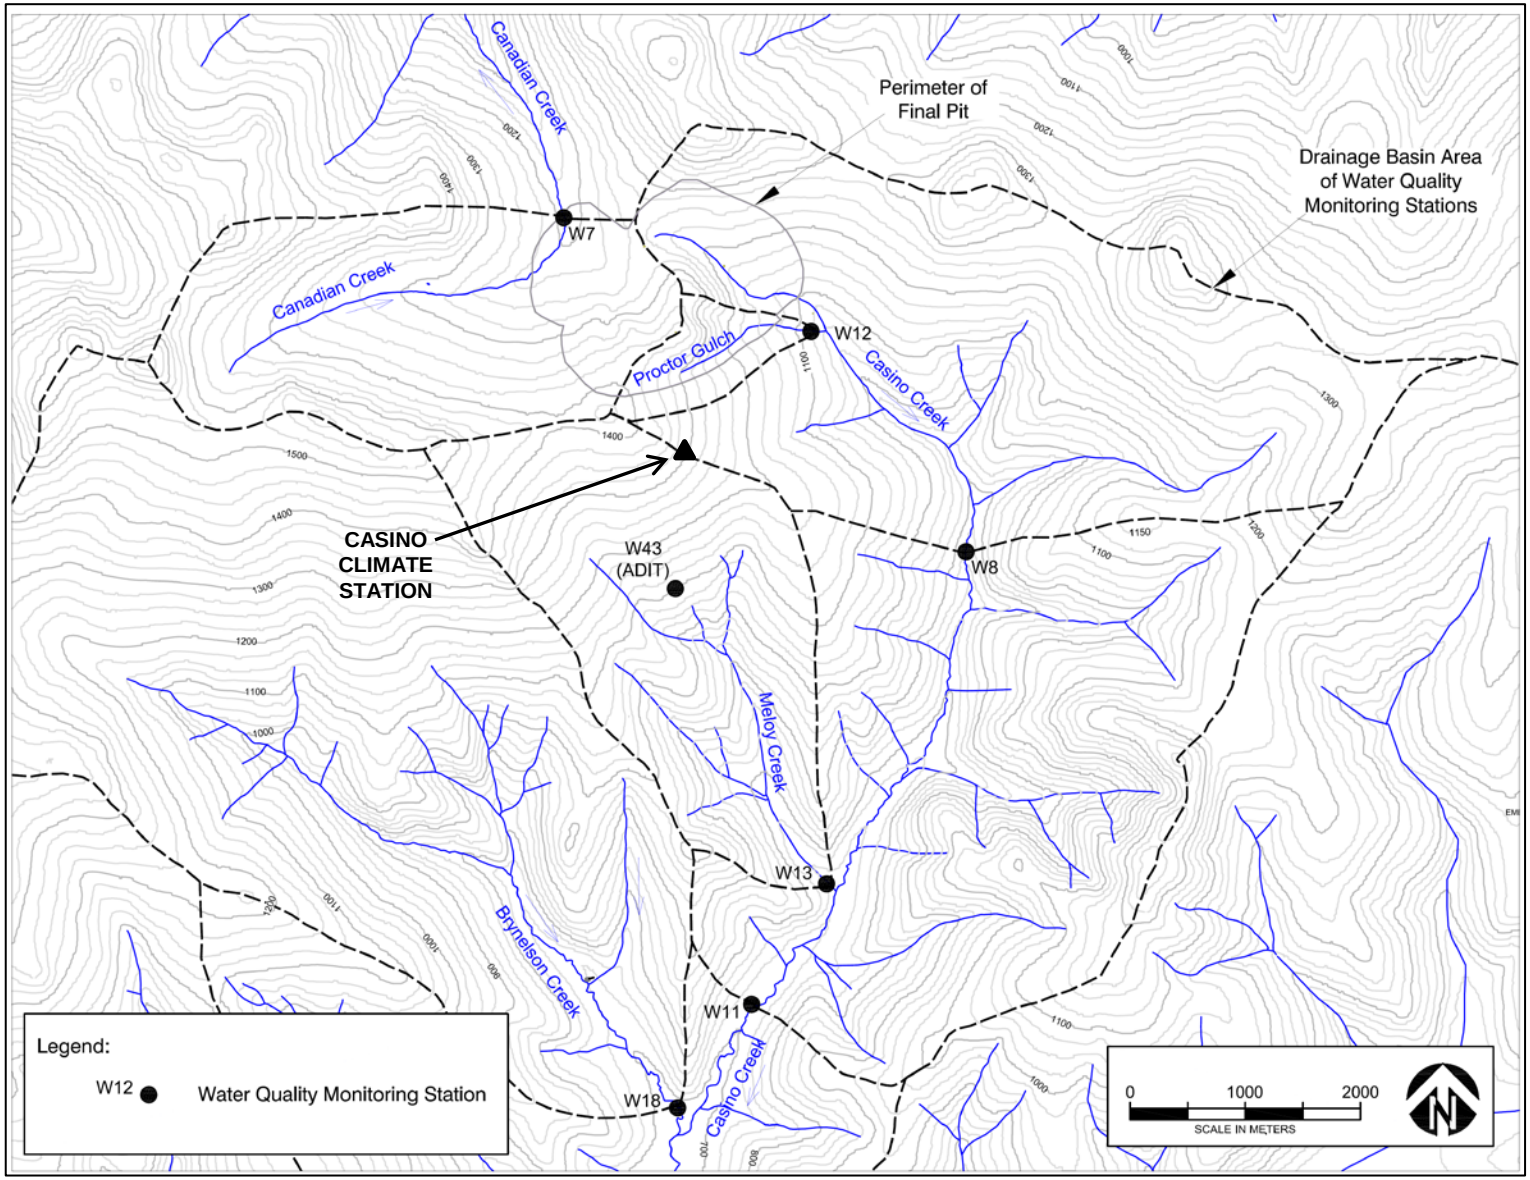

Figure 3-1. Climate and Water Quality Monitoring Stations at the Project Site

Table 3-1. Average Monthly Climate Conditions at the Casino Project Site

Month	Temp-erature (°C)	Evap-oration (mm)	Precip-itation (mm)	Rainfall (mm)	Snowfall (mm)	Snowmelt (mm)
Jan	-18.0	0	25	0	25	0
Feb	-14.2	0	19	0	19	0
Mar	-9.7	0	15	0	15	0
Apr	-1.9	2	13	0	13	15

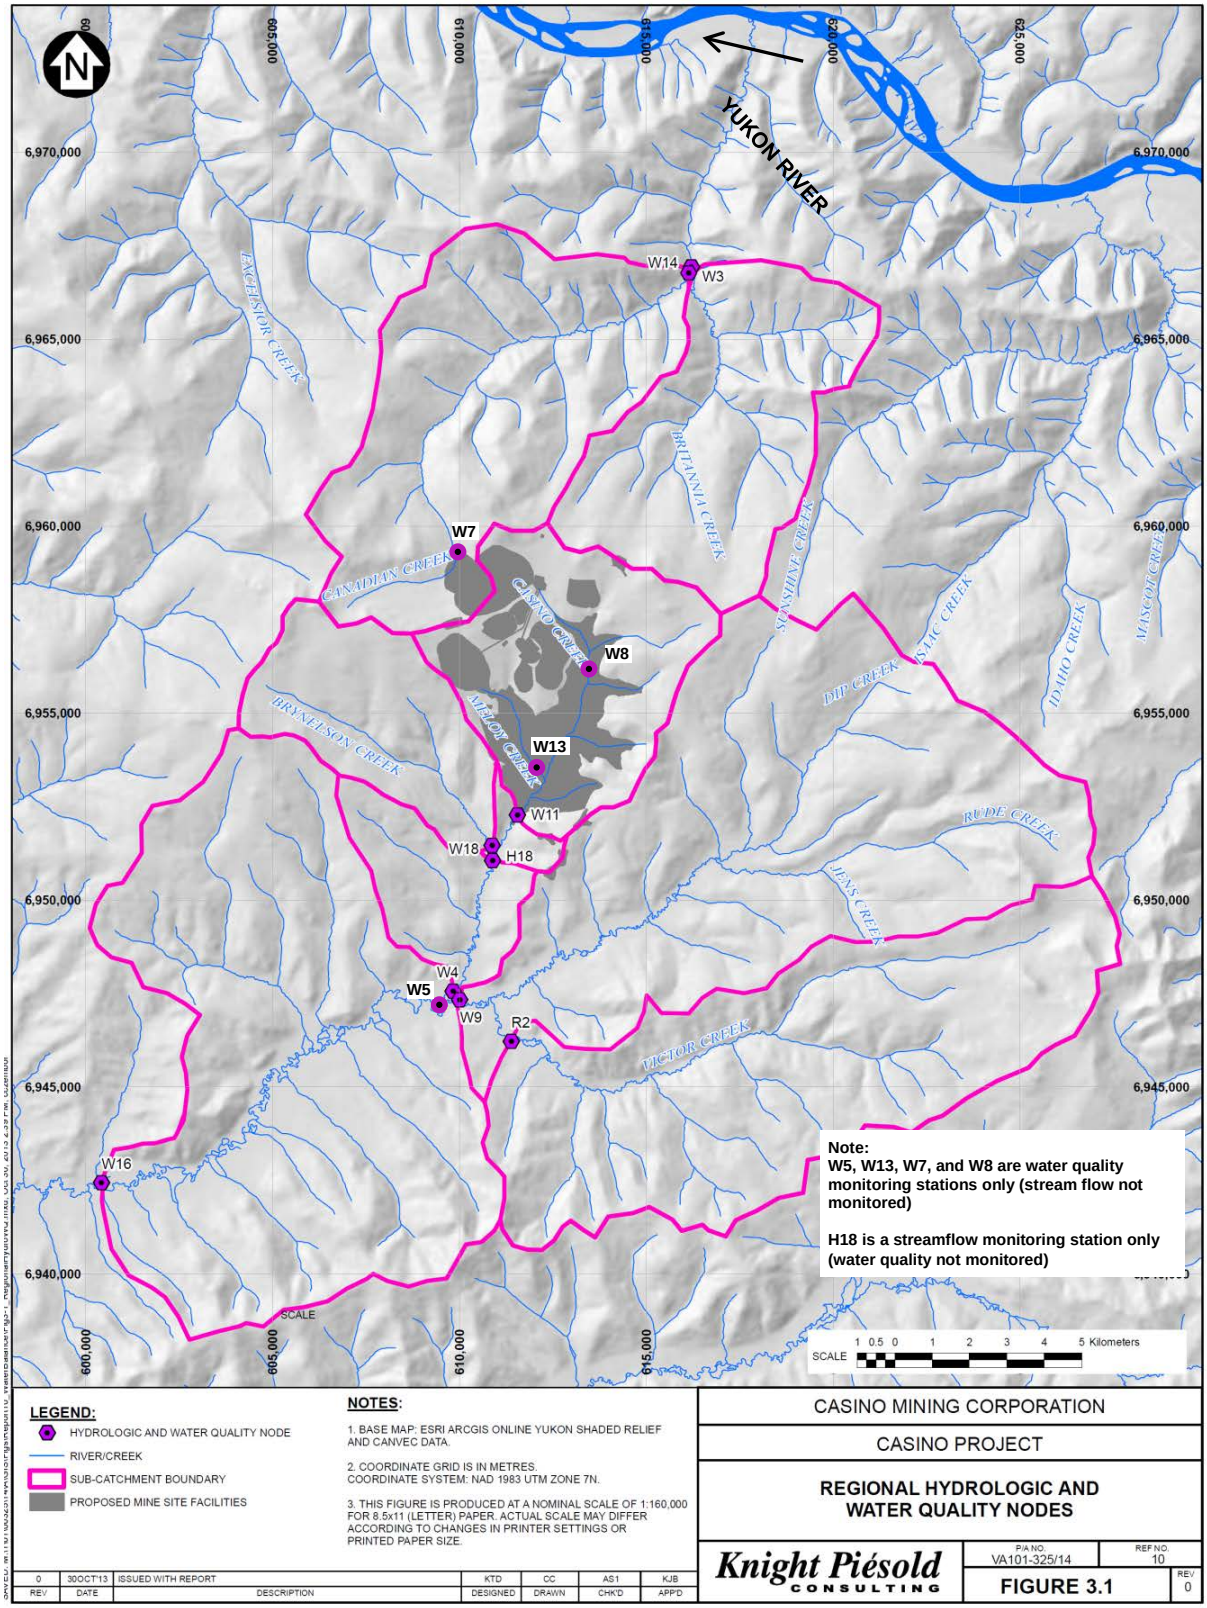
Average	**-3.2**		**38**			
Total		**303**	**460**	**305**	**155**	**100**



1. Average monthly values apply for an elevation of 1200 m.

3.3 Hydrology

The property is within the Yukon River drainage basin. The Project is situated in the Dip Creek and Britannia Creek watersheds. Casino Creek is a tributary to Dip Creek. Dip Creek drains southwest, eventually flowing into the White River, a tributary of the Yukon River. Canadian Creek is a tributary to Britannia Creek. Britannia Creek drains north, and discharges into the Yukon River. The footprint of the proposed Open Pit is situated along the existing watershed divide between Canadian Creek and Casino Creek.

The majority of creeks in the area observe peak discharges during May, and daily fluctuations in discharge due to permafrost active layer melt, and rainfall events from June to September. The annual hydrograph typically has a bimodal shape, with high flows resulting from snowmelt in the spring freshet period and a secondary peak in mid-summer from rainfall and permafrost melt events.

Stream flow data were collected from 1993 to 1994, and from 2008 to present at several locations around the Project area. Hydrometric (stream flow) monitoring station locations are presented on Figure 3-2. KPL combined site and regional hydrology data to characterise baseline hydrology conditions and summarized the results in the *Casino Baseline Hydrology Report* (KPL, 2013e).

Source: KPL, 2013c

Figure 3-2. Hydrology and Water Quality Monitoring Stations Surrounding the Project

3.4 Hydrogeology

The following section summarizes the results of *the 2012 Baseline Hydrogeology Report* that was completed by KPL (2013g). The Casino Project is situated within a region of discontinuous permafrost. Permafrost is inferred to be present at shallow depths on north-facing slopes and below organic soils in portions of the Casino Creek valley, and generally absent, or deeper, on south-facing slopes. The groundwater flow systems that develop within the Project area are controlled by the extent and spatial distribution of the permafrost in addition to topography and geology.

A surface and inferred groundwater flow divide bisects the deposit area, directing surface water and groundwater flow north toward Canadian Creek or south and east toward Casino Creek. Groundwater is inferred to discharge to surface throughout the year in creek valleys and sustains winter flows in Casino Creek and Canadian Creek. Four hydrostratigraphic units have been identified at the Project site, consisting of overburden, weathered bedrock, fresh bedrock, and fault zones. Each of the hydrostratigraphic units may be frozen or unfrozen based on the presence or absence of permafrost.

Groundwater elevations are lowest in April and May immediately preceding the spring freshet and are typically highest in August following snowmelt and summer rainfall. Relatively strong downward vertical hydraulic gradients have been observed within the upland areas of the proposed Open Pit where the water table is more than 100 m deep. Within the southeast lowlands of the proposed Open Pit, upward vertical hydraulic gradients and artesian conditions are present upslope of faults adjacent to Proctor Gulch at the head of Casino Creek. These artesian pressures suggest that faults may act as barriers to groundwater flow. Depth to groundwater along the hillslope is between 6 mbgs and 20 mbgs. Groundwater elevations are artesian within the Casino Creek valley.

3.5 Baseline Water Quality

Description of surface water quality was provided in the *Water and Sediment Quality Baseline Report* (PECG, 2013). Groundwater quality was summarized by KPL (2013g).

3.5.1 Surface Water Quality

A total of 26 sites were sampled for water quality between 2008 and 2012. Sites were concentrated in the Casino Creek (a tributary to Dip Creek) and Britannia Creek watersheds. Water quality station locations are shown on Figure 3-1 and Figure 3-2.

Water samples were collected and analyzed for a full suite of physical parameters, anions, nutrients and total and dissolved metals. Exceedances of the Canadian Council of Ministers of the Environment (CCME) guidelines for the protection of freshwater aquatic life were observed for a total of ten parameters (cadmium, copper, aluminum, iron, uranium, fluoride, zinc, lead, pH

and silver) throughout the Project area. The number of exceedances was highest for aluminum, cadmium, copper and iron. With the exception of uranium, exceedances were most numerous in the summer season (May to October), indicating a seasonal trend related to hydrological factors such as snow melt and stream flow.

In general, hardness, conductivity and nitrogen-based nutrients were higher in the winter months. Conversely, TSS, phosphorus-based nutrients, organic matter and metal concentrations were higher in the summer months for all sites, indicating a seasonal trend most likely directly related to hydrological factors such as surface runoff and stream flow.

The 2008-2012 water quality program confirmed the unique water chemistry of Proctor Gulch (W12) originally documented by Himmelright (1994). Exceedances of CCME guidelines for pH, copper, aluminum and iron were found in 100% of the 16 samples from Proctor Gulch. Fluoride, cadmium, lead and zinc were also elevated in samples from Proctor Gulch. Additionally, water quality at this site exhibited highest values for acidity (and lowest pH), hardness, conductivity, total dissolved solids and turbidity, as well as lowest values for alkalinity.

Spatially, it was observed that copper, aluminum and iron concentrations were highest at Proctor Gulch (W12) and decreased with successive sites downstream at W8, W11 and W4. This indicates that inflows from Casino Creek tributaries, Meloy Creek, Brynelson Creek and Austin Creek, effectively dilute the Casino Creek water.

Proctor Gulch consistently showed higher concentrations in the winter than in the summer for all the metals when groundwater was the major source of flow in the winter months. Some effects from Proctor Gulch are observed in Dip Creek at site W5, just downstream of Casino Creek, particularly for copper, cadmium, lead and zinc, as background levels upstream in the Dip Creek watershed at sites W22, R2 and W9 had lower concentrations of those metals.

A historical adit established to access a lead/zinc/silver deposit in the upper Meloy Creek watershed discharges groundwater in the spring and summer months (approximately May to August). This site (W43) was found to have the highest concentrations of cadmium, lead, silver and zinc of all the sites sampled. Never the less, of these four metals, only one cadmium sample (0.00004 mg/L in April 2011) exceeded CCME guidelines in the lower reach of Casino Creek at W4, due to the small flow from the adit relative to the total Casino Creek discharge.

Table 3-2 provides a summary of parameters that exceeded CCME guidelines in the upper Dip Creek (including Casino Creek) drainage basin.

Table 3-2. Parameters with Median Water Quality Exceeding CCME Guidelines

Station	Watercourse	Water Quality Parameters Exceeding CCME Guidelines in Baseline Discharge		
		Summer	Winter	Year-Round
W12	Proctor Gulch	Al, Cd, Cu, Fe, F, pH, Zn	Al, Cd, Cu, Fe, F, pH, U, Zn	Al, Cd, Cu, Fe, F, pH, Zn
W8	Upper Casino Creek	Al, Cd, Cu, Fe	Al, Cd, Cu	Al, Cd, Cu, Fe
W43	Adit	Ag, Cd, Cu, Pb, Zn	(no flow)	(no year-round flow)
W13	Meloy Creek	Cd, Pb	Cd, Cu, U	Cd
W11	Mid-Casino Creek	Al, Cd, Cu, Fe	Cd, Cu, U	Al, Cd, Cu, Fe
W18	Brynelson	Al	-	-
W4	Lower Casino Creek	Al, Cu	-	Cu
W9	Upper Dip Creek	Al	-	-
W5	Mid-Dip Creek	Al, Cu	-	Cu

Summer was defined by PECG as May to October (inclusive) and winter was November to April.

Although less pronounced, an overall similar spatial pattern for cadmium, zinc, copper, aluminum, iron and lead were observed for Canadian Creek and Britannia Creek. The uppermost site on Canadian Creek (W7) is situated in close proximity to the ore body and therefore may receive some base flow with similar water quality to Proctor Gulch. This site exhibits the highest concentration of these metals in the Britannia Creek watershed, decreasing downstream to the Yukon River.

3.5.2 Groundwater Quality

Groundwater chemistry is variable throughout the Project area and has been characterized in terms of the proposed Open Pit area, the hillslope area, and the Casino Creek valley area. Groundwater samples from the proposed Open Pit area were dominantly calcium-sulphate type, and from the hillslope area were dominantly calcium-bicarbonate type. Groundwater chemistry of samples collected from the Casino Creek valley area can generally be interpreted as intermediate to that of the hillslope and proposed Open Pit areas. The groundwater types vary along the Casino Creek valley but are generally characterized as calcium-bicarbonate-sulphate in the upper limits of the valley, calcium-magnesium-bicarbonate-sulphate type through the middle of the proposed TMF area, and calcium-bicarbonate in the vicinity of the proposed TMF embankment.

The deposit area is a sulphidic ore body that has been subjected to considerable weathering and oxidation. Sulphate is present in the mineralization (as gypsum/anhydrite) and as a result sulphate has been measured at very high concentrations in this area (up to 1,100 mg/L). Mean total dissolved solids (TDS) concentrations are indicative of groundwater that is moderately to highly mineralized. In the proposed Open Pit area, significant variability in groundwater metals

and metalloid concentrations was observed between samples collected from the Proctor Gulch monitoring wells and from monitoring well 94-337. The variability in the ore body geochemistry results in groundwater with low pH and low hardness in the vicinity of 94-337 and neutral pH and very hard water in the Proctor Gulch area. In the samples from 94-337, cadmium, cobalt, copper and zinc were detected at concentrations that exceeded the Yukon Contaminated Sites Regulation (YCSR) limits, and aluminum and iron were detected at concentrations that exceeded the CCME guidelines. In the Proctor Gulch area groundwater samples, cadmium and cobalt were detected at concentrations that exceeded the YCSR limits and arsenic, iron, uranium and zinc were detected at concentrations that exceeded the CCME guidelines.

In the hillslope area, mean TDS values in water collected from monitoring wells were indicative of slight to moderately mineralized groundwater. Samples from monitoring wells installed near the historic Meloy Creek mine adit reported higher mean TDS values than others from the hillslope area.

Slightly higher mean TDS and higher concentrations of sulphate, sodium, fluoride, and chloride were reported in water samples obtained from the shallow groundwater well compared to the deep well. In samples from the hillslope area, cadmium, copper, and zinc were the only metals detected at concentrations that exceed the CCME guidelines on a regular basis.

In the Casino Creek valley, mean TDS values for groundwater samples were indicative of slightly-to-highly mineralized conditions. Cadmium, copper, iron, and uranium were the only metals that were detected at concentrations exceeding the CCME guidelines on a regular basis from the vicinity of the proposed TMF in the Casino Creek valley area. The elevated concentrations were not widespread and are reflective of relatively heterogeneous groundwater chemistry conditions that may result from localized variability in mineralization and from mixing with groundwater originating from the deposit area. Arsenic and zinc were also reported at concentrations that exceeded the CCME guideline, but the exceedances were infrequent.

4 Mine Sources of Geochemical Mass Loading

Development of the proposed mine is expected to introduce sources of geochemical mass loading to the hydrologic and water management system of the Project site and downstream environment. Sources of geochemical mass loading at the Casino Project are described in the following sections. Source terms were developed by Lorax to predict the rate of mass loading from each source into the water management system of the Casino Project (Lorax, 2013). This section is unchanged from Section 4 of SEA (2013).

4.1 Open Pit Wall Rock

Blasting in the Open Pit leaves the wall rock fractured and exposed to weathering processes. The fractured rock will contribute mass loading into the Pit Lake via runoff from the pit walls. As the Pit Lake reaches its maximum storage capacity, exposed wall rock will be submerged, inhibiting potential oxidation and reactivity. A portion of the pit wall (i.e. the “high wall”) that is above the elevation of the final Pit Lake will remain un-submerged in perpetuity. Runoff from the high wall will be an on-going source of mass loading into the Pit Lake.

Pit wall runoff is expected to travel along preferential flow paths through the fractures of the unsubmerged pit wall rock. As a result, oxidation products could build-up on the the poorly drained wall rock surfaces. When the Pit Lake level rises and submerges the wall rock, those built-up oxidation products may be flushed into the Pit Lake. After submergence of the wall rock, oxidation products will no longer form on the saturated rock surfaces and no additional leaching is predicted to occur.

4.2 Ore Stockpiles

While the ore stockpiles are present during Operations, contact water (from rainfall and snowmelt) will drain from the rock as runoff or infiltration to groundwater. Runoff from the stockpiles will be captured by the TMF Pond. Hydrogeological modelling (KPL, 2013h) indicated that depending on the stockpile location, infiltrated contact water will flow to one or more of the following receptors: the TMF Pond, Open Pit, through the TMF Embankment, or through the TMF foundation.

Some residual ore may be present in the stockpiles following Operations if the ore is not economical to process. Unprocessed ore will be placed in the Open Pit at the end of Operations and during Closure. Upon submergence of the ore in the Pit Lake, the oxidation products that have built up on the ore during Operations are assumed to flush into the Pit Lake.

4.3 Processing Facility (Mill)

NAG and PAG tailings will be pumped from the Mill to the TMF as slurry. The water content of the tailings slurry will be process water from the Mill. Mass load in the slurry water will enter the TMF Pond.

Lorax (2013) assumed that select parameters (Sb, As, Mo, Se, and U) will accumulate in the process/reclaim water throughout Operations. That is, those water quality parameters will continue to build up in the TMF pond water, while others will be removed from reclaim water in the milling process.

4.4 Heap Leach Facility

Ore contact water from the HLF will be a source of loading. During Operations and rinsing of the HLF, the ore contact water will be kept within a closed system and will therefore not be a source of loading to other Project components, or to the receiving environment. During rinsing and draindown, the contact water will be treated and pumped to the Pit Lake. Following draindown, HLF toe seepage and surface runoff will discharge to the TMF Pond.

4.5 TMF Waste Rock and Tailings

Tailings and waste rock will be deposited in the TMF for long-term storage. Temporary and perpetual mass loading mechanisms from the stored mine wastes are described in the following sections.

4.5.1 Unsaturated Tailings

NAG tailings will remain unsaturated in the tailings beach and the TMF embankments. Contact water (runoff) from the tailings beach will drain into the TMF Pond, and runoff from the downstream face of the TMF embankments will drain downstream to be collected in the WMP.

4.5.2 Unsaturated Waste Rock

Waste rock will be placed at the upstream (north) end of the TMF. During Operations, the surface of the waste rock will be maintained above the operating level of the supernatant pond to provide a dry, stable placement surface for machine access to facilitate waste rock placement. Runoff from and infiltration through the unsubmerged portion of waste rock will carry a mass load into the TMF Pond.

Built up oxidation products that are not transported by runoff from the unsubmerged waste rock surfaces are assumed to be flushed into the TMF Pond when the supernatent pond level rises and submerges the waste rock.

4.5.3 Saturated Tailings and Waste Rock

Tailings and waste rock that are stored below the water surface in the TMF will be in chemical equilibrium with their porewater. Fluxes of water through the stored mine waste will lead to displacement of the porewater and mass transport from the deposited material into the TMF Pond, groundwater table, or TMF embankment.

4.6 Summary of Mine Loading Sources by Project Phase

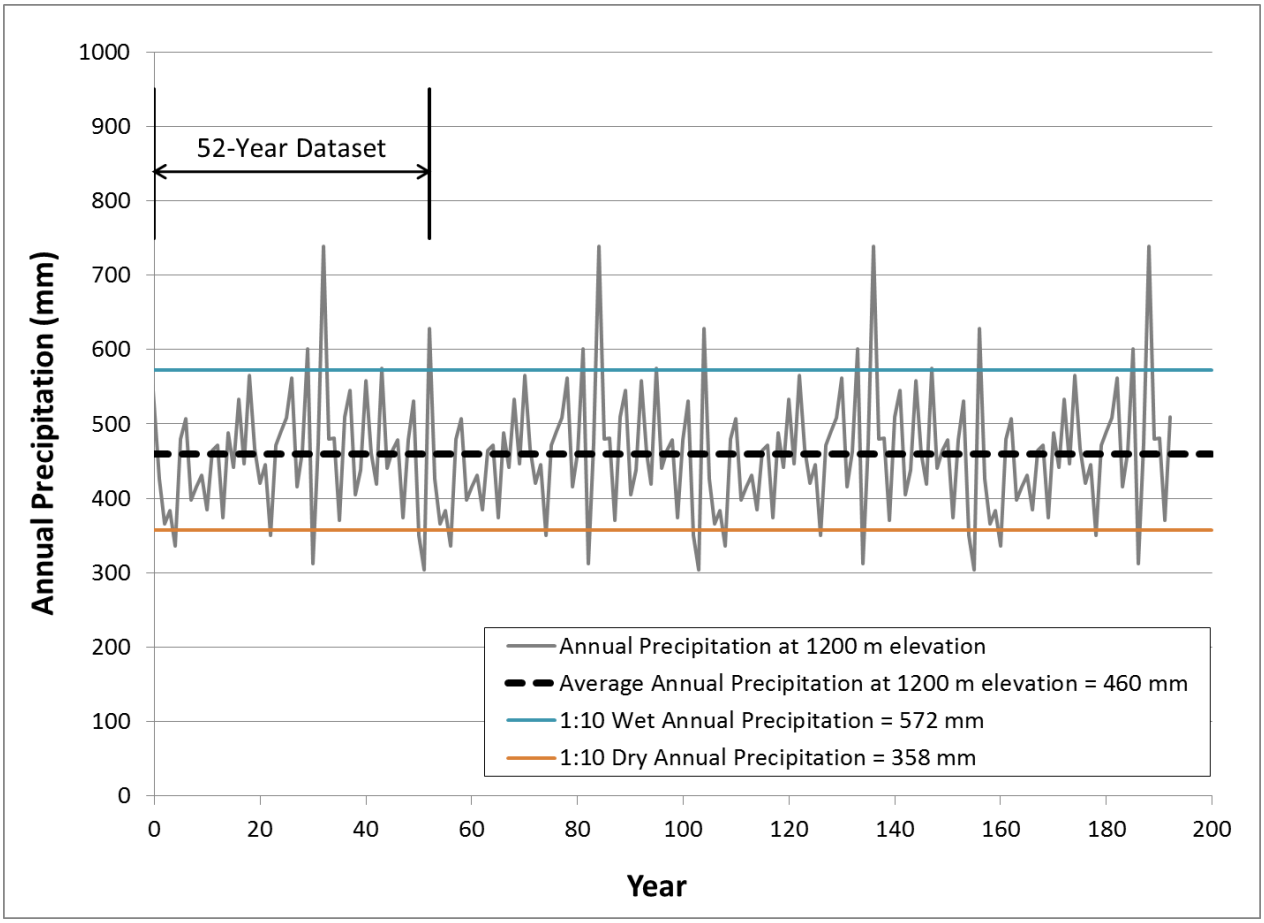
Table 4-1 illustrates the mine sources of loading by Project phase. Following closure of the mine the following loading sources are expected to contribute some mass loading in perpetuity: Open Pit high wall rock, tailings beach runoff, TMF embankment runoff, runoff from spent HLF ore and displaced porewater from saturated tailings and waste rock.

Table 4-1. Loading Sources by Project Phase

Source of Loading	Casino Project Water Management Phase				
	Construction	Operations	Wetland Construction	TMF Discharge	Pit Discharge
Open Pit wall rock (runoff)	■	■	■	■	■
Open Pit wall rock (flushing upon submergence)			■	■	
Ore Stockpile (runoff and infiltration)	■	■	■	(note 2)	
Ore Stockpile (flushing)			■		
Heap Leach Facility (rinsing and drain down)		■	■		
Heap Leach Facility (runoff from covered ore)				■	■
Saturated Tailings and Waste Rock (TMF seepage)		■	■	■	■
Unsaturated (NAG) Tailings (embankment and beach runoff)		■	■	■	■
Unsaturated Waste Rock (runoff and flushing)		■			

1. Shaded cells indicate a loading source during that Project phase.
2. Because ore stockpile seepage will enter the groundwater table, a lag time can be expected from when the contact water enters the groundwater and when it reaches its point of discharge.

5 Water Quality Model Overview



A water quality model was developed to predict mine drainage water quality for various components for each Project phase to evaluate the potential impact on water quality in the receiving environment. Mass transport (mass loading) rates were estimated for potential sources of contamination within the water management system. Flow rate (water balance) estimates were combined with mass loading rates, to predict water quality concentrations of substances at the Project site and in the receiving waters of the Project site. A water quality model was developed in 2013 which evaluated water quality given average annual hydrologic conditions, and was presented in SEA (2013). The water quality model was updated to account for inter-annual variability in site hydrology. The updated water quality model is described in the following sections.

5.1 Water Balance Model

A site-wide water balance model was developed by KPL and was used as the basis for the water quality model. A 52-year, continuous dataset of monthly weather conditions was developed by KPL in order to simulate the natural variability in hydrologic conditions (i.e. wet and dry periods) that can be expected at the site.

The input dataset to the water balance model was developed by correlating existing site weather data with regional weather data to derive a long-term synthetic dataset of monthly site conditions. A dataset of monthly hydrologic conditions (e.g. temperature, precipitation, streamflow) was developed from 52 years of continuous regional data. A correlation was established between the regional data and data collected at the Project site. The correlation was used to convert the regional dataset to a 52-year synthetic dataset for the Project site. Because the model was run over a simulation period of ~200 years, the 52-year input dataset repeated approximately four times during a given simulation. Figure 5-1 shows the synthetic dataset for annual precipitation over a 200 year simulation.

SEA carried out a frequency analysis on the 52 year dataset of annual precipitation values to estimate wet and dry years with 10-year return period (1:10). The results from the frequency analysis are shown on Figure 5-1.

Note: Annual values shown in this figure were calculated as annual the sum of monthly values from the input dataset.

Figure 5-1. Input Dataset of Annual Precipitation

5.2 Water Quality Model

SEA developed a mass load balance to predict the rate of contaminant transport through the modelled system. Source terms (Lorax, 2013) were combined with flow rates from the water balance to predict contaminant concentrations throughout the mine water management system and in the receiving (downstream) environment of the Casino Project.

A total of 27 water quality parameters (i.e. potential contaminants) were modelled and the full set of water quality model input values and results are provided in the Appendices of this document. This document summarizes input and output values for sulphate, fluoride, cadmium, copper, iron, molybdenum, selenium, and uranium to illustrate modelling methodology and results. Modelling results for the full set of water quality parameters are presented in the Appendices of this report.

The performance of the water quality management system was evaluated by plotting time-series of water quality model results (single realization) during infrequent wet and dry periods. 1:10 wet

and 1:10 dry years were selected for the evaluation. 1:10 wet and dry years are identified in the water quality output plots for Casino Creek and Dip Creek in Section 11.

5.3 Modelling Time-Steps and Timeline

The model simulation was run for a time period beginning a few years prior to Construction, and continued for 200 years following the beginning of Operations using monthly time steps. The Project timeline with respect to relevant Project activities are provided in Table 5-1.

Table 5-1. Milestone Dates for Water Quality Modelling

Project Year	Project Activity
-4	start of construction
-3	start of HLF processing and mining the Open Pit
1	start of milling (start of Operations)
18	final year of Open Pit mining
19	Open Pit dewatering stops, Pit Lake begins to form
19	end of waste rock placement and begin covering waste rock with tailings layer
19	begin rinsing HLF (pump surplus water to Open Pit)
22	final year of milling (end of Operations)
23	start of pumping TMF Pond to Open Pit
23	end of pumping of WMP to TMF, and begin pumping WMP to Open Pit
24	end of HLF rinsing and start of HLF drain down (pump to Open Pit)
27	end of pumping TMF to Open Pit
28	start of TMF filling by natural recharge
28	end of HLF drain down
29	HLF drainage directed to TMF Pond
35	end of pumping of WMP to Open Pit
35	initial discharge of TMF Pond and WMP (seasonal) to Casino Creek
109	initial discharge of Pit Lake to TMF (into North TMF Wetland)

5.4 Simplified Site-Wide Mass Loading Schematic

A simplified representation of the Casino Project water management system and receiving environment are presented schematically to illustrate the general flow paths of water and

potential contaminants through the system during Operations (Figure 5-2) and for long-term conditions (Pit Discharge Phase, Figure 5-3).

Descriptions of each of the drainage system components are presented in Section 6 (Open Pit), Section 7 (Heap Leach Facility), Section 8 (TMF Pond), Section 9 (Downstream Seepage), and Section 11 (Receiving Environment).

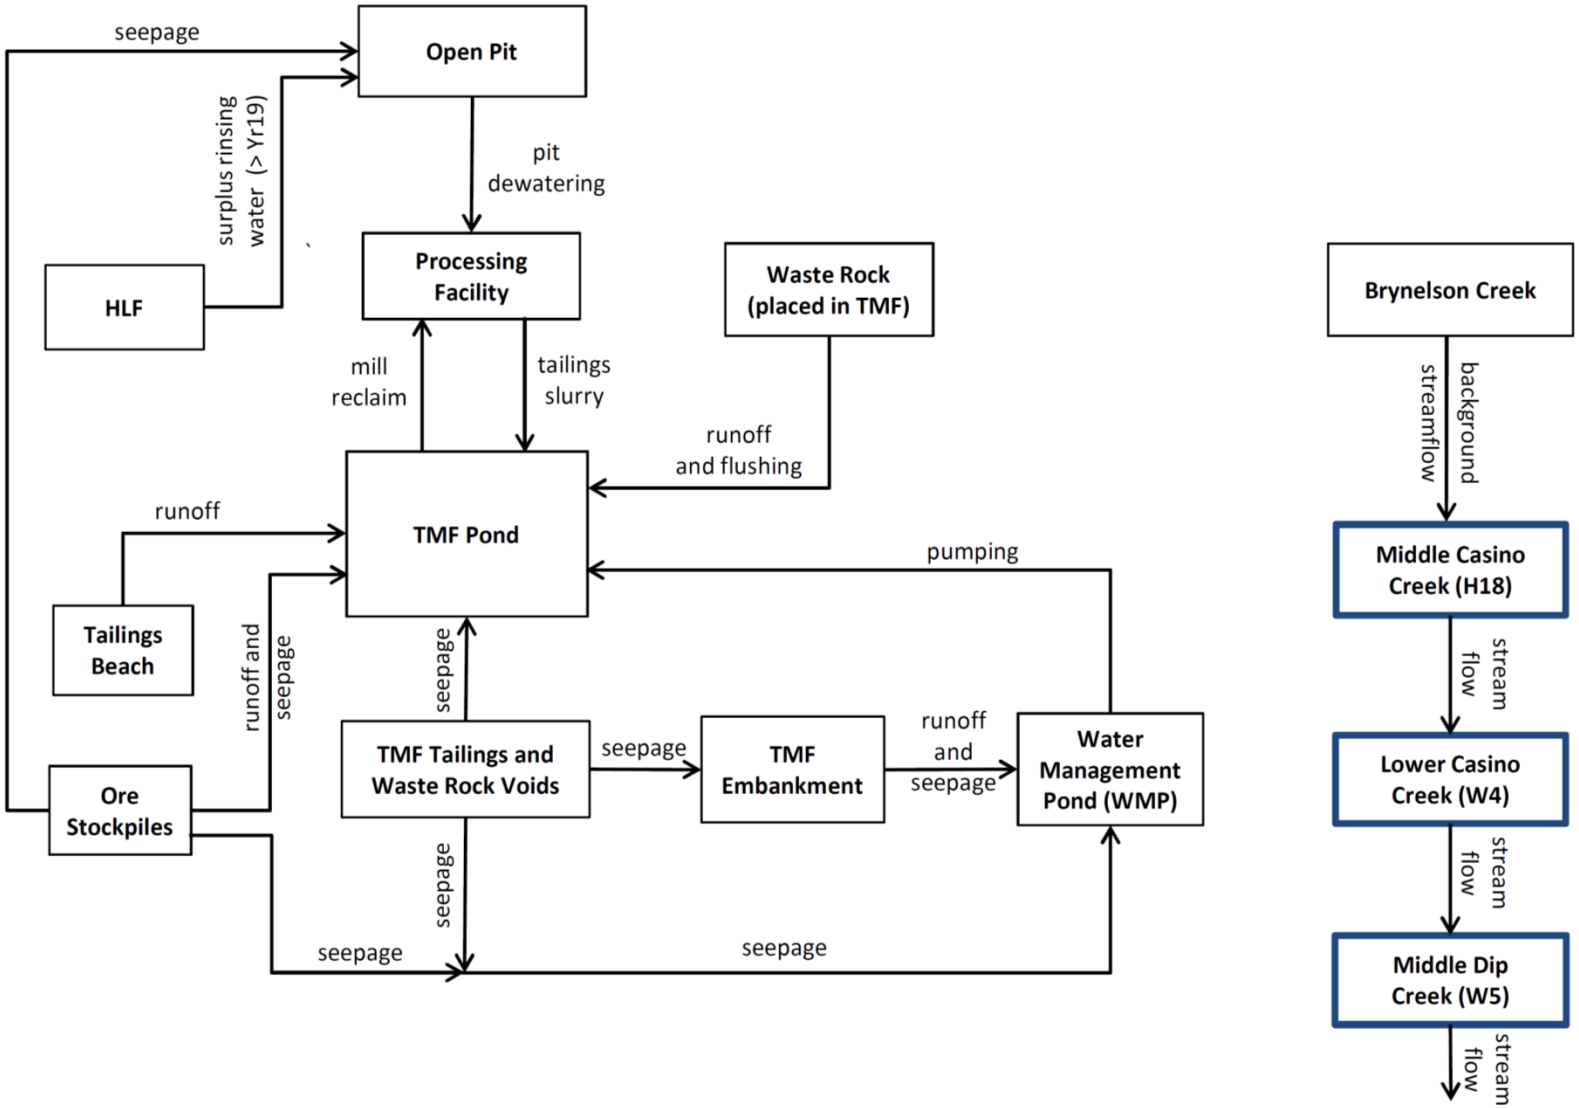


Figure 5-2. Simplified Mass Loading Schematic Casino Mine System (Operations)

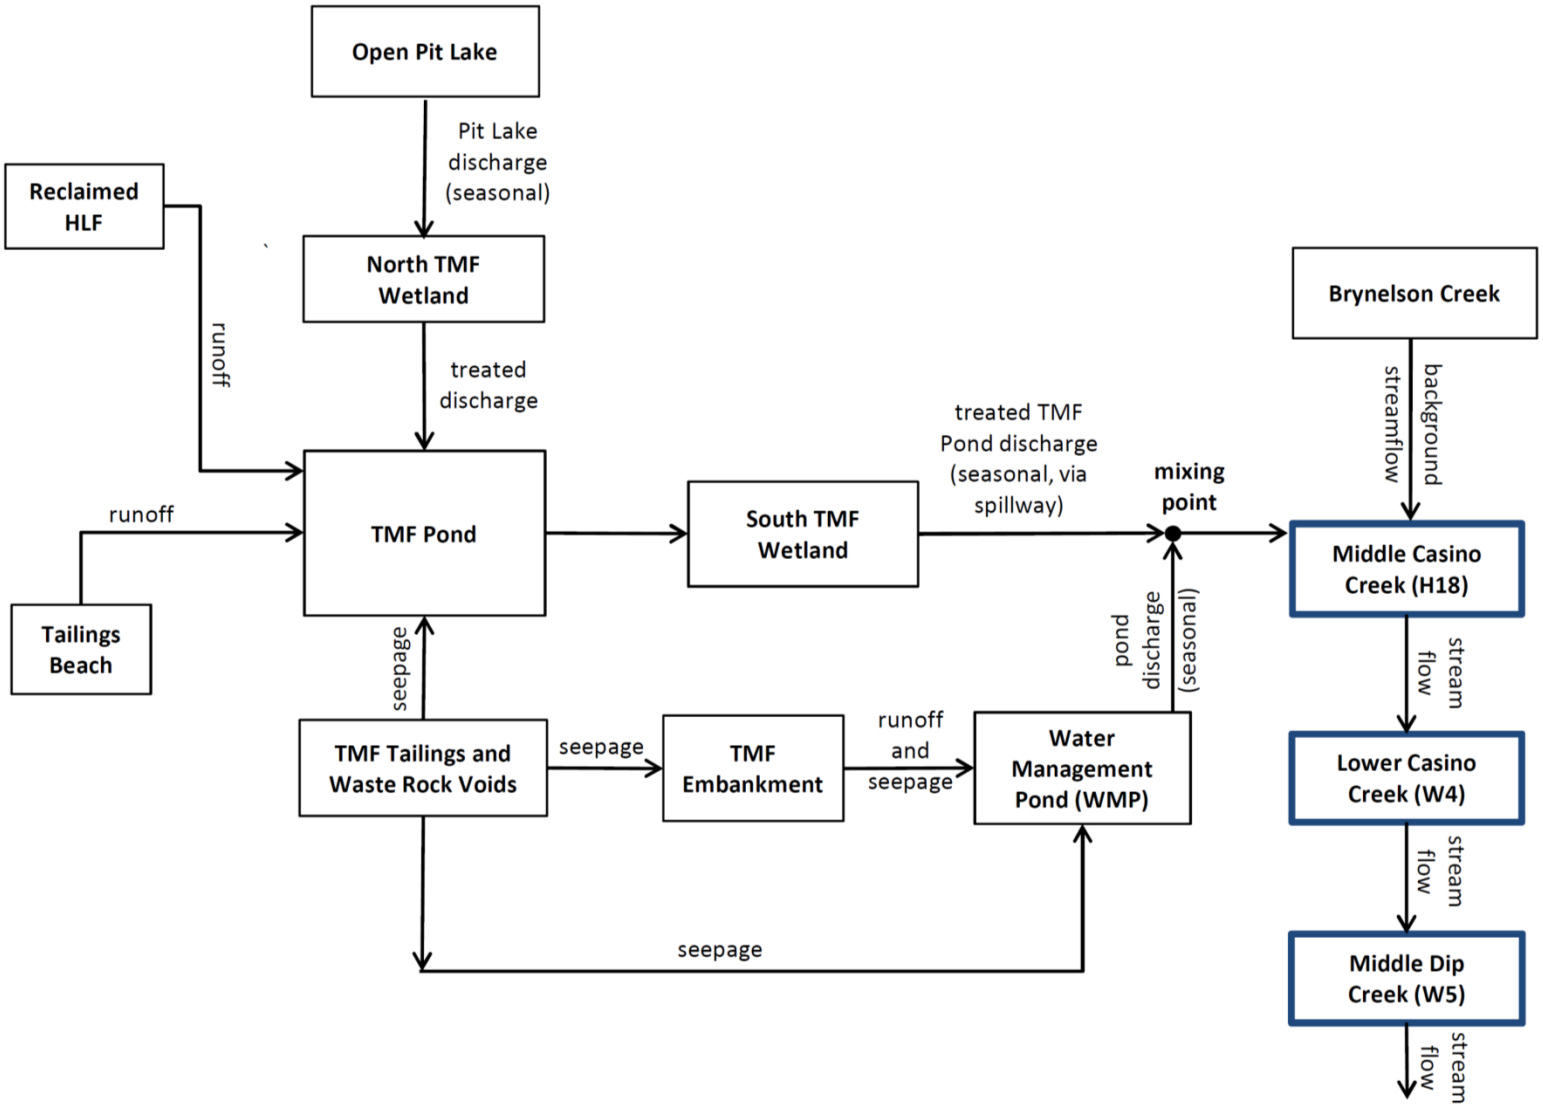

Figure 5-3. Simplified Mass Loading Schematic Casino Mine System (Pit Discharge Phase)

5.5 Modelling Platform

The model was developed using GoldSim modelling software. GoldSim is a standard platform for developing detailed water balance and water quality models for mine sites. A schematic view of one of the GoldSim model sub-components is provided in Figure 5-4 for illustration. The example includes four sub-containers (yellow boxes), one cell pathway (TMF_wq), four expressions ("f_x" icons), and one Dynamic Link Library element ("DLL" icon). Other types of GoldSim elements are incorporated into the model but are not part of this particular example. Information about GoldSim software can be readily obtained (GoldSim Technology Group LLC, 2013).

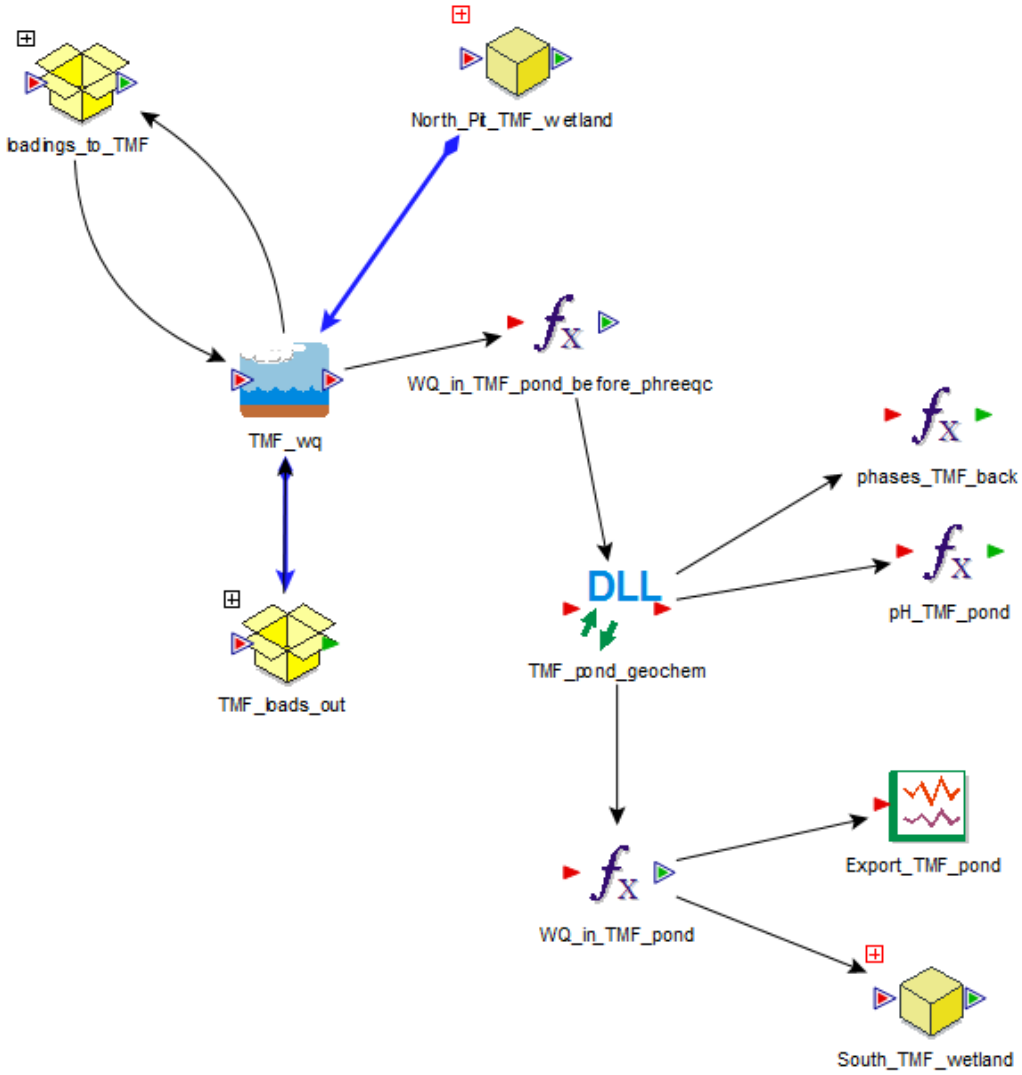

Figure 5-4. Example of the Casino Water Quality Model in GoldSim

5.6 GoldSim and PHREEQC Linkages

PHREEQC is geochemical modelling software developed by the United States Geological Survey. The mixing model in GoldSim was linked dynamically with PHREEQC at three model nodes: the Pit Lake, the TMF Pond, and the WMP. At each model node, a C++ DLL (dynamic link library) element was developed to represent the particular geochemical environment. Additional information related to geochemical modelling using PHREEQC is provided in Appendix I (Open Pit), Appendix IV (TMF Pond), and Appendix V (WMP).

During each timestep, GoldSim ran PHREEQC and the resulting concentrations returned from PHREEQC replaced the initial mixed concentrations. For example, as iron moves from a reducing enviromnment (groundwater seepage) to an oxiding environment (surface water), iron precipitates out of solution, and the concentration in water shifts accordingly. Without the dynamic link of GoldSim to PHREEQC, the water quality concentrations in the various water streams would be mis-represented. In GoldSim water quality is based purely on loads and flows, which does not incorporate the solubilities of each parameter.

5.7 Model Simulations

The model results are presented in two ways in this report:

1) Single Model Realization

   Results generated when one permutation (i.e. realization) of the input hydrology dataset was run with the model. Single realization results provide a time-series of model output which shows a representation of water quality that would result from a realistic range in hydrological conditions at the site. The output provides an indication of how high (or low) water quality concentrations may get, and how often those results are expected to occur. Time-series plots, and summary tables of water quality results for a single realization are presented throughout this report.

2) Monte-Carlo Summary (52 Realizations)

   The model was run 52 times. Each model run used a unique permutation (i.e. realization) of the input hydrology dataset. Of the 52 realizations run in the model, the first realization used the input dataset of monthly hydrology beginning from Year 1 of the synthetic dataset. The second realization began at Year 2, the next one began at Year 3, and so on. This continued until the 52nd realization, which began at Year 52 of the dataset. Figure 5-5 shows streamflow in Brynelson Creek for the first three model realizations as an example. A peak in monthly flow can be seen in Year 8 in Realization 1 (black line). That peak occurs in Year 7 in Realization 2 (dashed line), in Year 6 in Realization 3 (grey line), and so on (not shown in this example).

   The combined output from the 52 model runs represents the range in all possible model outputs resulting from all the possible permutations of the input hydrology dataset. A

statistical summary of the model output for the 52 realizations was generated for Casino and Dip Creek to be used as the basis for the aquatic impact assesment.

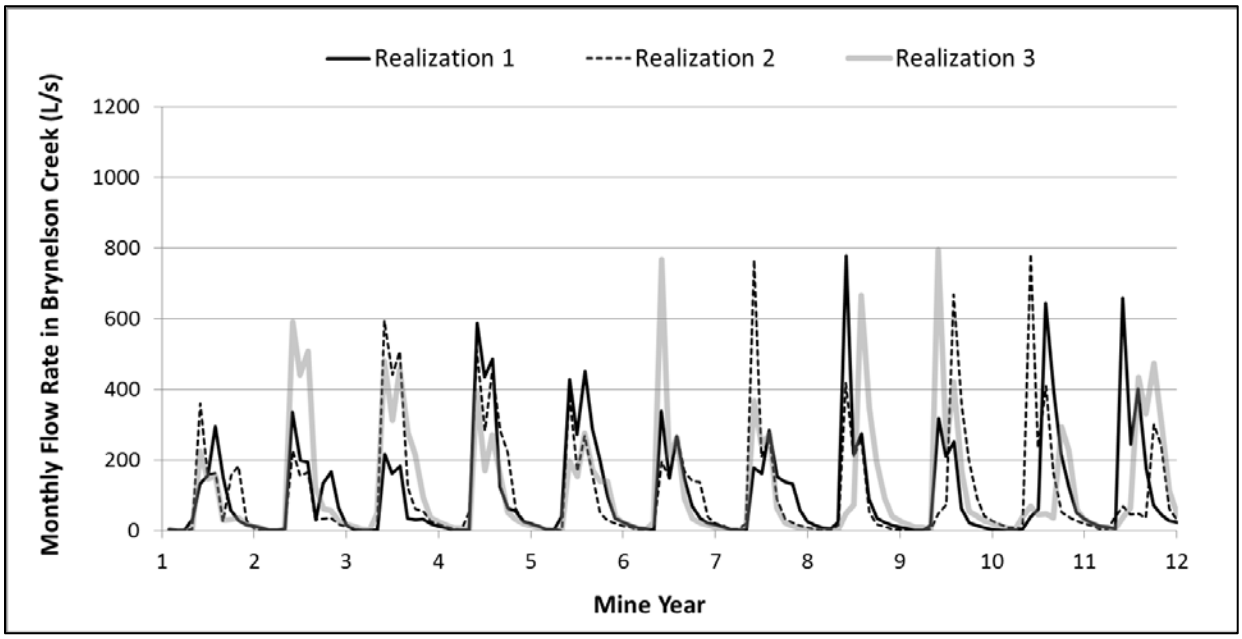

Figure 5-5. Brynelson Creek Streamflow for three Model Realizations

6 Open Pit Water Quality

Mining of the open pit will begin 4 years before the mill starts operating and will continue through the first 19 years of Operations. Dewatering will continue until Year 19 and collected water will be pumped to the mill as makeup. Pit water pumped to the Mill will take on the water quality of process water and will ultimately be discharged to the TMF Pond within the tailings slurry. Mill process water from the Open Pit dewatering was accounted for in TMF Pond water quality model (Section 8).

Following the cessation of dewatering in Year 19, the formation of the Pit Lake will commence by groundwater recharge, overland runoff, and direct precipitation on the water surface in the Open Pit. During the Wetland Construction Phase (Year 23 to Year 34), unused ore present in the surface ore stockpiles will be placed in the pit and TMF Pond water will be pumped to the Open Pit. Eventually (approximately Year 109), the Pit Lake will fill to its maximum water storage capacity. After that time, the Pit Lake will seasonally discharge to the TMF North Wetland for treatment prior to discharge to the TMF Pond.

A water quality model was developed for the Pit Lake (Year 19 and beyond). Pit Lake inflow and outflow sources of mass loading are summarized in Figure 6-1.

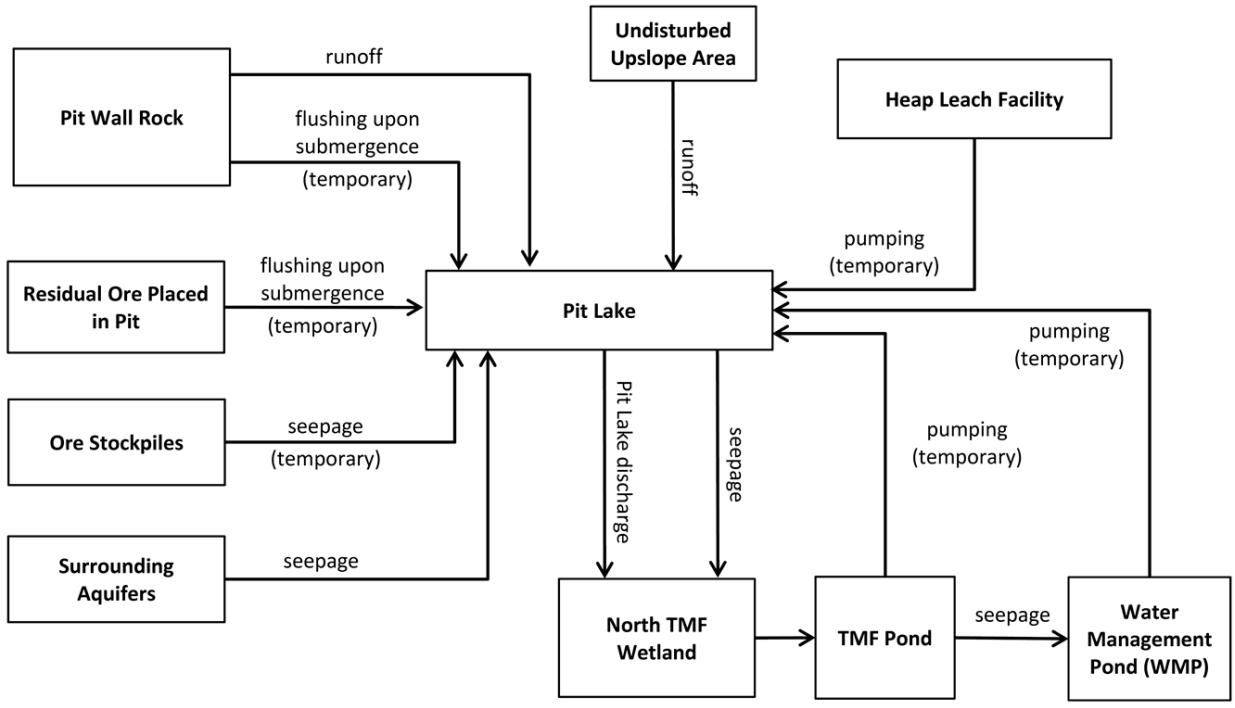

Figure 6-1. Mass Loading Flow Paths through the Pit Lake System

6.1 Water Balance Model Results

Based on the 52 realizations of the water balance simulation, the pit will most likely fill to its storage capacity and discharge to the North Wetland between Year 105 and Year 110. However, KPL (2015) established Year 109 as the best estimate for the beginning of the Pit Discharge Phase.

Average model output among the 52 model realizations are presented in Table 6-1 for 1) Wetland Construction Phase, 2) TMF Discharge Phase, and 3) Pit Discharge Phase.

Table 6-1. Pit Lake Water Balance Results

	Average Annual Discharge (L/s)		
	Wetland Construction Phase	TMF Discharge Phase	Pit Discharge Phase
INFLOWS			
Precipitation on Lake Surface	14	26	31
Groundwater Seepage	18	14	12
Ore Stokcpile Seepage	< 1	0	0
Pit Wall Runoff	28	18	15
Upslope Overland Runoff	35	35	36
Pumping from WMP	52	0	0
Pumping from TMF Pond	0 to 336 [2]	0	0
Pumping from the HLF	0 to 33 [3]	0	0
Total Inflow	123 to 522 [4]	93	95
OUTFLOWS			
Evaporation	11	21	24
Groundwater Seepage	0	7	11
Pit Lake Discharge	0	0	60
Total Outflow	11	28	95
Net (Inflow - Outflow)	112 to 511 [4]	65	0

1. Flow rates reported in this table are average results from 52 model realizations over the duration of each water management phase.
2. Constant pumping rate of 336 L/s for Year 23 to 27. Pumping ceases in Year 28 and beyond.
3. Constant pumping rate of 33 L/s for Year 24 to 28. Pumping ceases in Year 29 and beyond.
4. Range of inflow, resulting from temporary pumping from TMF and HLF.

According to the *Conceptual Reclamation and Closure Plan* (BCL, 2013), the total annual Pit Lake overflow volume will be discharged to the TMF wetland at a controlled rate during the warmest months of the year (June through September, inclusive) for optimal operation of the TMF wetland treatment system. KPL (2015) modelled the discharge as a flow of approximately 180 l/s over the four month period.

6.2 Mass Load Balance and Water Quality Model Results

Water balance flows (KPL, 2015) were combined with mine loading source terms (Lorax, 2013) and background water quality to predict mass loading rates of inflow and outflow of potential contaminants in the Pit Lake water. Water quality in the Pit Lake was calculated as the cumulative mass of a given substance in the Pit Lake water, divided by the water volume stored in the Pit Lake over a given time step interval. The Pit Lake mixing model output concentrations were assessed for solubility controls at each time step of the model simulation by coupling GoldSim and PHREEQC. This section provides a summary of the Pit Lake water quality model results. Modelling methodology and results are provided in Appendix I of this report.

As the Pit Lake water level rises, all wall rock below the water surface will become submerged, and loading was assumed to cease for that submerged portion of the wall rock. The total planar area of un-submerged wall rock was calculated for each model time-step. From that, the relative proportions of acidic and neutral un-submerged wall rock were calculated, and their respective loading rates into the Pit Lake were applied.

The mass loading balance between Pit Lake acidity loading and available alkalinity in the water (including neutralization potential available from the submerged wall rock) indicated that over the duration of the model simulation, the available alkalinity exceeds the acidity. Geochemical modelling indicated the pH of the Pit Lake will be near neutral.

The Pit Lake will discharge to the North TMF Wetland, an engineered wetland for the removal of certain contaminants. The wetland layout was designed by BCL (2013) and is illustrated on Figure 2-2. Clear Coast Consulting Inc. (2013) provided maximum water quality concentrations for water quality parameters (Table 6-2) from the North TMF Wetland.

In the water quality modelling, if the modelled TMF Pond water quality in the North TMF Wetland discharge was higher than the maximum treatment system concentrations, then water quality in North TMF Wetland discharge was set equal to the maximum effluent water quality (Table 6-2). If no treatment was specified, the modelled water quality loading from the Open Pit was assumed to report to the TMF Pond via the wetland.

Table 6-2. North TMF Wetland Maximum Effluent Water Quality

Water Quality Parameter		Maximum Effluent Water Quality (mg/L)
Sulphate	(SO_4)	15% reduction
Cadmium	(Cd)	0.000080
Copper	(Cu)	0.0040
Molybdenum	(Mo)	0.073
Mercury	(Hg)	0.000026
Selenium	(Se)	-
Silver	(Ag)	0.00010
Uranium	(U)	0.015
Zinc	(Zn)	0.030

Average annual water quality in the Pit Lake, and predicted North TMF Wetland discharge concentrations are provided in Table 6-1 for intial discharge of the Pit Lake (Year 109), and long-term conditions (Year 200) for a single model realization. Model output concentrations for all modelled water quality parameters are provided in Appendix I.

Table 6-3. Pit Lake Water Quality Model Results

Water Quality		Pit Lake Water Quality (mg/L)		North TMF Wetland Water Quality (mg/L)	
		Initial Pit Lake Discharge (Year 109)	Long-Term (Year 200)	Initial Pit Lake Discharge (Year 109)	Long-Term (Year 200)
pH		6.2	6.2		
Sulphate	(SO_4)	501	368	315	221
Fluoride	(F)	1.2	0.88	0.88	0.62
Cadmium	(Cd)	0.0038	0.0035	0.000080	0.000080
Copper	(Cu)	5.0	4.9	0.0040	0.0040
Iron	(Fe)	0.00090	0.00089	0.059	0.080
Molybdenum	(Mo)	0.19	0.10	0.068	0.063
Selenium	(Se)	0.0084	0.0052	0.0061	0.0036
Uranium	(U)	0.060	0.054	0.015	0.015

Individual contributions of each mass loading source are presented in Table 6-4 (initial pit discharge) and Table 6-5 for a typical year following discharge of the Pit Lake. Model output concentrations and individual contributions of mass loading sources are provided in Appendix I for all modelled water quality parameters.

Closure activities such as pumping from the HLF, TMF, and WMP, and disposal of residual ore stockpile rock will influence Pit Lake water quality upon initial discharge. However, those loading contributions will be temporary and will not affect the long-term water quality in the Pit Lake.

A portion of the pit wall (i.e. the "high wall") that is above the elevation of the final Pit Lake will remain un-submerged in perpetuity. Runoff from the high wall will be a perpetual source of mass loading into the Pit Lake. Generally, the acidic portion (Supergene Acidic or Hypogene Acidic) of the Open Pit high wall rock is expected to be the largest contributor of mass load into the Pit Lake in the long-term.

Table 6-4. Loading Source Contributions to the Pit Lake (Initial Discharge)

Pit Lake Loading Source	Fraction Contributing (%)							
	SO_4	F	Cd	Cu	Fe	Mo	Se	U
Runoff	3	2	2	0	0	0	0	0
Groundwater	15	7	7	1	27	1	0	9
Ore Stockpile Seepage	0	1	2	2	1	0	1	1
Pit Wall Rock	23	37	43	55	49	16	18	50
Ore Rock Flushing upon Submergence	10	18	37	41	22	5	51	28
WMP Pumping	10	9	2	0	0	11	5	4
TMF Pond Pumping	31	23	4	0	0	26	20	9
HLF Draindown	7	4	4	1	2	42	5	0
Total	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**

1. Total loading into the Pit Lake until initial discharge (Year 109).
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

Table 6-5. Loading Source Contributions to the Pit Lake (Long-Term)

Pit Lake Loading Source	Fraction Contributing (%)							
	SO_4	F	Cd	Cu	Fe	Mo	Se	U
Runoff	9	6	3	0	0	1	2	0
Groundwater	40	19	10	1	30	12	1	13
Pit Wall Rock	50	75	87	99	70	87	98	87
Total	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**

1. Year 200 was selected as the representative year for long-term conditions.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

7 Heap Leach Facility Water Quality Model

Crushed oxide gold ore will be placed on the HLF until end of Year 14. The ore will be leached with an aqueous cyanide solution and the pregnant solution extracted for gold and copper. The leaching will continue until recovery is no longer profitable. For modelling purposes, KPL (2013c) assumed leaching would continue until end of Year 18 and predicted that during that time the system will operate in a water deficit. That is, no surplus water will be produced by the HLF until after the end of Year 18.

After operations of the HLF, rinsing occurs from Year 19 to Year 23 and draindown occurs from Year 24 to Year 28. Surplus water will be directed to the Pit Lake, after treatment with a cyanide destruction circuit and a bioreactor for selenium and mercury (Clear Coast Consulting, 2013). A bioreactor is currently the preferred treatment method for selenium and mercury. Alternate treatment methods may also be considered to remove selenium and mercury during the rinsing and draindown phase.

Following draindown, the final slopes of the HLF will be graded, covered, and re-vegetated. The water quality model assumes that 20% of surplus water (i.e. 20% of net precipitation) infiltrates and becomes seepage at the toe of the HLF while the remaining 80% of surplus water is non-contact runoff. The non-contact runoff is modelled as background water quality (W13), similar to runoff from the land adjacent to the HLF. Both the toe seepage and the surface runoff from the HLF will be directed downslope to the TMF Pond. Table 7-1 provides a timeline of surplus HLF water management with predicted average annual flow rates from the KPL water balance (KPL, 2015).

Table 7-1. HLF Surplus Water Management

Project Year	Activity	Average Annual Surplus Water (l/s)	Surplus Water Management
-3 to 18	Processing	0	-
19 to 23	Rinsing	1.6	Treated and Pump to Open Pit
24 to 28	Drain Down	33	Treated and Pump to Open Pit
29 and beyond	Reclaimed Site	10.4	Non-contact runoff to TMF Pond
29 and beyond	Reclaimed Site	2.6	HLF seepage to TMF Pond

The HLF will be underlain by a Linear Low Density Polyethylene (LLDPE) liner (KPL, 2013a). As a result, a groundwater pathway from the HLF was assumed to be negligible. Discharge from the HLF toe seepage is incorporated into the water quality model.

Lorax (2013) provided a source term for three time periods: 1) rinsing and draindown; 2) 10 years following draindown; and, 3) long-term. The first set of source terms was applied during the rinsing and draindown period. The second set was applied for ten years following draindown (Year 29 to Year 38) while the water quality stabilizes to long-term conditions. Long-term water quality was applied for Year 39 and beyond.

Mass loading from the HLF to the Pit Lake during rinsing and draindown was adjusted for treatment by the bioreactor (Table 7-2). Following treatment in the bioreactor, the selenium and mercury levels are reduced to 0.02 mg/L and 0.00026 mg/L, respectively. This mitigation was designed to reduce selenium levels in the North TMF wetland (Clear Coast Consulting, 2013).

The bioreactor treatment may also remove other constituents of concern in addition to selenium and mercury (e.g. uranium, silver, copper, cadmium, arsenic), however the water quality model did not account for these reductions to allow for flexibility in the treatment method as more detailed designs are developed. The cyanide destruction circuit was accounted for in the source terms provided by Lorax.

Mass loading from the HLF to the TMF Pond was accounted for by SEA in the water quality modelling by multiplying the estimated HLF toe seepage flow rate by the estimated water quality (Table 7-2). The full set of HLF surplus water quality data is provided in Appendix III.

Table 7-2. HLF Surplus Water Quality

Water Quality Parameter	HLF Surplus Water Quality (mg/L)			
	Rinsing and Drain Down (Year 19 to 28)	Bioreactor Treatment* (Year 19 to 28)	10 Years Post Drain Down (Year 29 to 38)	Long Term (Year 39 and beyond)
WAD-Cyanide	5.0	5.0	0.030	
Sulphate (SO_4)	1,920	1,920	2,100	424
Fluoride (F)	2.1	2.1	3.0	1.3
Cadmium (Cd)	0.0084	0.0084	0.0050	0.00028
Copper (Cu)	2.8	2.8	0.016	0.0011
Iron (Fe)	9.5	9.5	0.0040	0.0040
Molybdenum (Mo)	4.2	4.2	4.2	0.94
Selenium (Se)	0.40	0.02**	0.23	0.098
Uranium (U)	0.0018	0.0018	0.63	0.17

* Mercury is also treated for in the bioreactor to the CCME guideline level (0.026 ug/L)

** This treatment level is based on Yukon Zinc (2010)

8 TMF Pond Water Quality

The Tailings Management Facility (TMF) will be the primary water and waste management component of the Project, and was designed by KPL to store approximately 956 million tonnes of tailings and up to 649 million tonnes waste rock and overburden (KPL, 2012). The TMF will be situated in the Casino Creek valley southeast of the Open Pit.

During Operations, waste rock and tailings slurry will be deposited in the TMF with the tailings supernatant water reclaimed via the reclaim system for reuse by the mill or by the cyclone sand plant. Site runoff, including runoff from the ore stockpiles will drain to the pond. During Operations, the WMP will collect the TMF embankment runoff and seepage and pump it back to the TMF pond.

Starting in year 23, the WMP will be pumped to the Open Pit rather than to the TMF, and the TMF Pond will be pumped to the Open Pit for a 5 year period and then the TMF will be allowed to refill by natural recharge. Once full, the TMF Pond will discharge to Casino Creek via an engineered spillway. The final phase will begin when the Open Pit discharges to the TMF Pond.

A water quality model was developed for the TMF Pond from Construction through to the Pit Discharge Phase. TMF Pond mass loading inflows and outflows are summarized for Operations (Figure 8-1), and the Pit Discharge Phase (Figure 8-2).

8.1 Water Balance Model Results

The TMF Pond will be pumped to the Open Pit for five years during Wetland Construction, and will refill by natural recharge and will discharge to Casino Creek in approximately Year 35. Inflow from tailings pore water will be highest during Operations due to tailings consolidation, and will gradually reduce during closure and post-closure as the tailings consolidation process slows and eventually stops. After that time, tailings and waste rock pore water displacement will be the result of groundwater fluxes through the tailings and waste rock voids.

A summary of annual inflows and outflows of water to the TMF Pond (derived from the KPL water balance model) is provided in Appendix IV (TMF Pond Water Quality Modelling).

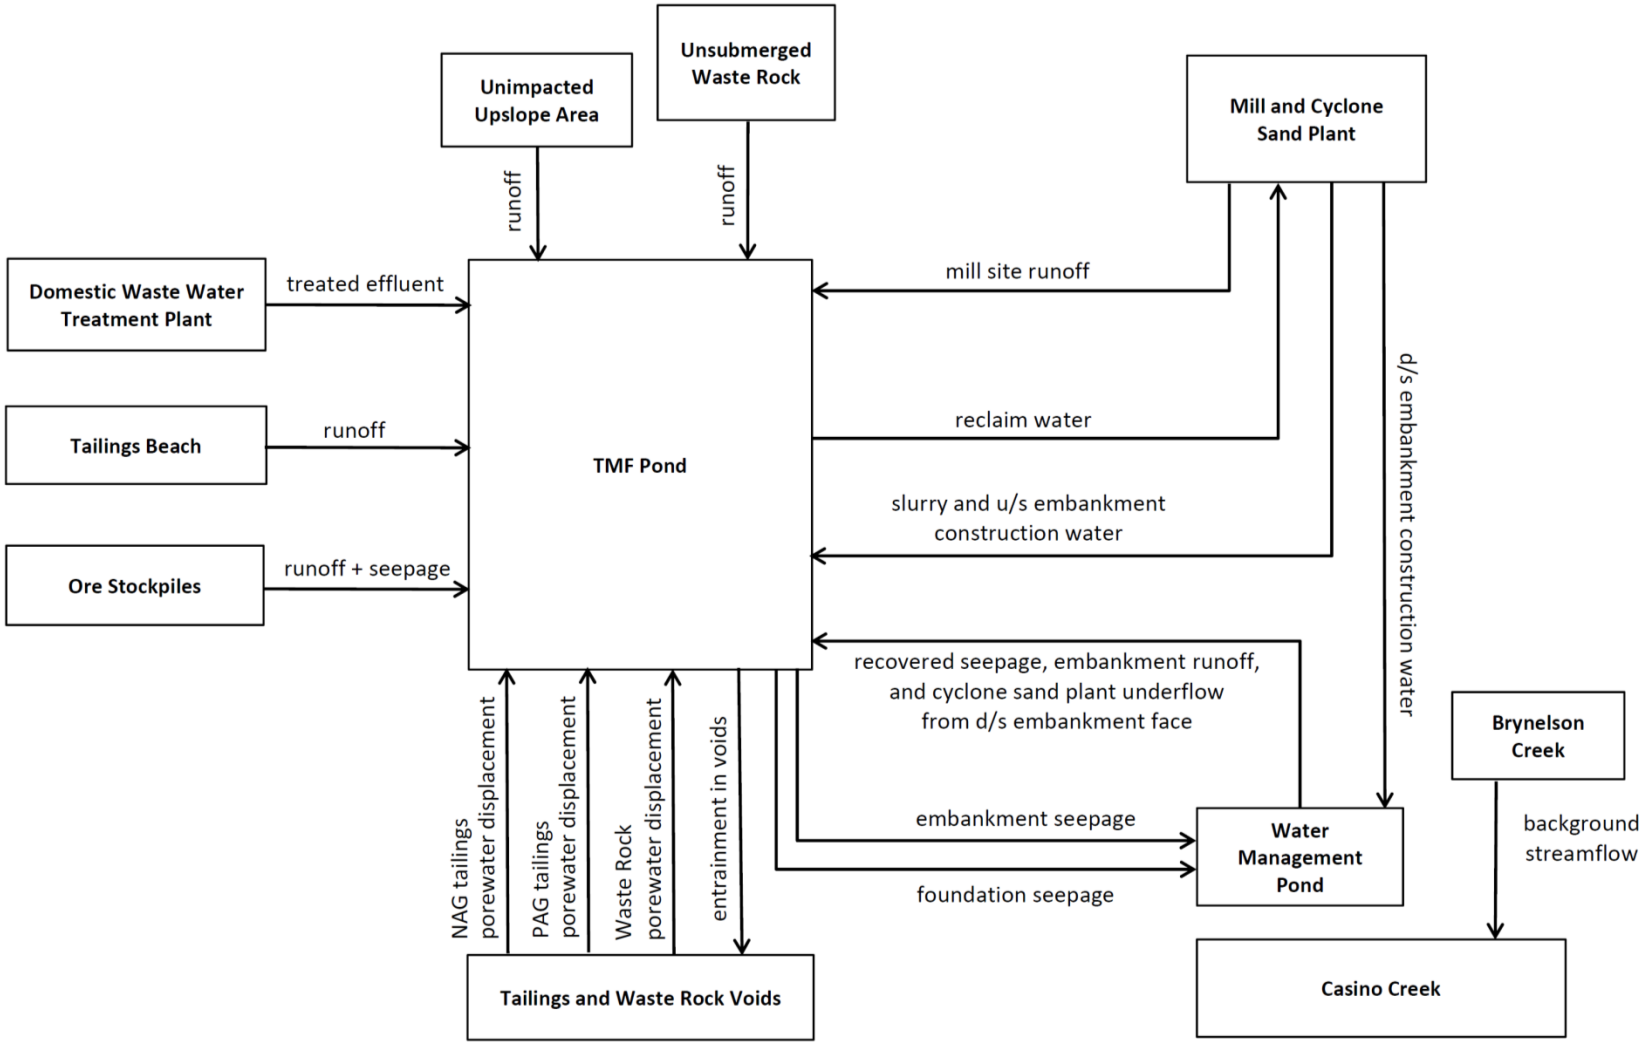

Figure 8-1. Mass Loading Flow Paths through the TMF Pond System (Operations Phase)

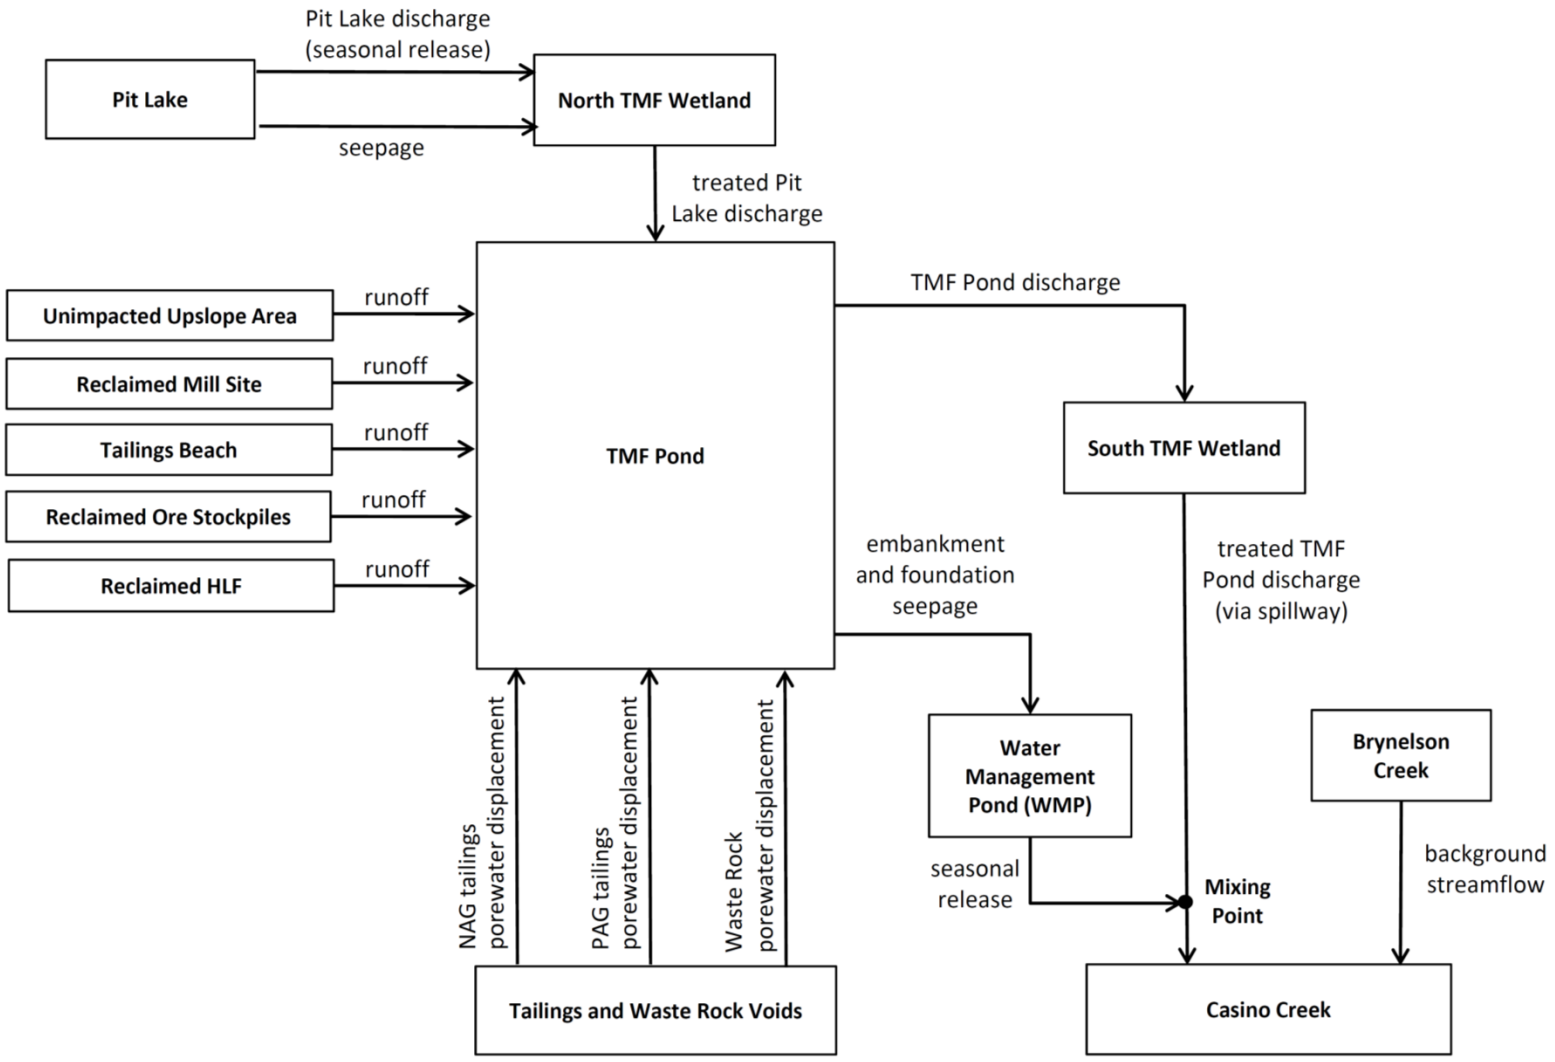

Figure 8-2. Mass Loading Flow Paths through the TMF Pond System (Pit Discharge Phase)

8.2 Mass Load Balance and Water Quality Prediction

Water balance flows (KPL, 2015) were combined with mine loading source terms (Lorax, 2013), and background water quality to predict mass loading rates of inflow and outflow of potential contaminants in the TMF Pond. Water quality in the TMF Pond was calculated as the cumulative mass of a given substance in the TMF Pond water, divided by the water volume stored in the TMF Pond in a given time step interval. The TMF Pond mixing model output concentrations were assessed for solubility controls at each time step of the model simulation by coupling GoldSim and PHREEQC. This section provides a summary of the model results. Modelling methodology and results are provided in Appendix IV.

After the Wetland Construction Phase, surplus TMF Pond water will discharge over the TMF spillway and into Casino Creek. Prior to discharge over the spillway, the TMF Pond water will travel through the South TMF Wetland, an engineered wetland for the removal of some contaminants. The wetland layout was designed by BCL (2013) and is illustrated on Figure 2-2.

Clear Coast Consultants (2013) provided maximum water quality concentrations for the South TMF Wetland effluent (Table 8-1). In the water quality modelling, if the modelled TMF Pond water quality in the spillway discharge was higher than the maximum treatment system concentrations, then water quality in the spillway discharge was set equal to the maximum water quality concentration of the wetland. If no treatment was specified, the modelled TMF Pond water quality was assumed to report to Casino Creek via the spillway, unchanged.

Table 8-1. South TMF Wetland Maximum Effluent Water Quality

Water Quality Parameter		Maximum Effluent Water Quality (mg/L)
Sulphate	(SO_4)	15% reduction
Cadmium	(Cd)	0.000080
Copper	(Cu)	0.0040
Molybdenum	(Mo)	0.073
Mercury	(Hg)	0.000026
Selenium	(Se)	-
Silver	(Ag)	0.00010
Uranium	(U)	0.015
Zinc	(Zn)	0.030

Annual TMF Pond water quality from one model realization, for select parameters, are provided for a typical year during Operations (Year 15), initial discharge of the TMF to Casino Creek (Year 35), and long-term, post Pit Lake discharge (Year 120) conditions. Model output concentrations are provided in Appendix IV for all modelled water quality parameters.

Water quality is provided (Table 8-2) for the TMF Pond water, and TMF Spillway discharge to illustrate the modelled effects of the treatment wetland.

Table 8-2. TMF Pond Water Quality Model Results

Water Quality Parameter		Average TMF Pond Water Quality (mg/L) [1]			
		Operations	Wetland Construction Phase	TMF Discharge Phase	Pit Discharge Phase
pH		6.1	6.8	6.9	6.9

Iron	(Fe)	0.0012	0.00030	0.00022	0.00023
Molybdenum	(Mo)	0.37	0.20	0.085	0.066
Selenium	(Se)	0.015	0.0069	0.0043	0.0043
Uranium	(U)	0.018	0.033	0.048	0.042
Water Quality Parameter		**Average TMF Spillway Water Quality (mg/L)**			
		Operations [2]	**Wetland Construction Phase [2]**	**Initial TMF Pond Discharge**	**Pit Discharge Phase**
pH		-	-	6.9	6.9
Sulphate	(SO_4)	-	-	283	225
Fluoride	(F)	-	-	0.65	0.63
Cadmium	(Cd)	-	-	0.000080	0.000080
Copper	(Cu)	-	-	0.0040	0.0040
Iron	(Fe)	-	-	0.00022	0.00023
Molybdenum	(Mo)	-	-	0.085	0.066
Selenium	(Se)	-	-	0.0043	0.0043
Uranium	(U)	-	-	0.015	0.015

1. Values represent average water quality results over the duration of each mining phase for a single model realization (realization #1).
2. TMF Spillway will have zero discharge during the Operations and Wetland Discharge Phases.

Individual contributions of each mass loading source are presented for each phase of mining in Table 8-3 to Table 8-6. Individual contributions of mass loading sources are provided in Appendix IV for all modelled water quality parameters.

In general, during TMF Discharge Phase, upward fluxes from porewater in the tailings and waste rock are the dominant loads to the TMF Pond. Once the Pit Discharge Phase begins, North Wetland discharge makes up a large portion of the overall load to the TMF Pond for some water quality parameters.

Table 8-3. Loading Source Contributions to the TMF Pond (Operations)

Source of Loading	Fraction Contributing (%)

9 TMF Water Management Pond Water Quality Model

The Water Management Pond (WMP) will collect surface runoff and seepage from the TMF embankments and the collected water will be pumped back to the TMF Pond during Operations and to the Open Pit during Wetland Construction Phase. Mass loading inflows and outflows to the WMP are presented in Figure 9-1 (Operations), and Figure 9-2 (Wetland Construction Phase).

Starting in the TMF Discharge Phase, seepage recovered downstream from the TMF embankments will be stored in the WMP through the low flow months of the year (winter), and released during those months when the TMF Spillway is discharging, and when Brynelson Creek flows are higher (spring, summer, and fall) such that the seepage water quality will be less influential on the water quality in Casino Creek. Mass loading inflows and outflows to the WMP during TMF Discharge and Pit Discharge Phases are presented in Figure 9-3.

9.1 Water Balance Model Results

KPL assumed in the water balance that 100% of the total TMF seepage, embankment runoff, and embankment construction water (i.e. Sand Plant underflow) will be captured in the WMP. Because the WMP water will be pumped back to the TMF Pond (Operations), or Open Pit (Wetland Construction Phase), the mine site will have zero discharge to Casino Creek during those phases.

Following the wetland construction phase, withdrawal and discharge from the WMP pond will occur from May to November through the following controls:

- In May, once Brynelson Creek is discharging at 20 L/s or more, the WMP will discharge at a ratio of 0.8 times the Brynelson Creek Flow. From June to November under typical conditions in Brynelson, the WMP will discharge at this ratio. However, for years with exceptionally low flow in Brynelson, the WMP will need to be discharged at a rate of up to 200 L/s to drain down stored water in the WMP in order to ensure there is storage capacity available for the following winter months.
- The release of the TMF pond will be controlled to further mitigate water quality in Casino Creek. This is especially important for drier periods when there is little-to-no water in Brynelson Creek. The ratio of TMF pond release to WMP release is set at 1.2 for June to November and 2.0 for May for the TMF Discharge Phase. These ratios were determined to avoid excess draw-down in the TMF pond and provide for a sufficient water cover over waste rock and tailings. The ratio of TMF pond release to WMP release varies from 1.2 to 2.5 for the Pit Discharge Phase as there is more water available in the TMF once the pit starts to discharge.

A summary of annual inflows and outflows of water to the WMP is provided in Appendix V.

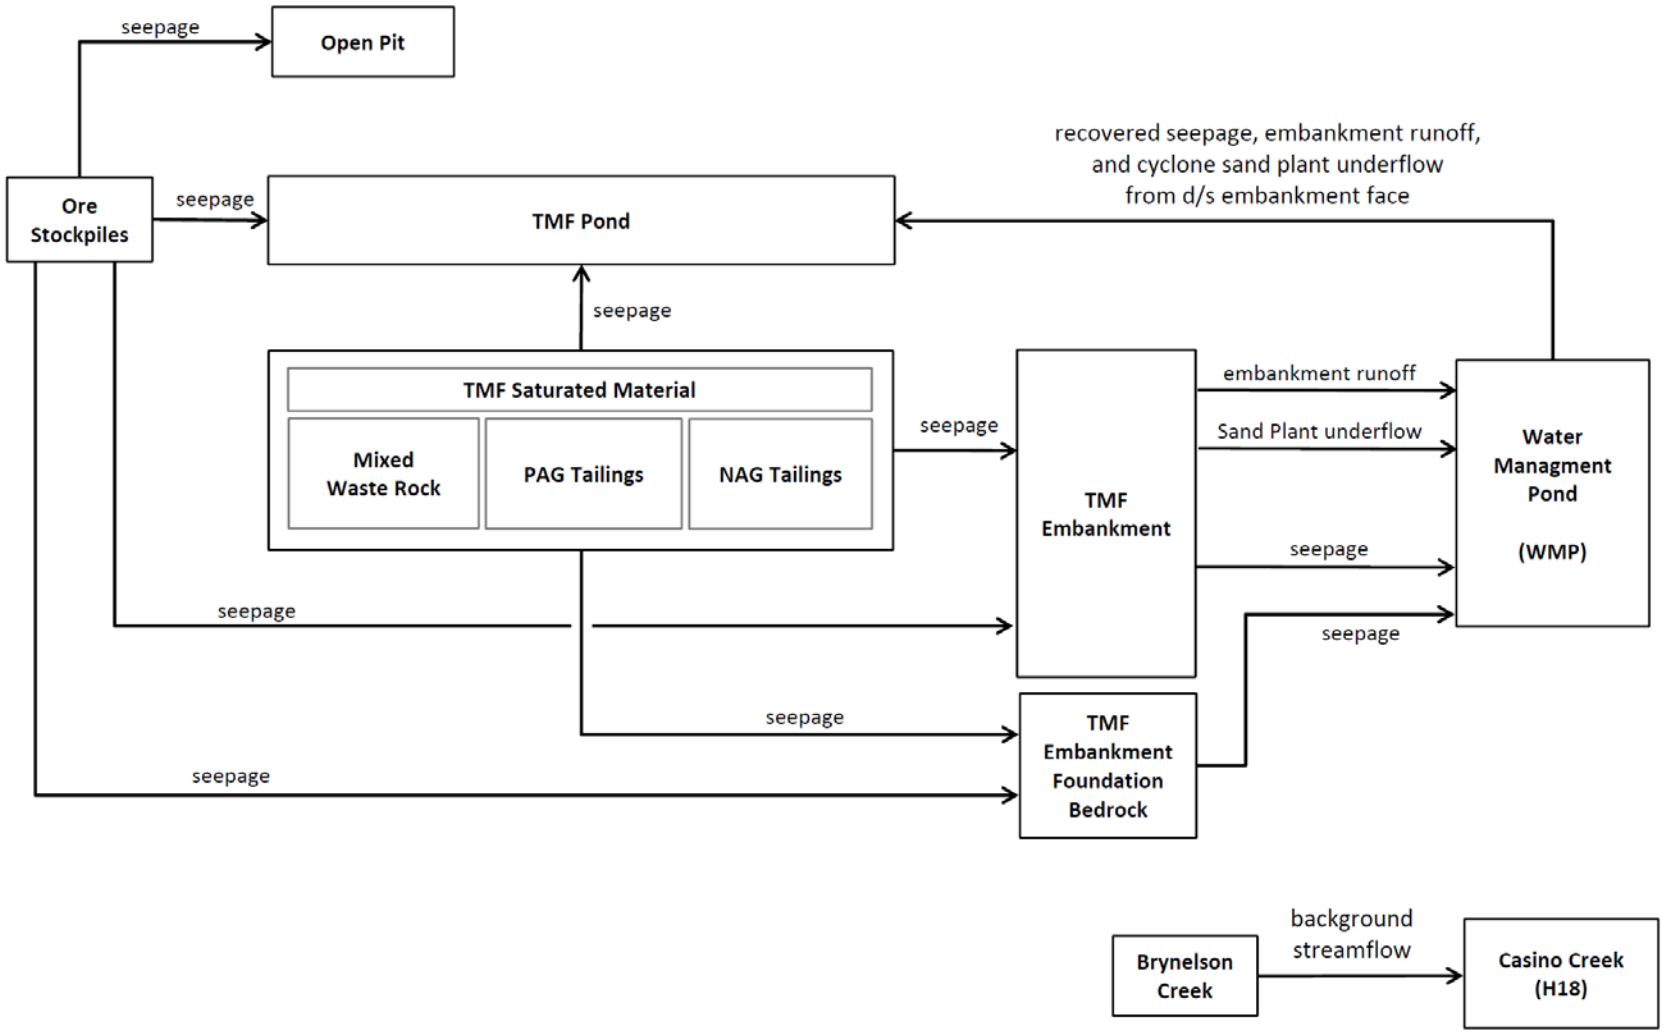

Figure 9-1. WMP Mass Loading Diagram (Operations Phase)

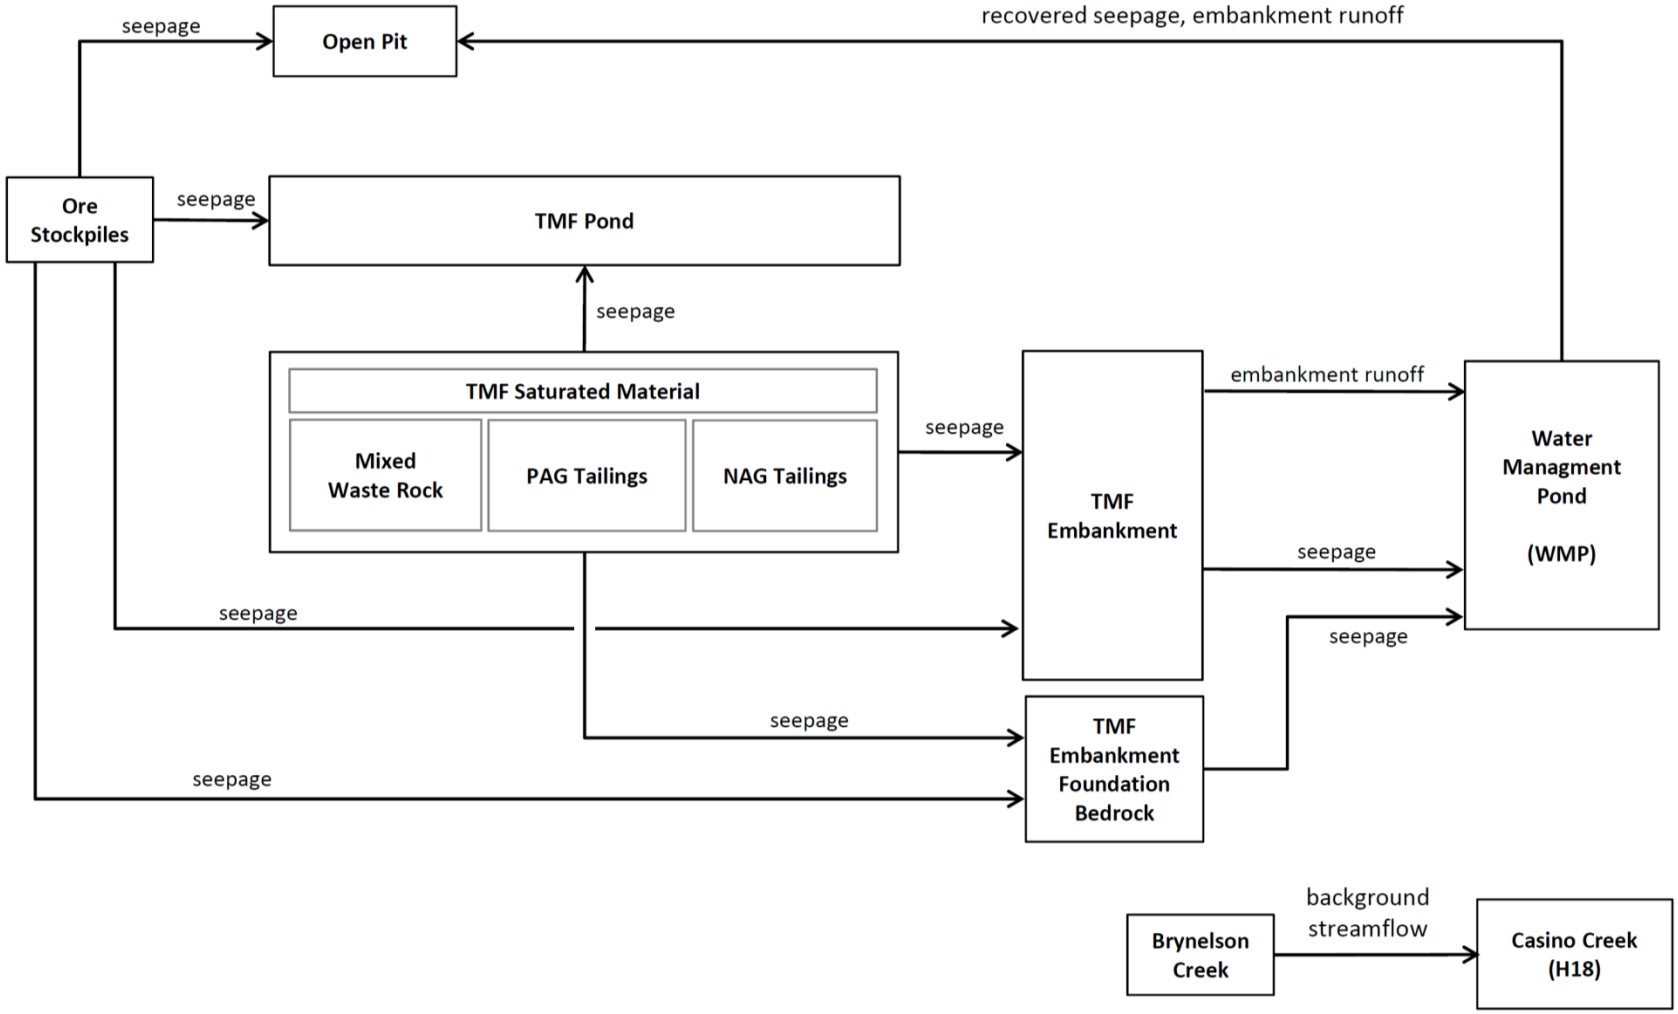

Figure 9-2. WMP Mass Loading Diagram (Wetland Construction Phase)

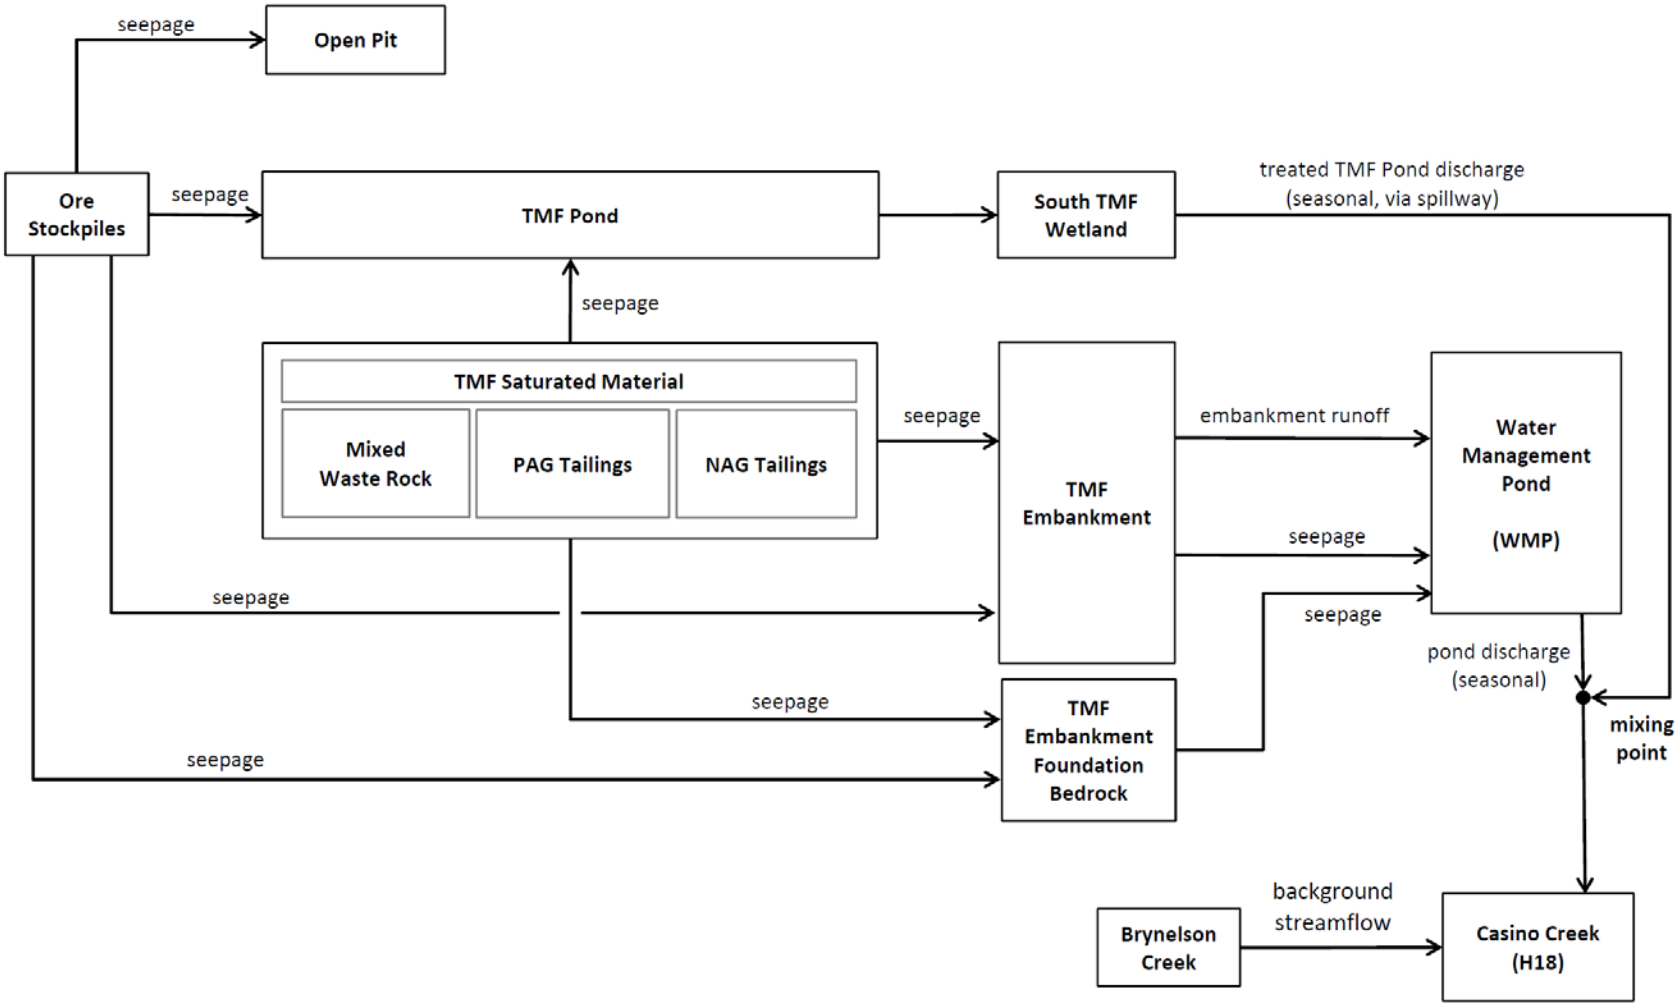

Figure 9-3. WMP Mass Loading Diagram (TMF Discharge and Pit Discharge Phases)

9.2 Mass Load Balance and Water Quality Prediction

Water balance flows (KPL, 2015) were combined with mine loading source terms (Lorax, 2013), and background water quality to predict mass loading rates of inflow and outflow of potential contaminants in the WMP. The WMP mixing model output concentrations were assessed for solubility controls at each time step of the model simulation by coupling GoldSim and PHREEQC. The pH of the WMP was predicted by PHREEQC to be near neutral. Water quality model results for select parameters are presented in Table 9-1. Modelling methodology and results are presented in detail in Appendix V of this report.

Table 9-1. Water Quality Results for the WMP

Water Quality Model Parameter		WMP Quality (mg/L) [1]		
		Pumped Back to TMF (Operations Phase)	Pumped Back to Pit (Wetland Construction Phase)	Released to Casino Creek (TMF Discharge and Pit Discharge Phases)
pH		6.2	6.4	6.4
Sulphate	(SO_4)	1,137	947	979
Fluoride	(F)	1.9	1.8	1.8
Cadmium	(Cd)	0.00063	0.0014	0.0012
Copper	(Cu)	0.021	0.044	0.038

2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

10 Mine Sources of Loading to the Receiving Environment

Total loading from mine sources were calculated and used as input to the receiving environment water quality modeling (Section 11). Loadings from mine sources, into the receiving environment, are expected to change throughout the Project life based on water management systems that are in place at a given time. The most notable milestone will be the transition from Wetland Construction Phase to TMF Discharge Phase, when the active water management systems will be discontinued. At that time, assuming acceptable water quality, pump-back of seepage from the WMP will stop, and the TMF Pond will discharge into Casino Creek. After that time, seepage that is collected in the WMP will be mixed with the TMF Spillway discharge during the open water season.

Mine loading sources are described in the following sections for the active water management phases (Operations and Wetland Construction), and passive water management phases (TMF Discharge and Pit Discharge).

10.1 Operations and Wetland Construction Phases

During Operations the WMP will be pumped back to the TMF Pond, and during Wetland Construction, the WMP will be pumped back to the Open Pit. As a result, there will be no mine sources of loading to Casino Creek during those phases.

10.2 TMF Discharge and Pit Discharge Phases

During TMF Discharge and Pit Discharge Phases, the WMP will be released during the open water season and will be allowed to mix with the TMF spillway discharge prior to entering Casino Creek. Background runoff from an area of about 1 km^2 is also expected to enter the total flow by the mixing point. The mixing point is shown schematically on Figure 9-3.

Monthly discharges at the mixing point are shown on Figure 10-1. Average, 5^{th} percentile (P5), and 95^{th} percentile (P95) from 52 realizations of the water balance are presented to show the expected range of flows at the mixing point.

Modelled water quality values for CoCs at the mixing point are presented in Table 10-1, by project phase. Metal Mining Effluent Regulation (MMER) values are presented in the table because the mixing point represents the point of discharge from the mine site into the receiving environment. The combined streamflow at the mixing point was calculated to be pH neutral using PHREEQC.

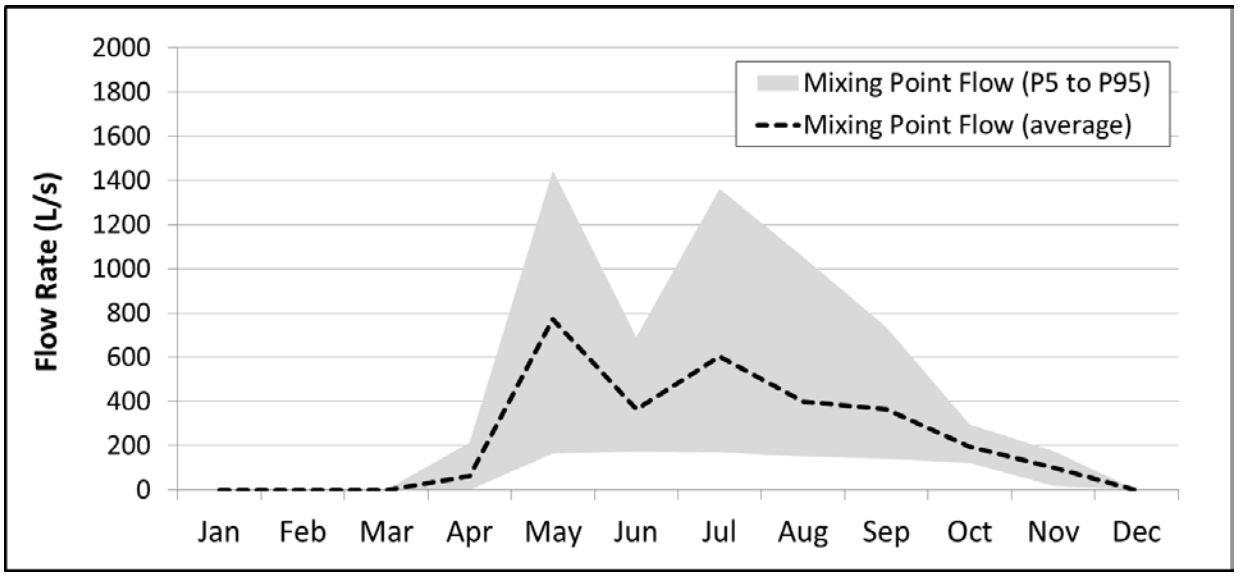

Figure 10-1. Monthly Flow of Mine Derived Water entering Casino Creek from the Mixing Point (Pit Discharge Phase)

Table 10-1. Water Quality of Mine Derived Water Entering Casino Creek

Water Quality Parameter		MMER (mg/L)	Mine Discharge Water Quality at the Mixing Point (mg/L) [1]					
			Operations and Wetland Construction Phase [2]		TMF Discharge Phase [3]		Pit Discharge Phase [3]	
pH		-	-		7.5		7.5	
Sulphate	(SO_4)	-	-		518		394	
Fluoride	(F)	-	-		1.1		0.93

Copper	(Cu)	0.3	-		0.017		0.012	
Iron	(Fe)	-	-		0.0029		0.0023	
Molybdenum	(Mo)	-	-		0.14		0.11	
Selenium	(Se)	-	-		0.0052		0.0049	
Uranium	(U)	-	-		0.024		0.021	
Annual Flow Components (L/s) [4]								
Background Runoff			0	(0)	4	(6)	4	(6)
TMF Pond Discharge			0	(0)	121	(197)	181	(301)
WMP Discharge			0	(0)	56	(93)	56	(93)
Total Flow at Mixing Point			**0**	**(0)**	**181**	**(296)**	**241**	**(400)**

1. Results in this table were generated from model output of a single model realization (Realization #1).
2. Zero discharge of mine derived water into Casino Creek during Operations, and Wetland Construction Phases.
3. Average of months when TMF and WMP water is released to Casino Creek (May to November). Average calculated from all years during each of the TMF Discharge and Pit Discharge Phases.
4. Annual flow components are presented in terms of average annual flow rate (presented without brackets), and average flow rate from May to November when TMF and WMP discharge occur (presented in brackets).

11 Receiving Environment Water Quality Model

Water quality was calculated for select locations downstream from the proposed mine. Selection of water quality prediction points, sources of loading, modelling methodology, and modelling results are presented in the following section.

11.1 Water Quality Prediction Points

All mine sources of loading are expected to report to Dip Creek watershed via Casino Creek. The following receiving environment water quality prediction points were selected:

- **Middle Casino Creek (H18)** – an existing stream flow monitoring station located immediately downstream from the confluence of Casino Creek and Brynelson Creek. The spillway discharge location is planned for approximately 250 m upstream of H18.
- **Lower Casino Creek (W4)** – an existing water quality and stream flow monitoring station located upstream of the confluence with Dip Creek.
- **Middle Dip Creek (W5)** – an existing water quality monitoring station, located a short distance downstream from the confluence of Casino Creek and Dip Creek.

11.2 Baseline (Pre-Mining) Stream Flow

Monthly baseline stream flow (existing conditions) for the water quality prediction points were calculated by KPL (2013a) in the water balance. Table 11-1 represents monthly streamflow averages of all (52) model realizations.

Table 11-1. Baseline Monthly Streamflow Estimates for Local Watercourses

Month	Middle Casino Creek (H18)	Lower Casino Creek (W4)	Middle Dip Creek (W5)
	Monthly Stream Flow (m^3/s)		
Jan	0.056	0.056	0.15
Feb	0.028	0.028	0.07

Sep	0.52	0.60	2.3
Oct	0.34	0.39	1.5
Nov	0.14	0.16	0.56
Dec	0.09	0.09	0.28
Mean Annual	**0.37**	**0.43**	**1.5**
Drainage Basin Area (km^2)	67	82	276
Mean Annual Runoff Depth (mm)	176	165	174

11.3 Post-Mining Streamflow

Water balance output for monthly flow rates in Casino Creek at H18 are presented on Figure 11-1 for a single model realization (Realization #1) to illustrate the expected variation in streamflow through the different mine water management phases. The total flow is broken down into components of background streamflow, and mine derived water entering Casino Creek. A ten year blow-up is included with the figure to illustrate the seasonal range observed within that 10 year period. A 1:10 year wet year and 1:10 dry year is identified on the water quality plot. The wet and dry years are labelled on the figure in terms of hydrologic years, rather than calendar years. Hydrologic year was assumed to run from November 1 to October 31 because precipitation begins to accumulate as snow and ice around the beginning of November.

Water balance output, of annual streamflow following the beginning of mining, are presented Table 11-2. Statistics were generated from the 52 model realizations to show the expected variation in annual flow in Casino and Dip Creeks.

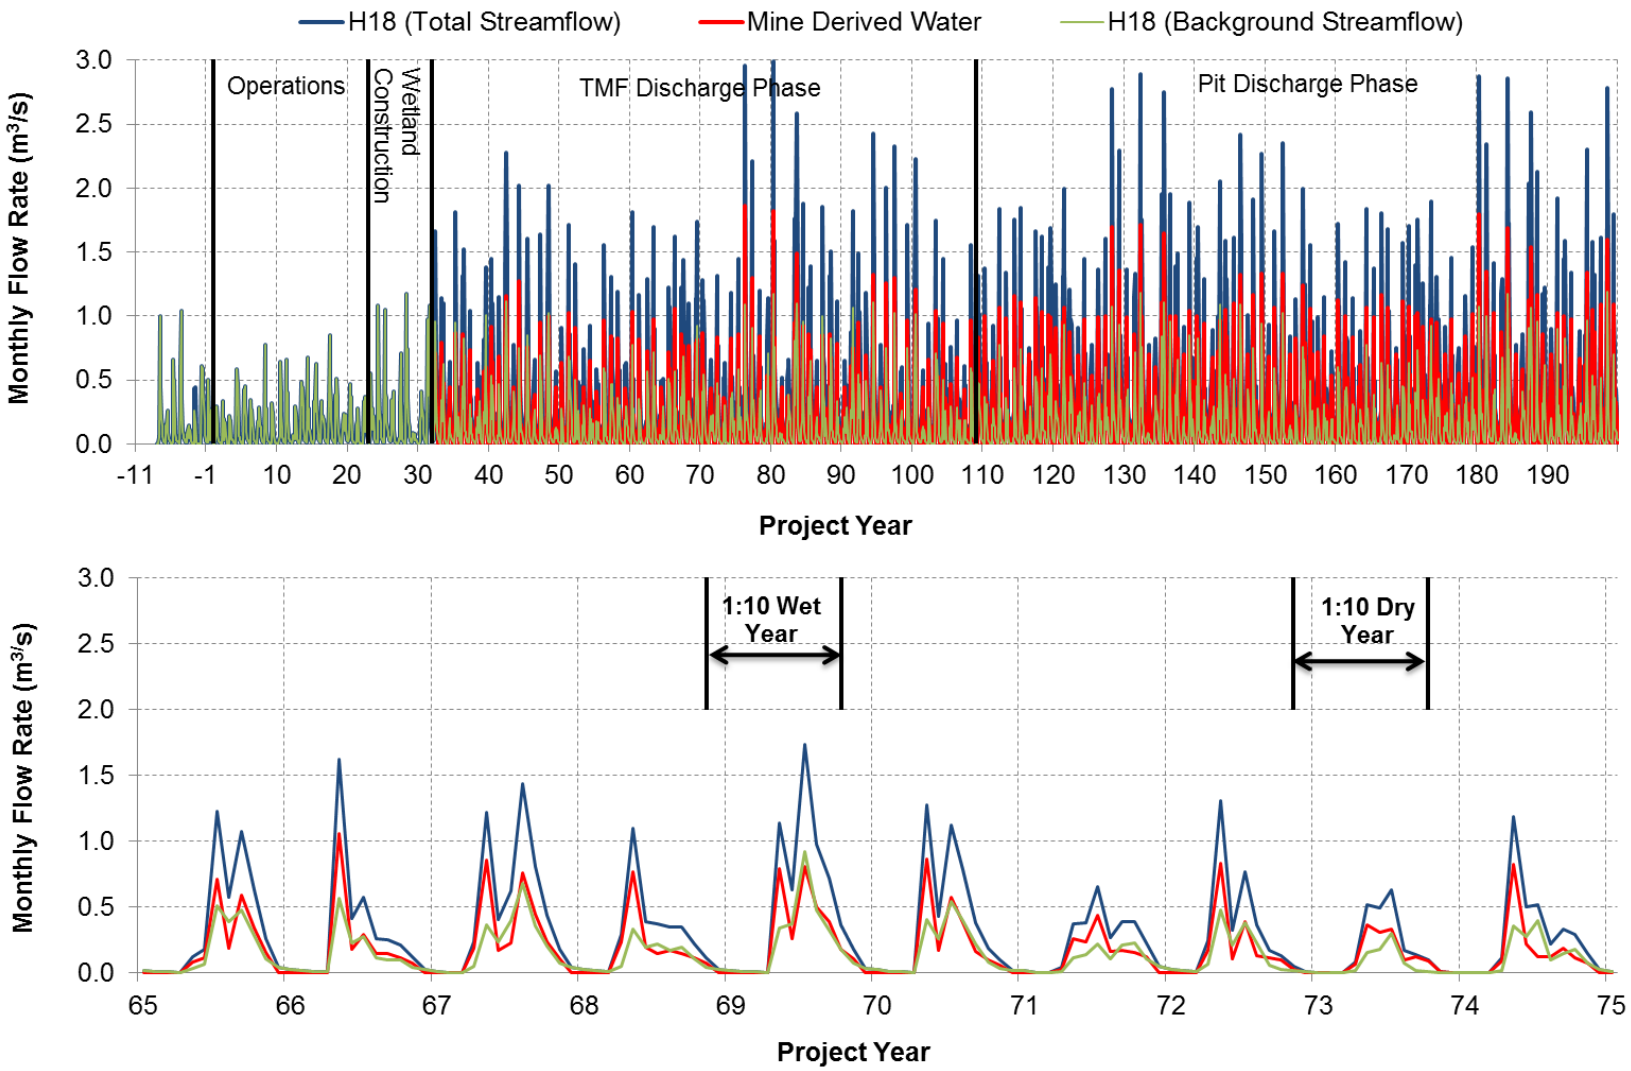

Figure 11-1. Monthly Flow Rate in Casino Creek at H18 (Realization #1)

Table 11-2. Post-Mining Streamflow Estimates for Casino and Dip Creek

	Annual Flow (m^3/s)											
	Operations and and Wetland Construction Phase				TMF Discharge Phase				Pit Discharge Phase			
	P5	P50	Mean	P95	P5	P50	Mean	P95	P5	P50	Mean	P95
H18 (Casino Creek)												
background streamflow	0.06	0.13	0.14	0.23	0.06	0.14	0.14	0.24	0.06	0.14	0.14	0.24
mine derived water	0	0	0	0	0.12	0.16	0.18	0.30	0.17	0.22	0.24	0.37
total streamflow	0.06	0.13	0.14	0.23	0.17	0.29	0.32	0.54	0.22	0.36	0.38	0.61
W4 (Casino Creek)												
background streamflow	0.07	0.18	0.20	0.34	0.07	0.19	0.20	0.35	0.07	0.19	0.20	0.35
mine derived water	0	0	0	0	0.12	0.16	0.18	0.30	0.17	0.22	0.24	0.37
total streamflow	0.07	0.18	0.20	0.34	0.19	0.35	0.38	0.65	0.24	0.41	0.44	0.72
W5 (Middle Dip Creek)												
background streamflow	0.55	1.3	1.3	2.2	0.55	1.3	1.3	2.2	0.54	1.3	1.3	2.2
mine derived water	0	0	0	0	0.12	0.16	0.18	0.30	0.17	0.22	0.24	0.37
total streamflow	0.55	1.3	1.3	2.2	0.67	1.4	1.5	2.5	0.71	1.5	1.5	2.5

1. Annual flow was calculated from 52 realizations of the model.
2. Mine derived flow is the combined discharge from the TMF Pond (via spillway) and WMP discharge.

11.4 Baseline Water Quality

Baseline water quality was grouped by PECG (2013) into winter (November to April) and summer (May to October) seasons. For water quality modelling, SEA subdivided the summer water quality data into two sub-seasons: Spring (May and June), and Summer (July to October). SEA used the seasonal median water quality to represent baseline water quality for modelling. Baseline water quality data are presented for W18 (Table 11-3), W4 (Table 11-4), W9 (Table 11-5), and W5 (Table 11-6). CCME guidelines for the protection of aquatic life are presented beside the water quality data for reference. All values are presented in total metal concentrations, not dissolved.

Table 11-3. Baseline Water Quality at Brynelson Creek (W18)

Water Quality		CCME Guideline (mg/L)	W18 Median Water Quality (mg/L)			
			All Data	Winter	Spring	Summer
Sulphate	(SO_4)	218	23	38	20	20

11.5 Mass Loading Sources

Mass loading of contaminants from mine sources and naturally occurring sources were accounted for in the modelling and are described in the following section.

11.5.1 Mine Sources

Loadings from the mine sources into the receiving environment are expected to change throughout the Project life based on water management systems that are in place at a given time. Calculation of loading from mine sources within the modelling timeframe is described in Section 10.

11.5.2 Background Loading

Naturally occurring loading present in the surface water from non-mining impacted areas was accounted for in the modelling. In this document, this source of mass loading is referred to as "background" loading.

At the proposed Casino mine site, the Upper Casino Creek drainage basin would be altered by mining from the development of the open pit and the construction of the TMF. Station W11 is located at the downstream-most location of the TMF. It was concluded by SEA that all area downstream from station W11 (except for the WMP) would remain essentially unaltered from pre-mining conditions. As a result, all areas downstream from, (i.e. outside of the W11 drainage basin) would contribute background loading to the modelled water quality prediction points.

This report presents background concentrations in total metal concentrations, not dissolved.

11.6 Mass Balance and Water Quality Modelling Equations

A mixing model was developed where the concentration of a given substance at each modelling point was calculated by adding the mass flow rate from each of the incoming loading sources, and dividing by the total volumetric flow rate at that modelling point.

The mass loading rate from each load source was calculated as the product of the concentration and the volumetric flow rate of water, as follows:

$$L = C * Q$$

Where:

- L is the mass loading rate for a given contaminant (mass of substance / time)
- C is the water quality concentration (mass of substance / volume of water); and
- Q is the flow rate of water in the modelled watercourse (volume of water / time)

Mass loading equations that were used to predict water quality in the receiving environment are presented in the following sub-sections for each modelling point.

11.6.1 Casino Creek (H18)

The total loading to H18 was calculated with the following relationship:

$$L_{H18} = L_{MINE} + L_{H18\ (BG)}$$

- L_{H18} total mass loading at H18
- L_{MINE} total mass load from mine derived sources
- $L_{H18\ (BG)}$ background mass loading at H18

Calculation of mine sources of mass loading is described in Section 10. The background loading was calculated as the naturally occurring loading in the stream flow downstream from the TMF, and upstream from the H18 monitoring point. The equation for background loading is as follows:

$$L_{H18\ (BG)} = Q_{H18\ (BG)} * C_{H18\ (BG)}$$

- $Q_{H18\ (BG)}$ background stream flow at H18
- $C_{H18\ (BG)}$ background water quality (concentration) at H18

Background stream flow at H18 was calculated in the water balance model (KP 2013a). Background water quality was assumed to be equal to baseline water quality from Brynelson Creek (W18) monitoring station because W18 makes up approximately 90% of the H18 background drainage basin.

11.6.2 Casino Creek (W4)

The total loading to W4 was calculated with the following relationship:

$$L_{W4} = L_{H18} + L_{W4\ (BG)}$$

L_{W4} total mass loading at W4
$L_{W4\ (BG)}$ background mass loading at W4

The background loading was calculated as the naturally occurring loading in the stream flow downstream from H18, and upstream from the W4 monitoring point. The equation for background loading was calculated as:

$$L_{W4\ (BG)} = Q_{W4\ (BG)} * C_{W4\ (BG)}$$

$Q_{W4\ (BG)}$ background stream flow at W4
$C_{W4\ (BG)}$ background water quality W4

Background stream flow at H18 was calculated as the difference between baseline stream flows station W4 and H18. Background water quality at W4 was assumed to be equal to baseline water quality at W18 because W18 makes up a large portion of the W4 background drainage basin, once the TMF is constructed.

11.6.3 Middle Dip Creek (W5)

Middle Dip Creek (W5) is immediately downstream from the confluence between Casino Creek (at W4) and Dip Creek (at W9). Because the Dip Creek drainage basin at W9 will not be impacted by the casino Project, baseline loading at W9 is combined with the predicted loading at W4, to calculate total mass loading at W5. Water quality predictions for W5 were based on the following mass balance relationship:

$$L_{W5} = L_{W4} + L_{W9\ (BL)}$$
$$L_{W9\ (BL)} = Q_{W9\ (BL)} * C_{W9\ (BL)}$$

L_{W5} predicted mass loading at W5
$L_{W9\ (BL)}$ baseline loading at W9
$Q_{W9\ (BL)}$ baseline stream flow at W9
$C_{W9\ (BL)}$ baseline water quality at W9

11.7 Water Quality Model Results – Single Model Realization

Single model realization results were generated when one permutation (i.e. realization) of the input hydrology dataset was run with the model. Single realization results provide a time-series of model output which shows a representation of water quality that would result from a realistic range in hydrological conditions at the site. The output provides an indication of how high (or low) water quality concentrations may get, and how often those results are expected to occur.

Water quality model results are tabulated in Table 11-7 for the eight parameters that were predicted to exceed CCME guidelines at least once during the model simulation. Water quality results are presented for all modelled parameters in Appendix VI. The predicted water quality was compared to CCME guidelines for all parameters with the exception of sulphate. There is no CCME guideline for sulphate and as a result the BCWQG was used. Hardness based guidelines were derived from median baseline hardness. CCME guidelines have not been defined as the target maximum water quality for the Casino Project; they have been compared to the water quality model results as a point of reference.

Time-series water quality plots are also presented in the following sections. Because there is a large amount of information plotted over the 200 year simulation, a ten year blow-up is included with the figures to illustrate the seasonal range observed within this period. A 1:10 year wet year and 1:10 dry year is identified on the water quality plots.

11.7.1 Casino Creek (H18 and W4)

Time series plots of Casino Creek results are presented for one model realization in Figure 11-2 to Figure 11-9. Water quality at model node H18 and W4 are plotted on the same figures as they are very similar.

The pH in Casino Creek was calculated (using PHREEQC) to be neutral.

Fraction contributing tables are presented for H18 (Table 11-8) to illustrate the relative proportions of mass loading from the TMF Pond, WMP, and background streamflow to the water quality modelling points. Values in Table 11-8 can be considered representative of W4 because there is no other significant source of loading between W4 and H18.

Table 11-7. Annual and Seasonal Water Quality Predictions in the Receiving Environment – Single Model Realization

1. Results presented in this table were generated from model output of a single model realization (Realization #1).
2. Results presented in this table represent average water quality for all years (or seasons) that fall within each phase of mining.
3. Shaded cells are modelled concentrations that exceed the CCME Guidelines for the protection of freshwater aquatic life. Water quality limits have not been established and the CCME guidelines are provided as a point of reference only.
4. BC Water Quality guideline for sulphate was used because CCME guidelines are not available.
5. Water quality guidelines for SO_4, Cd, Cu, Pb, and Ni are hardness dependent. Values presented in this table were calculated using the median baseline hardness of 111 mg/L as $CaCO_3$ (H18 and W4) and 90 mg/L as $CaCO_3$ (W5).

1. Average of all years during each phase, calculated from output from model Realization #1.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded and the total of individual values may not add to exactly 100.

11.7.2 Middle Dip Creek (W5)

Middle Dip Creek (W5) model results for one realization are presented in Figure 11-10 to Figure 11-17 for the eight parameters of interest. Fractions contributing from individual loading sources are presented in Table 11-9.

At W5, there is sufficient dilution that the water quality guidelines are met with the exception of cadmium, copper, fluoride, iron and selenium. For iron, the baseline/background water quality is higher than the predicted water quality. Molybdenum and sulphate guidelines were exceeded infrequently (i.e. about 3 times over the 200 year simulation). For copper, the baseline/ background is generally higher than the predicted post-mining water quality. Cadmium, copper, fluoride and selenium are discussed in more detail in the impact assessment. The pH was determined (using PHREEQC) to be neutral.

Table 11-9. Loading Source Contributions to W5 (TMF and Pit Discharge Phases)

Source of Loading	Fraction Contributing (%)							
	SO_4	F	Cd	Cu	Fe	Mo	Se	U
TMF Discharge Phase

11.8 Water Quality Model Results – Monte-Carlo Summary

The model was run 52 times. Each model run used a unique permutation (i.e. realization) of the input hydrology dataset. The combined output from the 52 model runs represents the range in all possible model outputs resulting from all the possible permutations of the input hydrology dataset. A statistical summary of the model output for the 52 realizations was generated to be used as the basis for the aquatic impact assessment. A summary of the monthly median (50^{th} percentile) water quality results for all modelled parameters is presented in Appendix IV (Table VI-11 to Table VI-13).

12 Summary and Discussion

A site-wide water quality model was developed for the proposed Casino Project. The model simulated water quality in the mine discharge and receiving environment and was based on a climate variability water balance model to account for inter-annual variability in hydrologic conditions. The model was used as a planning tool to help select water quality mitigation systems. This report documents updates to the previous model that was presented in the December 13, 2013 SEA report, with minor modifications resulting from the climate variability model.

The water quality model was developed within the GoldSim modelling platform, and included 27 water quality parameters (i.e. potential contaminants). The model simulation was run for a time period beginning a few years prior to Construction, and continued for 200 years following the beginning of Operations using monthly time steps. A synthetic dataset of monthly weather and hydrologic conditions was developed by KPL and was used as input to the model in order to simulate the natural variability in hydrologic conditions (i.e. wet and dry periods) that can be expected at the site.

Source terms were developed by Lorax (2013) and used as model input to calculate the mass loading rates from mine loading sources.

Geochemical modelling was integrated into the site-wide water quality model by use of dynamic links between GoldSim and PHREEQC software packages. The model nodes where geochemical solubility controls were calculated are as follows:

- Pit Lake;
- TMF pond; and
- WMP.

These nodes are locations where mixing of water streams occurs and solubility controls affect the concentrations of some water quality parameters (such as aluminum, copper and iron). PHREEQC was also used to determine pH in Casino and Dip Creek.

12.1 Water Quality Mitigations

The water quality model results were used as a rationale for the selection of a number of water quality mitigation systems. Initially, copper was used as the contaminant of concern (CoC) for mitigation planning because copper was predicted to exceed water quality targets by orders of magnitude based on the source terms. Once desired copper concentrations were achieved in model results, mitigations were considered for other CoCs including sulphate, fluoride, cyanide, cadmium, molybdenum, selenium, uranium, and iron.

Key Project mitigation plans for the Open Pit are as follows:

- The North TMF wetland was designed to passively treat the Pit Lake discharge. The Pit Lake water quality model results indicated that the discharge will be at tolerable concentrations and pH for successful treatment in the North TMF wetland.

Key project mitigations included in the water quality modeling for the HLF are as follows:

- Following HLF operations, surplus water will be treated and pumped to the Open Pit until the HLF cover is in place by year 29. Treatment will include cyanide destruction and removal of selenium and mercury in a bioreactor. Further cyanide degradation of the HLF discharge will occur as the Open Pit is filled.

- Surplus water will be directed to the Pit Lake following cyanide destruction and selenium and mercury treatment. Following drain-down, the HLF will be re-contoured and covered to promote runoff and minimize infiltration. The soil cover placed over the HLF is expected to reduce seepage from the toe of the HLF to 20% of the total net surplus water.

Key Project mitigation plans for the TMF are as follows:

- The upward migration of groundwater through the submerged waste rock in the TMF is expected to impact the water quality of the TMF Pond water. The South TMF wetland will be in place to passively treat TMF Pond water prior to discharge to Casino Creek.

- TMF pumping to the Pit Lake at closure will lower the water level in the TMF and will create suitable working conditions for the construction of the TMF wetlands.

- The placement of waste rock in the upstream (northern) end of the TMF where there will be minimal loading contribution to the foundation seepage.

The wetland passive treatment systems were designed by Clear Coast Consulting Inc. Passive treatment by the North and South wetlands was modelled as follows:

- The wetlands treat Cd, Cu, Mo, Hg, Ag, Zn to the CCME guideline;

- The wetlands treat SO4 to 85% of the inflow concentration (i.e., 15% removal).

Key Project mitigation plans for seepage water quality management:

- Source control for one of the six ore stockpiles was identified as an appropriate Project mitigation. The groundwater seepage pathway from the southern-most ore pile was estimated to have the greatest potential influence on Casino Creek water quality. As a result, the Project proposal incorporates mitigation (e.g., groundwater seepage collection) to intercept 90% of potentially contaminated stockpile drainage. The collected discharge will be directed to the TMF pond.

- Water collected in the TMF seepage Water Management Pond (WMP) will be pumped back into the TMF Pond until the end of operations. Following Operations, the WMP will be temporarily pumped to the Open Pit until discharge of the TMF Pond commences.

- Following mine closure, the WMP will store winter seepage and release it during the open water season when it will mix with the TMF Pond discharge prior to release to Casino Creek. Mixing the discharges will allow for dilution of the WMP release, especially when there is little-to-no flow expected in Brynelson Creek, a tributary to Casino Creek.

12.2 Results of the Model

Time series model results of a single realization of the model were plotted for the CoCs to illustrate the variability in water quality that can be expected as a result of a realistic range of site hydrologic conditions. For reference, baseline water quality at the Casino Creek and Dip Creek modelling nodes are presented (Section 11) with the predicted water quality and the CCME guideline.

Modelled years corresponding to 1:10-year wet and 1:10-year dry conditions were identified on the water quality output plots for the CoCs to illustrate how water quality can be expected to result from those infrequent events. The results showed that the water bodies on site (Pit Lake, TMF Pond, and WMP) will be able to produce more or less consistent inter-annual water quality in the receiving environment by balancing mine derived water between wet and dry years such that it can be released to the receiving environment when sufficient assimilative capacity is available.

The model results show some exceedances of water quality guidelines in Casino Creek. This list includes sulphate, fluoride, cadmium, copper, iron, molybdenum, selenium, and uranium. At Middle Dip Creek (W5), guidelines were exceeded for fluoride, cadmium, copper, iron, and selenium. For iron, the baseline water quality exceeds guidelines, and is higher than the predicted water quality. Molybdenum and sulphate concentrations were exceeded infrequently (i.e. about 3 times over the 200 year simulation).

Mine discharge water, and the resulting streamflow in Casino and Dip Creeks were predicted (using PHREEQC) to be pH neutral.

13 Closure

This document was prepared by SEA for Casino Mining Corporation. The material in it reflects SEA's judgement in light of the information available to SEA at the time of document preparation. Any use which a third party makes of this document or any reliance on decisions to be based on it is the responsibility of such third parties.

We trust this water quality assessment meets your requirements for the Casino Project. If you have any questions, please contact the undersigned.

Yours truly,

1 Introduction

The Casino Project (the Project) is a proposed mining project in the west-central Yukon. The deposit will be mined using open pit methods, with a nominal mill throughput of approximately 120,000 tonnes/day of ore over a 22 year operating life. Milling operations will produce molybdenum and copper concentrates through conventional flotation circuit milling and gold and silver doré will be produced by cyanide heap leaching.

The open pit will be up to 600 m deep and up to 2400 m wide when finished. After mining, dewatering of the open pit will cease and a Pit Lake will form by groundwater recharge, overland runoff, and direct precipitation on the water surface. During mine decommissioning, any unused ore present in the stockpiles will be placed in the pit. Surplus water from the Water Management Pond (WMP), Tailings Management Facility (TMF) Pond, and Heap Leach Facility (HLF) will be temporarily pumped to the Open Pit to mitigate water quality concerns for Casino and Dip Creeks.

A water quality model was developed to predict mine drainage water quality and the potential for effects on the receiving environment of the proposed Casino Mine. A site-wide water balance was developed by Knight Piésold Limited (KPL) and was used by Source Environmental Associates Inc. (SEA) as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim.

A water balance model was initially developed by KPL in 2013 (and is described in KP. 2013a). The 2013 water balance was run using average annual estimates for hydrologic conditions at the site. Water quality modelling for the average annual water balance was carried out by SEA. Modelling methodology and results were reported in SEA (2013).

In 2014, a climate variability water balance model was developed by KPL (and is described in KPL, 2015) to account for the expected variability in hydrological conditions (i.e. wet and dry periods) from year to year. SEA used the climate variability water balance as the basis for the water quality model that is described herein.

This report presents the methodology and results of the water quality predictions for the Pit Lake model. This report contains all information relevant to the water quality model, and repeats the pertinent information previously provided in the December 2013 report (SEA, 2013). A comparison between the SEA (2013) Pit Lake water quality modelling report and this report is provided in Table 1-1.

Table 1-1. Comparison between 2013 and 2015 Modelling Reports

Concept	SEA (2013) Report	Applies to this Report
Water Balance Input Dataset	Average monthly hydrologic conditions (e.g. precipitation, temperature, streamflow, etc.) were used as input for every year of the model simulation.	Inter-annual variation in hydrologic conditions was applied throughout the model simulation. Water balance output flows were calculated from a synthetic, long-term (52 year) input dataset of monthly hydrologic conditions. The synthetic dataset was derived from regional and site data. **Rationale:** Using the range of monthly flows is more conservative (compared to using average annual flows) because realistic wet and dry periods can be simulated.
Estimation of Wet and Dry Years	n/a - wet and dry years were not simulated.	1-in-10 year wet and dry years were identified in the water quality output time-series plots. **Rationale:** To illustrate how the water quality management system will perform as a results of infrequent wet/dry periods.
Monte-Carlo Analysis (Stochastic Modelling)	Stochastic modelling was not carried out.	Model simulations included 52 unique input hydrology datasets. A statistical summary was generated from the water quality model output for the 52 realizations. **Rationale:** To account for all possible water balance flow scenarios that could result from the input hydrology dataset.
Project Phase Start Dates for TMF Discharge Phase and Pit Discharge Phase	Project dates were based on KPL (2013) water balance model output.	Project dates were based on KPL (2015) water balance model results.
WMP Pumping to the Open Pit (Wetland Construction Phase)	During the Wetland Construction Phase, the WMP was assumed to be pumped to and mixed with the TMF Pond.	During the wetland construction phase, the WMP will be pumped to the Open Pit. **Rationale:** Mass load from the WMP by-passes the TMF Pond by pumping directly to the Open Pit.

Concept	SEA (2013) Report	Applies to this Report
Pit Water Quality PHREEQC Input Assumptions	Assumption was that all available NP in the pit walls was released during submergence and fully mixed in the pit. This results in neutral pH and low copper concentration (~0.4 mg/L).	Assumption is that the available NP in the pit walls will be a source of buffering. Only the NP required for buffering is released. This change in the assumptions resulted in a predicted Pit Lake pH of about pH 6.2 and higher copper concentrations (about 5 mg/L rather than 0.4 mg/L). **Rationale:** The updated assumption used in 2015 is more conservative because not all the NP in the wall rock will be released and mixed with the pit lake during initial submergence of wall rock.
CoC List	7 CoCs were reported. The CoC list did not include fluoride.	Fluoride was added as a CoC, so 8 CoCs are reported. **Rationale**: Fluoride was added as it exceeded a generic water quality guideline in Casino and Dip Creeks.

2 Casino Project Water Management Phases

The Casino Project life was sub-divided into five water management phases (Table 2-1) in this document. Project years are described in years relative to the beginning of milling operations. For example, Year -2 refers to the second year before Operations begins, and Year 2 refers to the second year of Operations. Relevant project activities related to water quality modeling are provided in Table 2-1.

Table 2-1. Water Management Phases

Water Management Phase	Project Year	Water Management Activities
Construction	-4 to -1	• overburden stripping • mining and stockpiling of ore
Operations	1 to 22	• Final year of Open Pit Mining, year 18 • Final year of milling, year 22 • Dewatering from Open Pit will be pumped to mill to be used as make up water until end of Year 18. • Beginning in Year 19, dewatering will be discontinued, and the Open Pit will be allowed to fill with water by groundwater recharge, overland runoff, and direct precipitation. Pit Lake will begin to form. • Beginning Year 19, Surplus HLF ore rinsing water will be pumped to the Pit Lake.
Wetland Construction	23 to 34	• Any unprocessed ore will be placed in the Open Pit. • Construction of the North TMF Wetland that will eventually be used for treatment of the discharge from the Pit Lake. • WMP water will be pumped to the Open Pit • Year 24 to Year 28 – HLF drain down water pumped to Pit Lake • Year 23 to Year 27 – TMF Pond water will be pumped to Pit Lake • Year 28 to 34 – TMF fills with natural recharge
TMF Pond Discharge	35 to 109	• TMF Pond will discharge to Casino Creek via South TMF Wetland • No changes to Pit Lake water management
Pit Lake Discharge	>109	• Pit Lake will discharge to the North TMF Wetland treatment system. Treated effluent from the wetland will discharge to the TMF Pond.

3 Model Overview

A site-wide water balance model was developed by KPL and was used as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim. SEA combined the water balance flows with mine loading source terms (Lorax, 2013), and background water quality to predict water quality in the Pit Lake for 27 water quality parameters. A schematic showing the mass transport flow paths through the Pit Lake system is presented in Figure 3-1.

A 52-year model input dataset of monthly weather conditions was developed by KPL in order to simulate the natural variability in hydrologic conditions (i.e. wet and dry periods) that can be expected at the site. The model was run over a time-frame from beginning of Pit Lake formation, to 200 years after the beginning of Operations. Because the model was run over a simulation period of ~200 years, the 52-year input dataset repeats approximately four times during a given simulation.

The model results are presented in two ways in this report:

1) Single Model Realization

   Results generated when one realization of the input hydrology dataset was run with the model. Single realization results provide a time-series of model output which shows a representation of water quality that would result from a realistic range in hydrological conditions at the site. The output provides an indication of how high (or low) water quality concentrations may get, and how often those results are expected to occur. Time-series plots and summary tables of water quality results for a single realization are presented throughout this report.

2) Monte-Carlo Summary (52 Realizations)

   The model was run 52 times. Each model run used a unique input hydrology dataset. The combined output from the 52 model runs (i.e. realizations) represents the range in all possible model outputs resulting from all the possible permutations of the input hydrology dataset. Average annual water balance results presented in this report were generated from the Monte-Carlo Summary results.

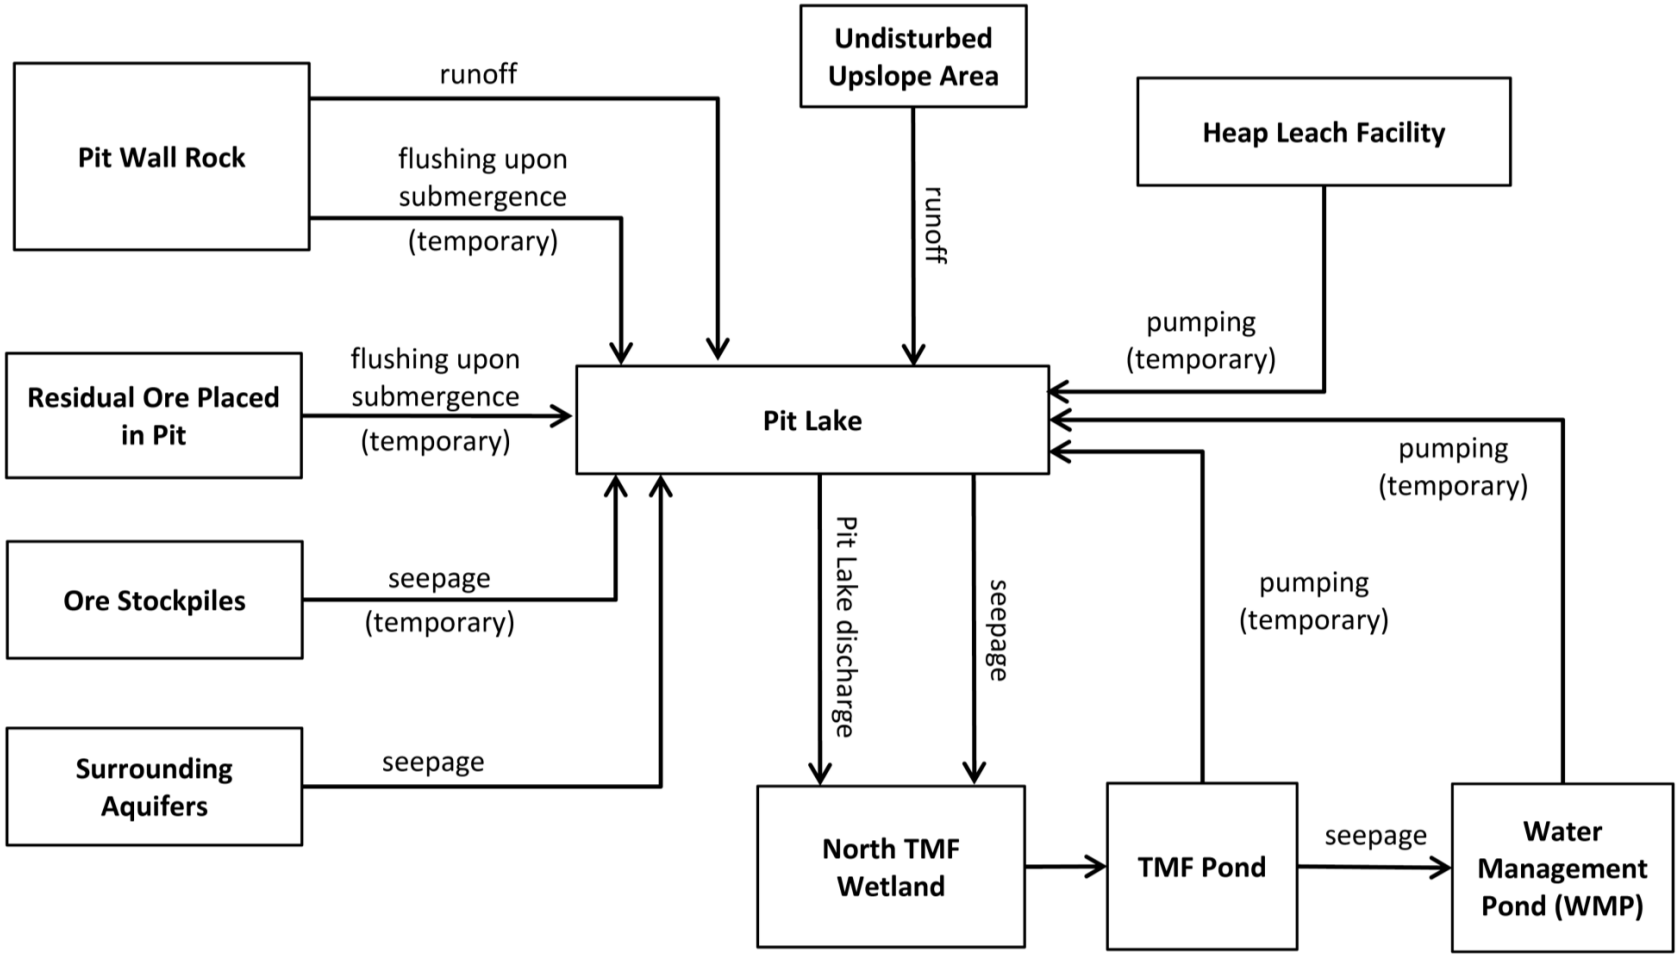

Figure 3-1. Mass Transport Flow Paths through the Post-Closure Pit Lake System

4 Pit Lake Water Balance Model

The KPL (2015) water balance model was developed to estimate the Pit Lake inflow and outflow rates, and the time required for the Pit Lake to fill and overflow. The following characeristics of the Open Pit were provided to SEA from KPL:

- maximum storage capacity of the pit = 280 Mm^3
- maximum water surface elevation of the Pit Lake = 1095 m
- total planar area of exposed pit walls (Pit Lake empty) = 3.14 km^2
- total planar area of exposed pit walls (Pit Lake full) = 1.16 km^2
- final planar area of the Pit Lake = 1.98 km^2

As the Pit Lake fills with water, the total water volume and surface area of water stored within the Pit Lake will vary. Pit Lake water surface elevation versus storage capacity and surface area (Figure 4-1) were provided to SEA by KPL with their Goldsim water balance model.

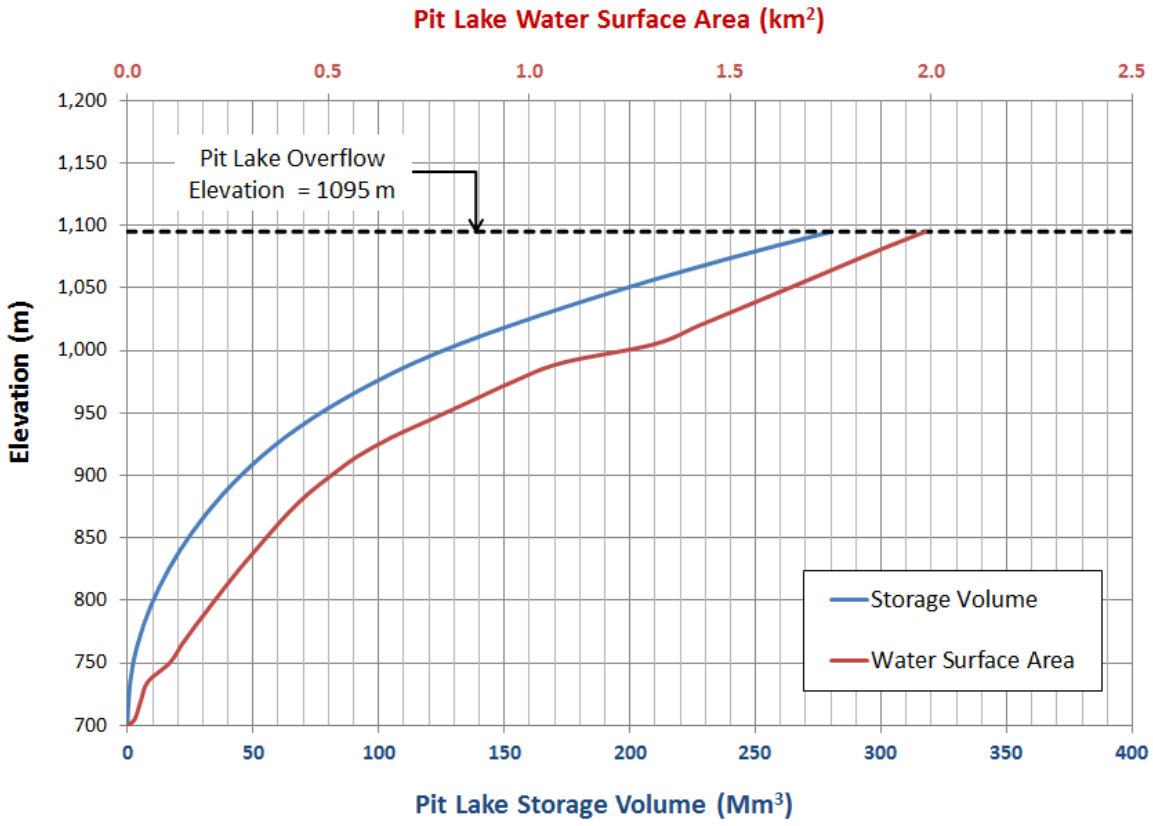

Figure 4-1. Pit Storage-Elevation and Area-Elevation Curves

The 52 realizations of the water balance (KPL, 2015) simulation showed that the Pit will likely fill to its storage capacity and discharge to the North Wetland between Year 105 and Year 110. KPL established Year 109 as the best estimate of the beginning of the Pit Discharge Phase. A summary of annual Pit Lake inflows and outflows from the 52 model realizations are presented in Table 4-1 for each water management phase. Some description of the water balance flows are provided in Section 5 as they are related to the development of the Pit Lake mass balance and water quality model.

Table 4-1. Pit Lake Water Balance Model Results

	Average Annual Discharge (L/s)		
	Wetland Construction Phase	TMF Discharge Phase	Pit Discharge Phase
INFLOWS			
Precipitation on Lake Surface	14	26	31
Groundwater Seepage	18	14	12
Ore Stokcpile Seepage	< 1	0	0
Pit Wall Runoff	28	18	15
Upslope Overland Runoff	35	35	36
Pumping from WMP	52	0	0
Pumping from TMF Pond	0 to 336 [2]	0	0
Pumping from the HLF	0 to 33 [3]	0	0
Total Inflow	123 to 522 [4]	93	95
OUTFLOWS			
Evaporation	11	21	24
Groundwater Seepage	0	7	11
Pit Lake Discharge	0	0	60
Total Outflow	11	28	95
Net (Inflow - Outflow)	112 to 511 [4]	65	0

1. Flow rates reported in this table are average results from 52 model realizations over the duration of each water management phase.
2. Constant pumping rate of 336 L/s for Year 23 to 27. Pumping ceases in Year 28 and beyond.
3. Constant pumping rate of 33 L/s for Year 24 to 28. Pumping ceases in Year 29 and beyond.
4. Range of inflow, resulting from temporary pumping from TMF and HLF.

According to the *Conceptual Reclamation and Closure Plan* (BCL, 2013), the total annual Pit Lake overflow volume will be discharged to the TMF wetland at a controlled rate during the warmest months of the year (June through September, inclusive) for optimal operation of the TMF wetland treatment system. KPL (2015) modelled the discharge as a flow of approximately 180 l/s over the four month period.

5 Pit Lake Water Quality Model

A mixing model was developed to predict water quality for 27 water quality parameters in the Pit Lake as it fills and eventually discharges to the North TMF Wetland treatment system. Water balance flows (from KPL) were combined with mine loading source terms (from Lorax, 2013) and background water quality (from SEA) to predict mass loading rates of inflow and outflow of potential contaminants in the Pit Lake water. This section provides a summary of the Pit Lake water quality modelling methodology.

Tables of model input and output values are provided for each modelled water quality parameter in Appendix I - A (model input) and Appendix I - B (model results).

5.1 Mass Load Inflows

5.1.1 Precipitation

The monthly inflow of precipitation into the Pit Lake was calculated as the top surface area of the Pit Lake, multiplied by the monthly depth of precipitation. The Pit Lake surface area varied from 0 km^2 (immediately following mine closure), to 1.98 km^2 (when the Pit Lake level was at its maximum elevation of 1095 m). As a result, the inflow of precipitation to the Pit Lake water surface varied during the period of time when the Pit Lake was filling. Average annual inflow to the final Pit Lake from the KPL (2015) water balance model is provided in Table 4-1.

While precipitation was accounted for in the water balance, no load was associated with precipitation in the water quality model.

5.1.2 Background Runoff

Runoff from the upslope undisturbed area was calculated as the monthly surplus water multiplied by drainage area. Annual surplus water was calculated by KPL (2015) to be 150 mm (average of all model realizations). The final pit will intercept runoff from approximately 6.8 km^2, and 0.6 km^2 of undisturbed areas within the Canadian Creek, and Casino Creek drainage basins, respectively (total area of 7.4 km^2).

The mass loading rate into the Pit Lake from overland runoff was calculated as the monthly rate of overland runoff inflow, multiplied by the monthly water quality concentrations of the overland runoff.

A total of 18 water quality samples were collected at the Upper Canadian Creek (W7) monitoring station between 2008 and 2012 (PECG, 2013). The median value of all water quality samples from station W7 (Appendix I - A, Table I-A1) was used to represent average annual

overland runoff water quality draining to the Pit Lake from undisturbed areas surrounding the perimeter of the pit.

5.1.3 Background Groundwater

KPL (2015) calculated the groundwater inflow into the pit from the surrounding upslope groundwater catchments to be 33 l/s at the end of operations and 12 l/s once the pit reaches its maximum Pit Lake elevation (1095 m). In the KPL water balance model, groundwater inflow decreased linearly from 33 l/s to 12 l/s proportionally to water surface elevation in the pit as the Pit Lake water surface elevation varied from 700 m (Pit Lake empty) to 1095 m (Pit Lake full).

The load contributions to the Pit Lake from background groundwater were calculated as the monthly rate of groundwater inflow, multiplied by the estimated groundwater inflow water quality. The *2012 Baseline Hydrogeology Report* (KPL, 2013b) provides groundwater monitoring station information and water quality analysis results. Median water quality from each of the monitoring wells in the vicinity of the Open Pit (94-337, HG10-01, HG10-02, HG10-04, HG10-07) were combined by SEA to represent average annual water quality of the groundwater entering the Pit Lake. The representative background groundwater water quality that was used by SEA in the water quality modelling is provided in Appendix I - A (Table I-A1).

5.1.4 Seepage from Ore Stockpiles

While the ore stockpiles are present during Operations, contact water (from rainfall and snowmelt) will drain from the rock as runoff or infiltration to groundwater. Runoff from the stockpiles will be captured by the TMF Pond. Hydrogeological modelling (KPL, 2013c) indicated that depending on the stockpile location, infiltrated contact water will flow towards either the TMF Pond or the Open Pit and seepage from the Hypogene Low Grade Ore, Supergene Sulphide Low Grade Ore, and Marginal Grade Ore Stockpile would continue to flow into the Open Pit for a few years after the Pit Lake begins to form (i.e. after Year 19).

Seepage concentrations into the Open Pit Lake were calculated by combining the seepage flow rates with mass loading rates, and mass of rock in the stockpiles. Calculation methodology of stockpile mass loading to the Open Pit is described in Appendix II (Ore Stockpile Water Quality Modelling).

5.1.5 Pit Wall Runoff

Pit wall runoff for a given time-step was calculated as the monthly surplus water multiplied by the planar area of un-submerged pit walls. The planar area of un-submerged pit wall decreased incrementally from the maximum value (immediately following closure) to the minimum value (at final Pit Lake level) in each monthly time-step as the Pit Lake surface elevation increased and submerged the wall rock.

Fracturing of open pit mine walls due to blasting exposes the wall rock to the process of weathering. The fractured rock can be expected to contribute mass loading into the Pit Lake following mine closure. Source terms were developed by Lorax (2013) for each of mineralization zones that are expected to be exposed on the Casino pit wall, including: Oxide Cap (CAP), Supergene (SUP), and Hypogene (HYP).

The estimated planar areas of each mineralization zone were provided by Lorax (2013) and were subdivided into pit wall areas above and below the ultimate pit water surface elevation of 1095 m. The values used in the model are given in Table 5-1.

Table 5-1. Pit Wall Planar Area by Mineralization Zone

Mineralization Zone	Planar (Horizontal Projection) Area (m^2)		
	Below 1095 m Elevation	Above 1095 m Elevation	Total
Hypogene (HYP)	1,900,064	351,665	2,251,729
Supergene (SUP)	65,496	493,435	558,931
Oxide Cap (CAP)	0	320,340	320,340
Total	**1,965,560**	**1,165,440**	**3,131,000**

After Lorax (2013)

Lorax (2013) provided a derivation of geochemical source terms for the exposed Casino pit wall rock. The source terms were developed by scaling loading rates measured in laboratory-based kinetic tests (unsaturated columns and standard humidity cells) to field conditions. Average annual source term loading rates were provided based on a horizontal planar 1 m^2 unit area of exposed pit wall to allow for the terms to be applied in a dynamic water quality prediction model with time integrated wall exposures. Loading rates are presented in Appendix I – A (Table I-A2).

Results of acid-base accounting (ABA) analyses by Lorax indicated that a large portion of the SUP and HYP zones are potentially acid generating (PAG). Therefore, both acidic and neutral source terms were provided for the HYP and SUP mineralization zones in addition to the single CAP source term.

The rate at which the HYP and SUP pit wall rock acidifies will influence the Pit Lake chemistry. Weathering rates observed in neutral pH humidity cells were used by Lorax to estimate NP depletion rates and predict time until acidification. Lorax (2013) developed the following relationships to estimate the proportion of acidic and neutral pit wall for 200 years following initial exposure of the pit wall rock (t is in years):

$$\text{Fraction NP Depletion (HYP)} = 0.00258t + 0.08$$

$$\text{Fraction NP Depletion (SUP)} = -1.31\times10^{-9}\,t^4 + 6.24\times10^{-7}\,t^3 - 1.04\times10^{-4}\,t^2 + 0.00838t + 0.45$$

Figure 5-1 illustrates the component parts of acidic and neutral wall rock that were calculated using the equations (from Lorax) for the duration of the model simulation. Beyond the model simulation time frame, a portion of supergene and hypogene wall rock will remain neutral even after long-term exposure.

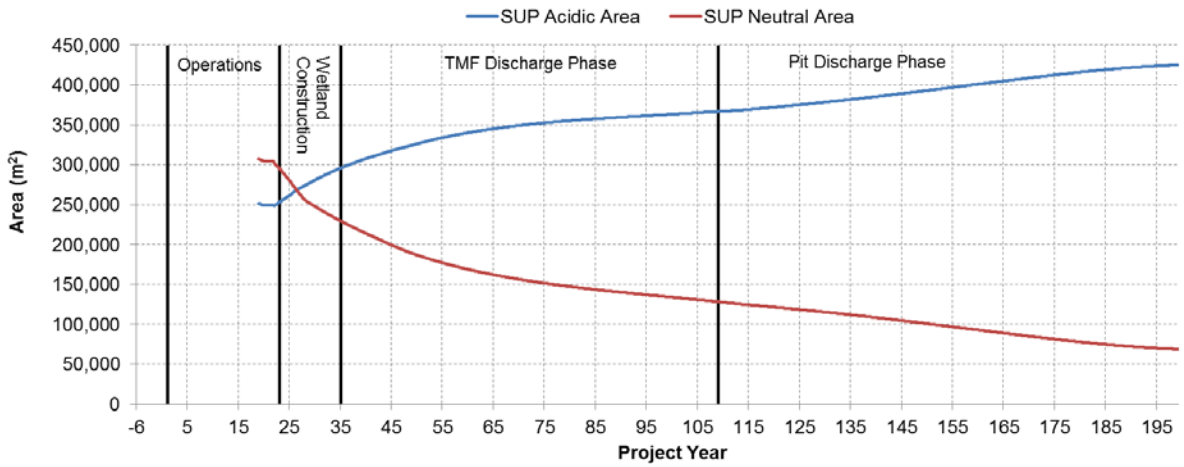

Figure 5-1. Areas of Supergene Acidic and Supergene Neutral wall rock in the Pit Wall with time

5.1.6 Pit Wall Rock Submergence

Pit wall runoff can be expected to travel along preferential flow paths through the fractures of the pit wall rock. As a result, a portion of the oxidation products that form on the walls would not be regularly flushed from those poorly drained portions of the wall rock surfaces. However, as the Pit Lake elevation rises and submerges the wall rock, those built-up oxidation products could be flushed into the Pit Lake. Lorax (2013) derived source terms to account for the build-up and flushing of oxidation products from the wall rock as follows:

$$L = m / (A * t)$$

Where:

L is the wall rock build-up source term (mg/m^2/year)
m is mass of oxidation products built up on the wall rock (mg);
A is the planar area of exposed wall rock (m^2); and
t is the length of time the wall rock is exposed to the atmosphere (years).

The wall rock build-up source term values derived by Lorax are presented in Appendix I-A (Table I-A2) of this document.

In a given time step of the model, the mass of built-up substance flushed from wall rock into the Pit Lake were calculated as the product between the wall rock flushing source term (in $mg/m^2/year$), planar area of wall rock submerged during that time step (m^2), and the duration (years) the wall rock was exposed to the atmosphere prior to submergence. The model conservatively assumes that all of the accumulated oxidation product could dissolve in to the pit lake during the timestep when the rock becomes flooded.

In order to assess the time of exposure at the time of wall rock submergence, the pit shell was sub-divided into elevation bands of equal exposure times (from the time they were mined) at the end of open pit mining. The higher elevations have a longer exposure time than the lower elevation bands that were mined out last. Table 5-2 shows a breakdown of the incremental exposure times that were assumed by SEA.

Table 5-2. Time of Exposure of Pit Wall Rock at the End of Mining

Elevation Band	Incremental Average Wall Rock Exposure Time (yr)
700 m – 800 m	1
800 m – 900 m	2
900 m – 1000 m	6
1000 m – 1050 m	11
1050 m – 1095 m	16
> 1095 m	20

The modelling approach used to estimate the geochemical effect of the mine walls on the Pit Lake water quality generally follows *The Minewall Approach*, developed as a formal standardized technique for the MEND program, which is documented by Morin and Hutt (2004). As the Pit Lake level rises, all wall rock below the water surface is submerged, and loading ceases for that submerged portion of the wall rock. The total planar area of un-submerged wall rock was calculated for each model time-step. From that, the relative proportions of acidic and neutral un-submerged wall rock were calculated, and their respective loading rates into the Pit Lake were applied.

The total exposure time for a submerged band of wall rock was calculated as the average wall rock exposure time prior to the start of pit filling (i.e., during mining) (Table 5-2), plus the number of years that elapsed after the Pit Lake filling began and until submergence of that elevation band of wall rock.

5.1.7 Flushing from LGO Placed in Open Pit

It was assumed that following mining, 5% of the low grade ore and 100% of the Marginal Ore Stockpile would be backfilled into the pit. The Gold Ore and Supergene Oxide Ore were assumed to be processed completely. Table 5-3 shows the total ore masses, and estimated

mass of each pile that was assumed by SEA to be placed in the Pit Lake after mining. The total mass of gold ore was incorrectly reported in the SEA (2013) report as 35,000,000 tonnes. The corrected value is presented in Table 5-3. The discrepancy was the result of a typographical error in the report and did not result in any error in the 2013 modelling results.

Table 5-3. Summary of Ore Stockpiles Placed in the Open Pit

Stockpile	Mass (tonnes)	
	Total Ore to Pile	Unused Ore Placed in Pit
Gold Ore	56,674,000	0
Supergene Oxide Ore	32,410,000	0
Supergene Oxide LGO	14,043,000	702,150
Supergene Sulphide LGO	39,351,000	1,967,550
Hypogene LGO	90,433,000	4,521,650
Marginal Ore	8,837,100	8,837,100
Total	**241,748,100**	**16,028,450**

In KPL's water balance, a specific gravity of 2.8 was assumed for ore for displacing volume in the pit water balance. The total volume of ore in the Pit Lake would account for a reduction in available water storage volume of 5.7 Mm^3.

When the ore is placed in the Open Pit, the built-up oxidation products from the rock surfaces could be flushed into the Pit Lake. Lorax (2013) estimated the loading from each ore type going to the Pit Lake (Appendix I-A, Table I – A2).

5.1.8 Pumping from the TMF

Water in the TMF pond will be pumped to the Open Pit from Year 23 to Year 27 at an average pumping rate of 336 L/s (total volume of 53 Mm^3) to lower the TMF Pond level and create suitable working conditions for the construction of the TMF wetlands and TMF closure spillway. Pumping to the Open Pit will also help fill the pit faster.

Mass transport from the TMF Pond was calculated as the concentration in the TMF Pond, multipled by the pumping rate over a given time-step. Water quality of the TMF Pond water was calculated by SEA in the water quality model. Development of the TMF Pond model is described in Appendix IV (TMF Pond Water Quality). Average TMF Pond water quality over the five year duration of pumping to the Open Pit is provided in Appendix I - A (Table IA-1).

5.1.9 Pumping from the Heap Leach Facility

Closure of the facility will begin by rinsing (Year 19 to Year 23) and drain down (Year 24 to Year 28). Surplus water will be directed to the Pit Lake, after treatment for cyanide destruction and removal of selenium and mercury (Clear Coast Consulting, 2013).

KPL estimated that the rinsing will take place from Year 19 to Year 23 with an average annual pumping rate of 1.6 L/s to the Pit Lake from the HLF. Draindown was estimated to take place from Year 24 to Year 28 at an average flow rate of 33 L/s. After drain down (Year 29 and beyond), pumping to the Pit Lake will stop, and drainage from the HLF will be directed down slope to the TMF Pond.

Mass transport from the HLF to the Pit Lake was calculated as the concentration in pumped surplus water, multiplied by the pumping rate over a given time-step. Water quality of the rinsing and drain down water was estimated by Lorax (2013) prior to treatment and is summarized in Appendix I - A (Table IA-1). Following treatment, the selenium and mercury levels are reduced to 0.02 mg/L and 0.00026 mg/L, respectively. This mitigation was designed to reduce selenium levels in the North TMF wetland (Clear Coast Consulting, 2013).

5.1.10 Pumping from the Water Management Pond

During the Wetland Construction Phase (Year 23 to 34), water collected in the WMP will be pumped directly to the Open Pit. The WMP water quality will be a function of background overland runoff, TMF embankment runoff, TMF embankment seepage and TMF foundation seepage. Prediction of the WMP water quality is described in Appendix V. Water quality of the WMP water pumped to the Open Pit is summarized in Appendix I – A (Table IA-1).

5.2 Mass Load Outflow

5.2.1 Evaporation

The monthly outflow from the Pit Lake due to evaporation was calculated as the top surface area of the Pit Lake for a given time-step, multiplied by the monthly depth of evaporation. Average annual lake evaporation was estimated by KPL (2015) to be 390 mm.

While evaporation was accounted for in the water balance, no load was associated with evaporation in the water quality model.

5.2.2 Groundwater

KPL (2015) estimated the net groundwater outflow from the pit to the surrounding down gradient catchments would be 0 l/s before the pit level reached the tailings pond elevation of approximately 990 m and would increase to about 11 l/s by the time the pit reaches its maximum Pit Lake elevation (approximately 1095 m).

The rate of mass transport exiting the Pit Lake for a given time-step was calculated as the concentration in the Pit Lake, multipled by the groundwater outflow rate.

5.2.3 Pit Lake Discharge

After the pit fills to its maximum storage capacity, surplus Pit Lake water will be released into the TMF where it will initially flow through the North TMF Wetland treatment system prior to discharge to the main TMF Pond. On an annual basis, the total volume of overflow would equal the total Pit Lake inflow volume, minus evaporation and seepage losses. The pit discharge will be regulated such that flow will only occur during the open water season when the North TMF Wetland is the most biologically productive. KPL predicted that for average annual conditions, the Pit Lake would be released at an average rate of 180 L/s over a four month period in the summer.

The rate of mass transport exiting the Pit Lake discharge for a given time-step was calculated as the concentration in the Pit Lake, multipled by the rate of release of Pit Lake water.

5.3 Calculation of Pit Lake Water Quality

Water quality in the Pit Lake was calculated in Goldsim with a “cell pathway” modelling component. The Pit Lake mixing model output concentrations were assessed for solubility controls at each time step of the model simulation by coupling GoldSim and PHREEQC. PHREEQC is a geochemical modelling software developed by the United States Geological Survey. To accurately predict pH, all water quality inputs to PHREEQC were charge balanced, and the residual balance was placed on either chloride or sodium. During each timestep, Goldsim ran PHREEQC and the resulting concentrations were returned from PHREEQC. The calculated water quality from PHREEQC at each time step became the input concentration to the North TMF wetland. The assumptions used in the PHREEQC pit lake model are listed in Table 5-4.

Additional available NP is associated with submerged rock, and was conservatively based on equations developed by Lorax (2013) for HYP wall rock and SUP wall rock. For modelling purposes, it was assumed that available NP was consumed to maintain near neutral pH conditions within the Pit Lake. The amount of remaining wall rock NP was calculated at each time-step.

Full mixing throughout the water column was assumed, such that geochemical conditions would be the same throughout the pit. This is considered to be a worst case assumption. Typically, pit lake stratification results from the denser water near the bottom of the pit lake having the worse water quality and the lighter overlying water near the lake discharge elevation having better quality water. Assuming fully-mixed conditions is typically considered a conservative assumption.

Table 5-4. PHREEQC Assumptions used in the Pit Lake Model

PHREEQC Input Assumptions	
Equilibrium Phases (minerals form solid phase - precipitate forms at some point during the simulation)	$Fe(OH)_3(a)$, $Al(OH)_3(a)$, Jarosite ($KFe^{3+}{}_3(OH)_6(SO_4)_2$) Malachite ($Cu_2CO_3(OH)_2$),
Equilibrium Phases (no mineral formation)	$Cd(OH)_2(a)$, $Cu(OH)_2$, $CuCO_3$, $Zn(OH)_2$, $ZnCO_3$:H_2O, Alunite ($KAl_3(SO_4)_2(OH)_6$) Gypsum ($CaSO_4$)$2H_20$, Otavite ($CdCO_3$), Smithsonite ($ZnCO_3$), Tenorite (CuO),
Database	wateq4f
pH	Charge balance (PHREEQC determines pH of solution and alkalinity)
PE	14 (oxidizing)
Temperature	5^0C
Oxygen	Atmospheric conditions
CO_2	pCO_2 = -2
Stratification	Full mixing throughout the water column was assumed, such that geochemical conditions would be the same throughout the pit.

6 Results and Discussion

6.1 Water Quality Predictions

Annual water quality in the Pit Lake is provided for select parameters in Table 6-1 for intial discharge of the Pit Lake (Year 109) to the North TMF wetland, and long-term conditions (Year 200). Model output concentrations for all modelled water quality parameters are provided in Appendix I - B.

Table 6-1. Pit Lake Water Quality Model Results

Water Quality		Pit Lake Water Quality (mg/L)	
		Initial Pit Lake Discharge (Year 109)	Long-Term (Year 200)
pH		6.2	6.2
Sulphate	(SO_4)	504	368
Fluoride	(F)	1.2	0.88
Cadmium	(Cd)	0.0038	0.0035
Copper	(Cu)	5.0	4.9
Iron	(Fe)	0.00090	0.00089
Molybdenum	(Mo)	0.19	0.10
Selenium	(Se)	0.0084	0.0052
Uranium	(U)	0.060	0.054

Time-series plots of Pit Lake water quality model output concentrations are provided for select parameters (Figure 6-1 to Figure 6-8) to illustrate water quality variations over the duration of the model simulation. Negligable inter-annual variation in pit lake water quality occurred as a result of dry and wet hydrologic conditions because the pit lake is a very large storage reservoir and fluctuations in water and mass loading will be attenuated.

6.2 Post Closure Pit Lake pH

The PHREEQC results (Figure 6-9) show a near neutral pH over the duration of the simulation. There is excess NP in the hypogene wall rock that will be a source of buffering for the Pit Lake water.

Results presented in the SEA (2013) report were generated under the assumption that all available NP in the pit walls would be released during initial submergence of the wall rock, and would become fully mixed with the Pit Lake water at that time. The resulting model output was neutral pH (~pH 7.1 to pH 7.2) water and low copper (~0.4 mg/L). However, not all of the NP can be expected to be released from the wall rock upon initial submergence. The assumption was conservatively revised in this assessment, such that only the NP required for buffering will be released from the submerged wall rock. This results in a Pit Lake pH of about pH 6.2 (pH 6.0 to pH 6.5) with higher copper concentrations (~5 mg/L).

Furthermore, in both the 2013 and 2015 simulations, the pit lake was assumed to be supersaturated with CO_2, shown in Table 5-4 (pCO_2= -2), instead of atmospheric (pCO_2 = -3.45). Superstation of CO_2 results in a slightly higher concentration in copper than would result from atmospheric conditions.

6.3 Natural Degradation of Cyanide

HLF operations were assumed to be complete in Year 19. Surplus rinsing and drain down water will be pumped to the Open Pit after that time. Numerous gold mining operations located in Canada make use of the natural degradation processes for removal of cyanide from site water. Generally WAD-CN is removed rapidly – essentially all WAD-CN dissipates during a single open water season. The half-life of WAD-CD is very short – as little as a few hours, as the solution pH drops below pH 8. For the purposes of the model, it has been conservatively assumed the half-life is 0.05 years (18 days). Total cyanide was assumed to degrade more slowly, with a half-life of 0.5 years. Because the Pit Lake will not discharge for approximately 85 years after the final year of drain down pumping to Pit Lake (Year 28), cyanide degradation will remove this source prior to initial discharge of the Pit Lake.

6.4 Individual Contributions from Loading Sources

Individual contributions of each mass loading source are presented for select water quality parameters. Table 6-2 represents cumulative loading contributions at the time of initial discharge of the Pit Lake.

Table 6-3 represents the long-term (perpetual) contributions and was calculated from annual mass loading inflows at the end of the simulation (Year 200). Loading contributions for all water quality parameters are presented in Appendix I-B.

Closure activities carried out during the Wetland Construction Phase (pumping from the HLF, TMF and WMP, and disposal of residual stockpile ore rock) will influence Pit Lake water quality upon intial discharge, but those loading contributions will be temporary and will not affect the long-term water quality in the Pit Lake.

A portion of the pit wall (i.e., the “high wall”) that is above the elevation of the final Pit Lake will remain un-submerged. Runoff from the high wall will be a perpetual source of mass loading into the Pit Lake. The acidic portion (Supergene Acidic or Hypogene Acidic) of the Open Pit high wall rock is expected to be the largest contributor of mass load into the Pit Lake in the long-term.

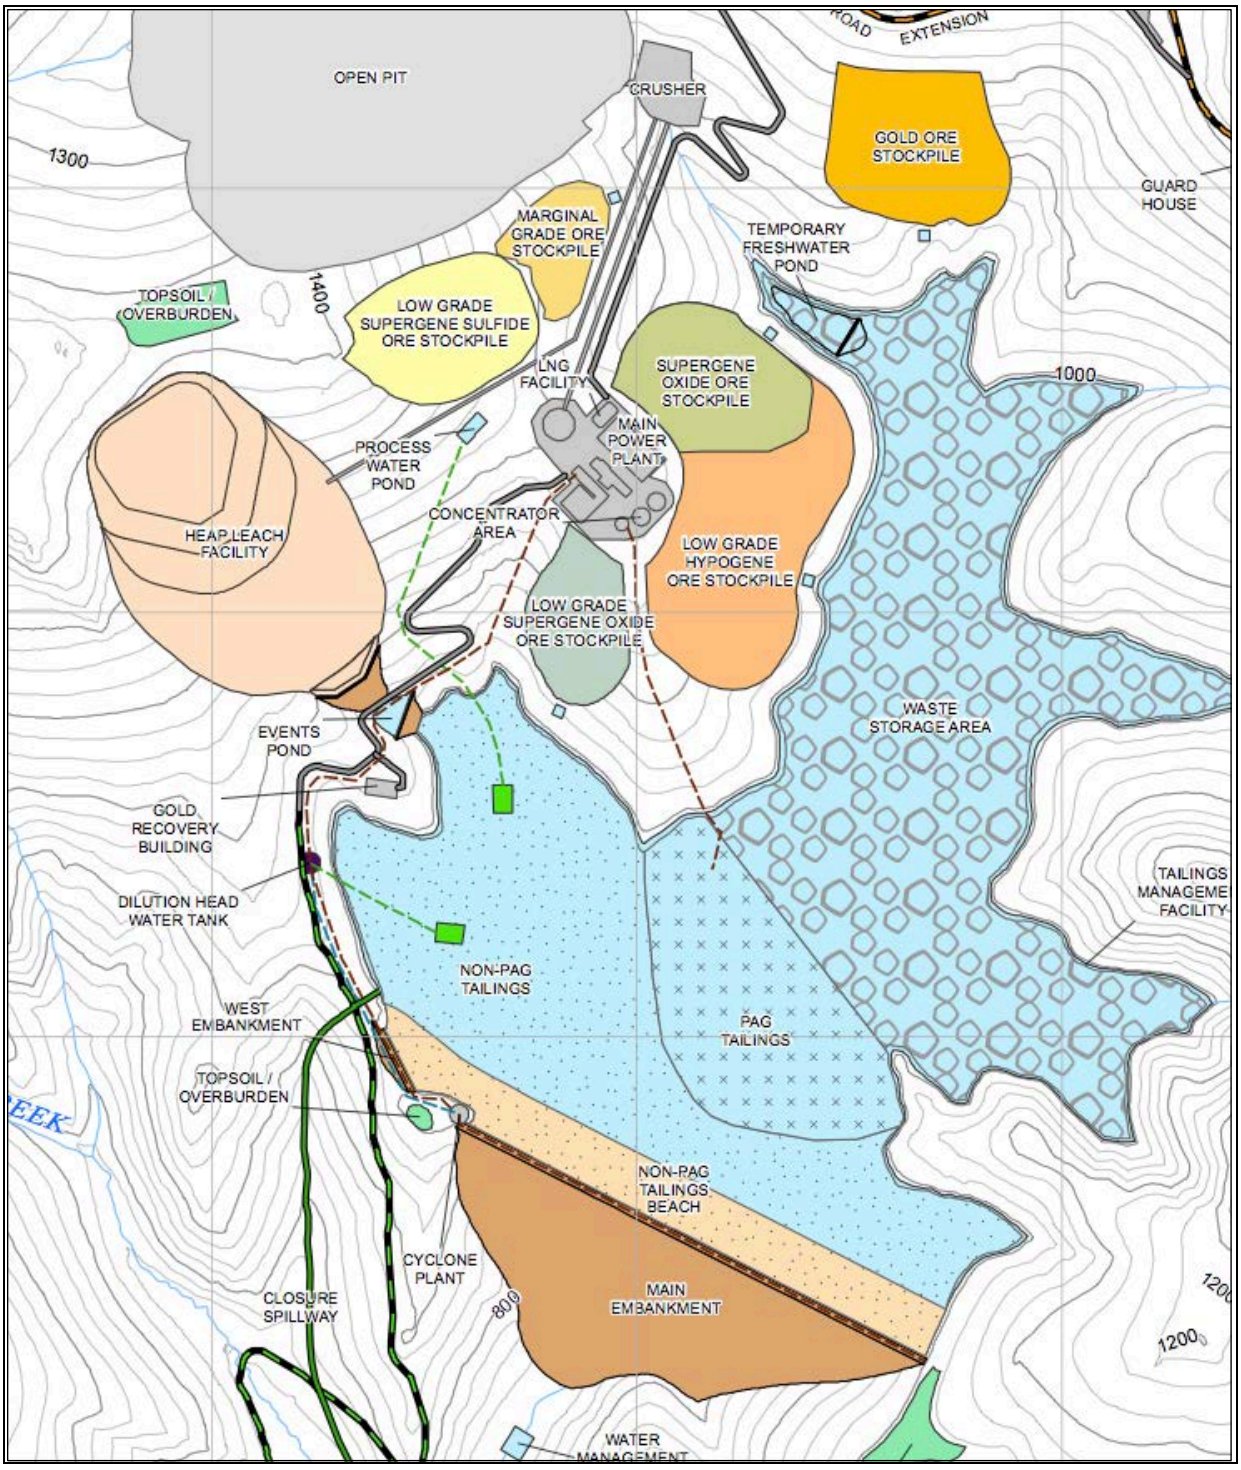
1 Introduction

During Operations of the Casino Project (the Project), six types of ore will be temporarily stockpiled on surface. The stockpiles include:



- Gold Ore;
- Supergene Oxide Ore;
- Low Grade Supergene Oxide;
- Low Grade Hypogene;
- Low Grade Supergene Sulphide; and,
- Marginal Grade Ore (MGO).

The gold ore will be crushed then processed in the Heap Leach Facility (HLF), and the marginal ore, should it not be economical to mill, will be backfilled to the Open Pit. The remaining 4 piles will be milled in the processing facility throughout the life of the mine. Stockpile locations are shown on Figure 1-1. The schedule of ore stockpiling rock is provided in Appendix II-A (Table II - A 1).

While the ore stockpiles are present during Operations, contact water (from rainfall and snowmelt) will drain from the rock as runoff or will infiltrate to groundwater. Runoff from the stockpiles will be captured by the TMF Pond. Prior to construction of the TMF, runoff water from the stockpiles will be conveyed to the temporary Freshwater Storage Pond (FWSP) in the northern upper reach of the final TMF footprint. The FWSP water will be used to supply makeup water to the HLF (KPL, 2013a). Hydrogeological modelling results (KPL, 2013b) indicated that depending on the stockpile location, infiltrated contact water will flow to one or more of the following receptors: the TMF Pond; Open Pit; TMF Embankment; or TMF Foundation bedrock.

Because the stockpiles will be temporary structures, they will be temporary sources of loading. The transient effect of the stockpiles on the site-wide water quality was accounted for by Source Environmental Associates Inc. (SEA) in the water quality model.

This document summarizes the calculation methodology and results of mass loading from the stockpiles to the various receptors around the project site. Mass transport rates were calculated using flow rates from the KPL (2015) water balance model, combined with geochemical source terms provided by Lorax (2013), and the stockpile schedule from KPL (2013c). Hydrogeological modelling results from KPL (2013b) were used to predict average travel times of groundwater from the stockpiles to their receptors.

Adapted from KPL, 2013a

Figure 1-1. Ore Stockpile General Arrangement at Maximum Footprint

2 Water Quality Model

A site-wide water quality model was developed by SEA. The model simulation was run with monthly time steps for a timeline beginning a few years prior to Construction, through to 200 years following the beginning of Operations.

Project years are described in this document relative to the beginning of milling Operations. For example, Year -2 refers to the second year before Operations begins, and Year 2 refers to the second year of Operations. Construction will span from Year -4 to Year -1, and Operations from Year 1 to Year 22. Modelling methodology and results are presented in the following sections.

2.1 Modelling Approach

The rate of mass transport from the ore (via contact water) was calculated for 27 water quality parameters using source terms from Lorax (2013) and water balance flows from KPL (2015). Ore stockpile source terms from Lorax include both a loading rate based on the amount of rock present in the stockpile (i.e. mass of constituents per mass of rock) and a maximum concentration limit based on solubility controls. In the GoldSim model, development of the total loadings in mass flow rate per time (e.g. kg/month) for each ore pile was the first step in a multi-step process.

Once the total load for each constituent was determined for an ore pile, this total load was then partitioned by the annual quantity of flow to surface water and groundwater. Surface water runoff was directed to the TMF pond. Groundwater loadings were further partitioned into the following four pathways shown on Figure 2-1.

- Seepage to the TMF Pond
- Seepage to the Open Pit
- Seepage to the TMF Embankment
- Seepage to the TMF Foundation

Once the total load (Section 2.2) was partitioned to a groundwater pathway (Section 2.3), a delay was applied in the water quality model to simulate the travel time (Section 2.4) for the loading from the stockpile to the receptor.

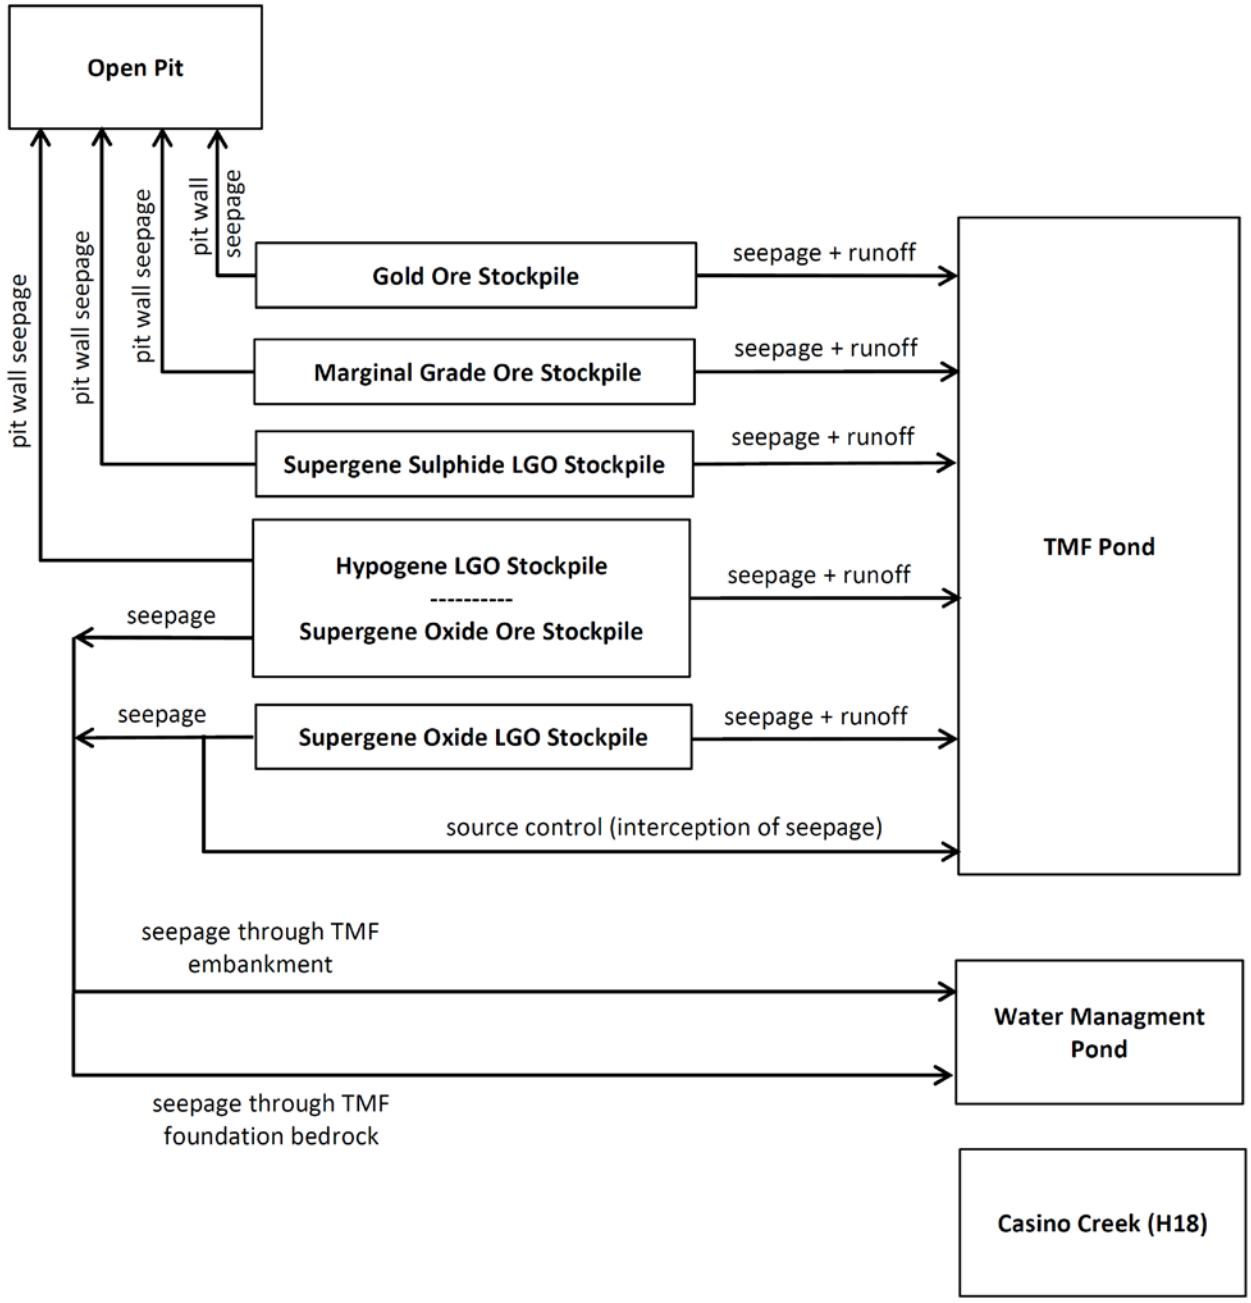


Figure 2-1. Mass Loading Pathways from the Ore Stockpiles

2.2 Mass Loading from Ore Stockpiles

The amount of rock stockpiled on surface directly affects the quantity and quality of the ore stockpile contact water. The ore deposition schedule is summarized in Appendix II-A (Table II - A1). Mass loading rate source terms for the six ore stockpiles were developed by Lorax (2013) on an annual basis and are presented in Appendix II-A (Table II - A 2). The source term loading rates were multiplied by the total rock mass stored in the stockpiles to calculate total load from the ore piles during a given model time-step. The loading concentrations from the ore piles were compared to solubility controls for the suite of parameters. Lorax (2013) provided maximum allowable contact water concentrations (Appendix II-A, Table II - A 3) based on water availability and solubility constraints. The total mass load in the contact water was reduced if the resulting contact water concentration exceeded the maximum allowable concentration provided by Lorax (2013).

Lorax predicted the pH of the contact water to be pH 4.7 for the Gold Ore, pH 7.2 for the Low Grade Hypogene Ore, and pH 3.2 for the other stockpiles (Table II - A 4). Water quality modeling indicated that only the Low Grade Hypogene Ore stockpile would be affected by solubility controls (the solubility controls apply to copper, iron and other parameters that are relatively insoluble at neutral pH). Time series plots of copper mass loading rates from the Supergene Oxide Ore (Figure 2-2) and the Low Grade Hypogene stockpile (Figure 2-3) illustrate the calculated total mass loading from the stockpiles.

Once the mass loadings from each stockpile were determined, the next step in the model was to partition the total load into the flow pathways to receptors (Section 2.3).

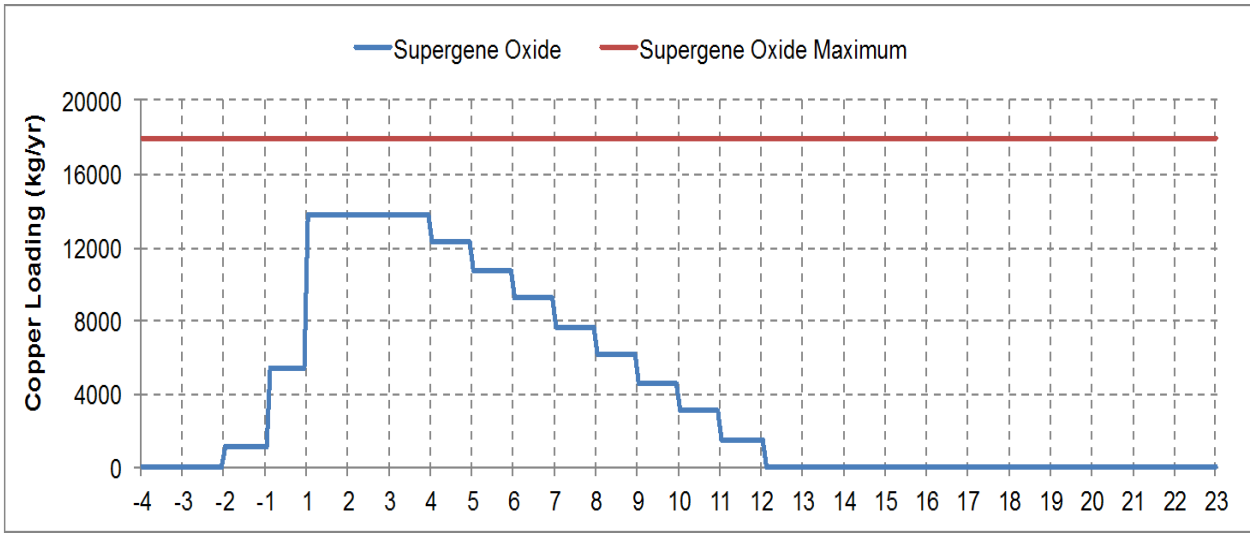

Figure 2-2. Copper Loadings and Maximum Solubility in the Supergene Oxide Ore Stockpile Drainage

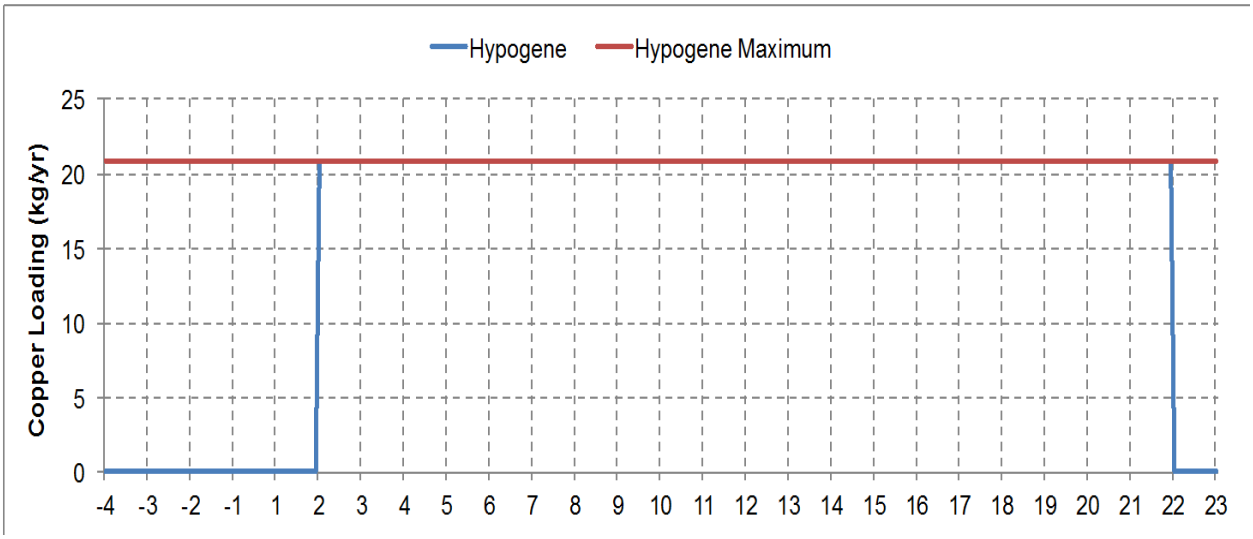

Figure 2-3. Copper Loadings and Maximum Solubility in the Hypogene Low Grade Ore Stockpile Drainage

2.3 Partition Loadings by Pathway

The ore contact water is expected to follow several possible pathways from the stockpiles. Surface water (runoff) from all stockpiles will report to the TMF Pond. The ratio of the annual surface water flow to the total contact water flow was used to partition the loading to surface water for each stockpile. The remainder of the loading was allocated as seepage between up to four groundwater pathways.

KPL (2013b) provided relative proportions of the total seepage by individual flow pathways for three snapshots in time: Year 4, Year 10, and Year 19. Because the values were fairly similar among the three snapshots in time, constant ratios for partitioning were used for the duration of the model. Table 2-1 shows the assumption used in the SEA model. Year 19 was used to represent the flow (and load) partitioning for all years of the model simulation, with the following exceptions:

- Year 10 was used for the Supergene Oxide Ore as it does not exist at year 19 (it is replaced by the Hypogene pile) and
- Year 10 was used for the Low Grade Supergene Sulphide and Marginal Grade Ore as to be more conservative because by year 19 there is no seepage to the TMF pond.

Initial modelling results indicated that seepage from the Low Grade Supergene Oxide stockpile could potentially have a noticeable (albeit temporary) effect on Casino Creek water quality. Interception of seepage (i.e., source control) was integrated into the project description to mitigate the potential impacts of the Low Grade Supergene Oxide seepage on water quality in Casino Creek. KPL (2013b) assumed that 90% of the seepage will be recovered and conveyed to the TMF Pond.

Table 2-1. Stockpile Seepage Partitioning by Receptor in the Water Quality Model

Stockpile Receptor	Fraction of Total Seepage Discharge (%)
Gold Ore Stockpile	
Open Pit	20%
TMF Pond	80%
Supergene Oxide	
Open Pit	4%
TMF Pond	95%
TMF Embankment Seepage	1%
TMF Foundation Seepage	0%
Low Grade Supergene Oxide Ore Stockpile [2]	
TMF Pond (via overland runoff)	65%
TMF Pond (via intercepted seepage) [2]	31.5%
TMF Embankment Seepage [2]	2.5%
TMF Foundation Seepage [2]	1.0%
Low Grade Hypogene Ore Stockpile	
Open Pit	3%
TMF Pond	95%
TMF Embankment Seepage	1%
TMF Foundation Seepage	1%
Low Grade Supergene Sulfide Ore Stockpile	
Open Pit	95%
TMF Pond	5%
Marginal Grade Ore Stockpile	
Open Pit	95%
TMF Pond	5%

1. Values in this table were adapted from KPL (2013b).
2. Values in the table represent the seepage partitioning with the proposed seepage interception system in place. Without the system in place, 25% of total seepage would result in embankment seepage, and 10% of the total seepage would result in foundation seepage. With the interception system in place, 31.5% of the total seepage will be intercepted and discharged to the TMF Pond during Operations.

2.4 Delay of Seepage along Pathway

To simulate groundwater flow velocities in the seepage, a time delay was applied to the seepage mass loading in the water quality model. The seepage was assumed to report to its receptor after a period of time equal to an estimated seepage travel time. Median, minimum, and maximum seepage travel times from the stockpiles to their receptors were approximated by KPL (2013b).

SEA calculated an average travel time in the GoldSim model using a triangular probability distribution to produce a base case value. Travel time calculation from the gold ore stockpile to the Open Pit is shown on Figure 2-4. The resulting mean time delay was calculated to be 3.8 years, based on minimum (1.3 years), maximum (7.3 years) and median (2.8 years) delays that were provided by KPL (2013b).

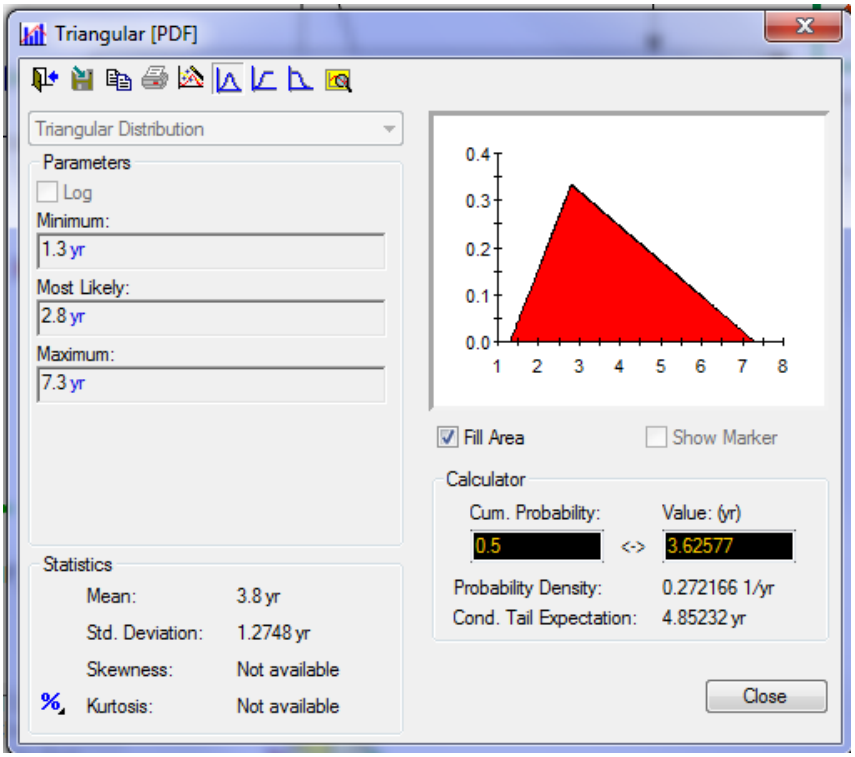

Figure 2-4. Gold Ore Stockpile Time Delay GoldSim Calculations

The calculated average values used in the model are presented in Table 2-2.

Table 2-2. Average Travel Time from Stockpile to Receptor

Stockpile Receptor	Average Travel Time to Discharge Location (Years)
Gold Ore Stockpile	
Open Pit	3.8
TMF Pond	1.8
Supergene Oxide	
Open Pit	2.7
TMF Pond	3.8
TMF Embankment Seepage	8.3
TMF Foundation Seepage	15.0
Low Grade Supergene Oxide Ore Stockpile	
TMF Pond	9.2
TMF Embankment Seepage	7.7
TMF Foundation Seepage	27.7
Low Grade Hypogene Ore Stockpile	
Open Pit	2.7
TMF Pond	3.8
TMF Embankment Seepage	8.3
TMF Foundation Seepage	15.0
Low Grade Supergene Sulfide Ore Stockpile	
Open Pit	3.4
TMF Pond	33.2
Marginal Grade Ore Stockpile	
Open Pit	3.4
TMF Pond	33.2

Adapted from KPL (2013b)

3 Summary and Results

The ore stockpile water quality modelling methodology respected the principal of mass conservation. The total loading from each ore pile was partitioned to the appropriate receptors in the fully-integrated water quality model.

Loadings from the ore stockpiles to the various receptors will vary over time. Generally, the rate of loading from the ore stockpiles will vary proportionally to the stockpile mass.

During Operations, the majority of the loads will be captured by runoff to the TMF Pond, or by groundwater intercepted by the TMF Pond or Open Pit. A lag time was applied to the stockpile seepage water to simulate the travel time that it will take for the stockpile contact water to reach the receptors as seepage. Application of the time delay resulted in some seepage reaching the TMF Pond, TMF Embankment and TMF Foundation after Operations.

Because the stockpiles will be temporary structures, they will be temporary sources of loading. Based on the stockpile schedule (Table II-A1), combined with the estimates for average travel times (Table 2-2), all water quality effects to the receptors were predicted to cease by Year 55 of the model simulation.

The water quality model was used to evaluate where mitigation measures can be implemented to minimize the influence of stockpile loading on the receiving environment water quality. Interception of seepage (i.e. source control) from the Low Grade Supergene Oxide stockpile was incorporated into the input assumptions for partitioning of loads to the receptors, such that most of the load from this stockpile was directed to the TMF Pond.

Calculated rates of mass transport at the stockpile loading receptors are presented (in kg/year) in Appendix, II-B for Years 5, 15, 25 and 35. The mass loading calculations showed that the Supergene Oxide and Low Grade Supergene Sulphide stockpiles will be largest sources of stockpile mass loading for most parameters during the Operations phase. The Low Grade Supergene Oxide and the Marginal Ore stockpiles produce lower loading, and the Gold Ore stockpile loadings are lower still. The copper loadings from the Hypogene stockpile were calculated to be the lowest as they are limited by the maximum solubility of copper in the neutral pH drainage from this ore pile as predicted by Lorax (2013).

1 Introduction

The Casino Project (the Project) is a proposed mining project in the west-central Yukon. The deposit will be mined using open pit methods, with a nominal mill throughput of approximately 120,000 tonnes/day of ore over a 22 year operating life. Milling operations will produce molybdenum and copper concentrates through conventional flotation circuit milling and gold and silver doré will be produced by cyanide heap leaching.

The Tailings Management Facility (TMF) will be the primary water and waste management component of the Project. The TMF was designed by Knight Piesold Ltd (KPL) to store approximately 956 million tonnes of tailings and up to 649 million tonnes of waste rock and overburden (KPL, 2012). The TMF will be situated in the Casino Creek valley southeast of the Open Pit. Two embankments, the Main Embankment, and the West Saddle Embankment will be constructed across the Casino Creek valley to create the storage impoundment.

A water quality model was developed to predict mine drainage water quality and the potential for effects on the receiving environment of the proposed Casino Mine. A site-wide water balance was developed by KPL and was used by Source Environmental Associates Inc. (SEA) as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim.

A water balance model was initially developed by KPL in 2013 (and is described in KP, 2013a). The 2013 water balance was run using average annual estimates for hydrologic conditions at the site. Water quality modelling for the average annual water balance was carried out by SEA. Modelling methodology and results were reported in SEA (2013).

In 2014, a climate variability water balance model was developed by KPL (and is described in KPL, 2015) to account for the expected variability in hydrological conditions (i.e. wet and dry periods) from year to year. SEA used the climate variability water balance as the basis for the water quality model that is described herein.

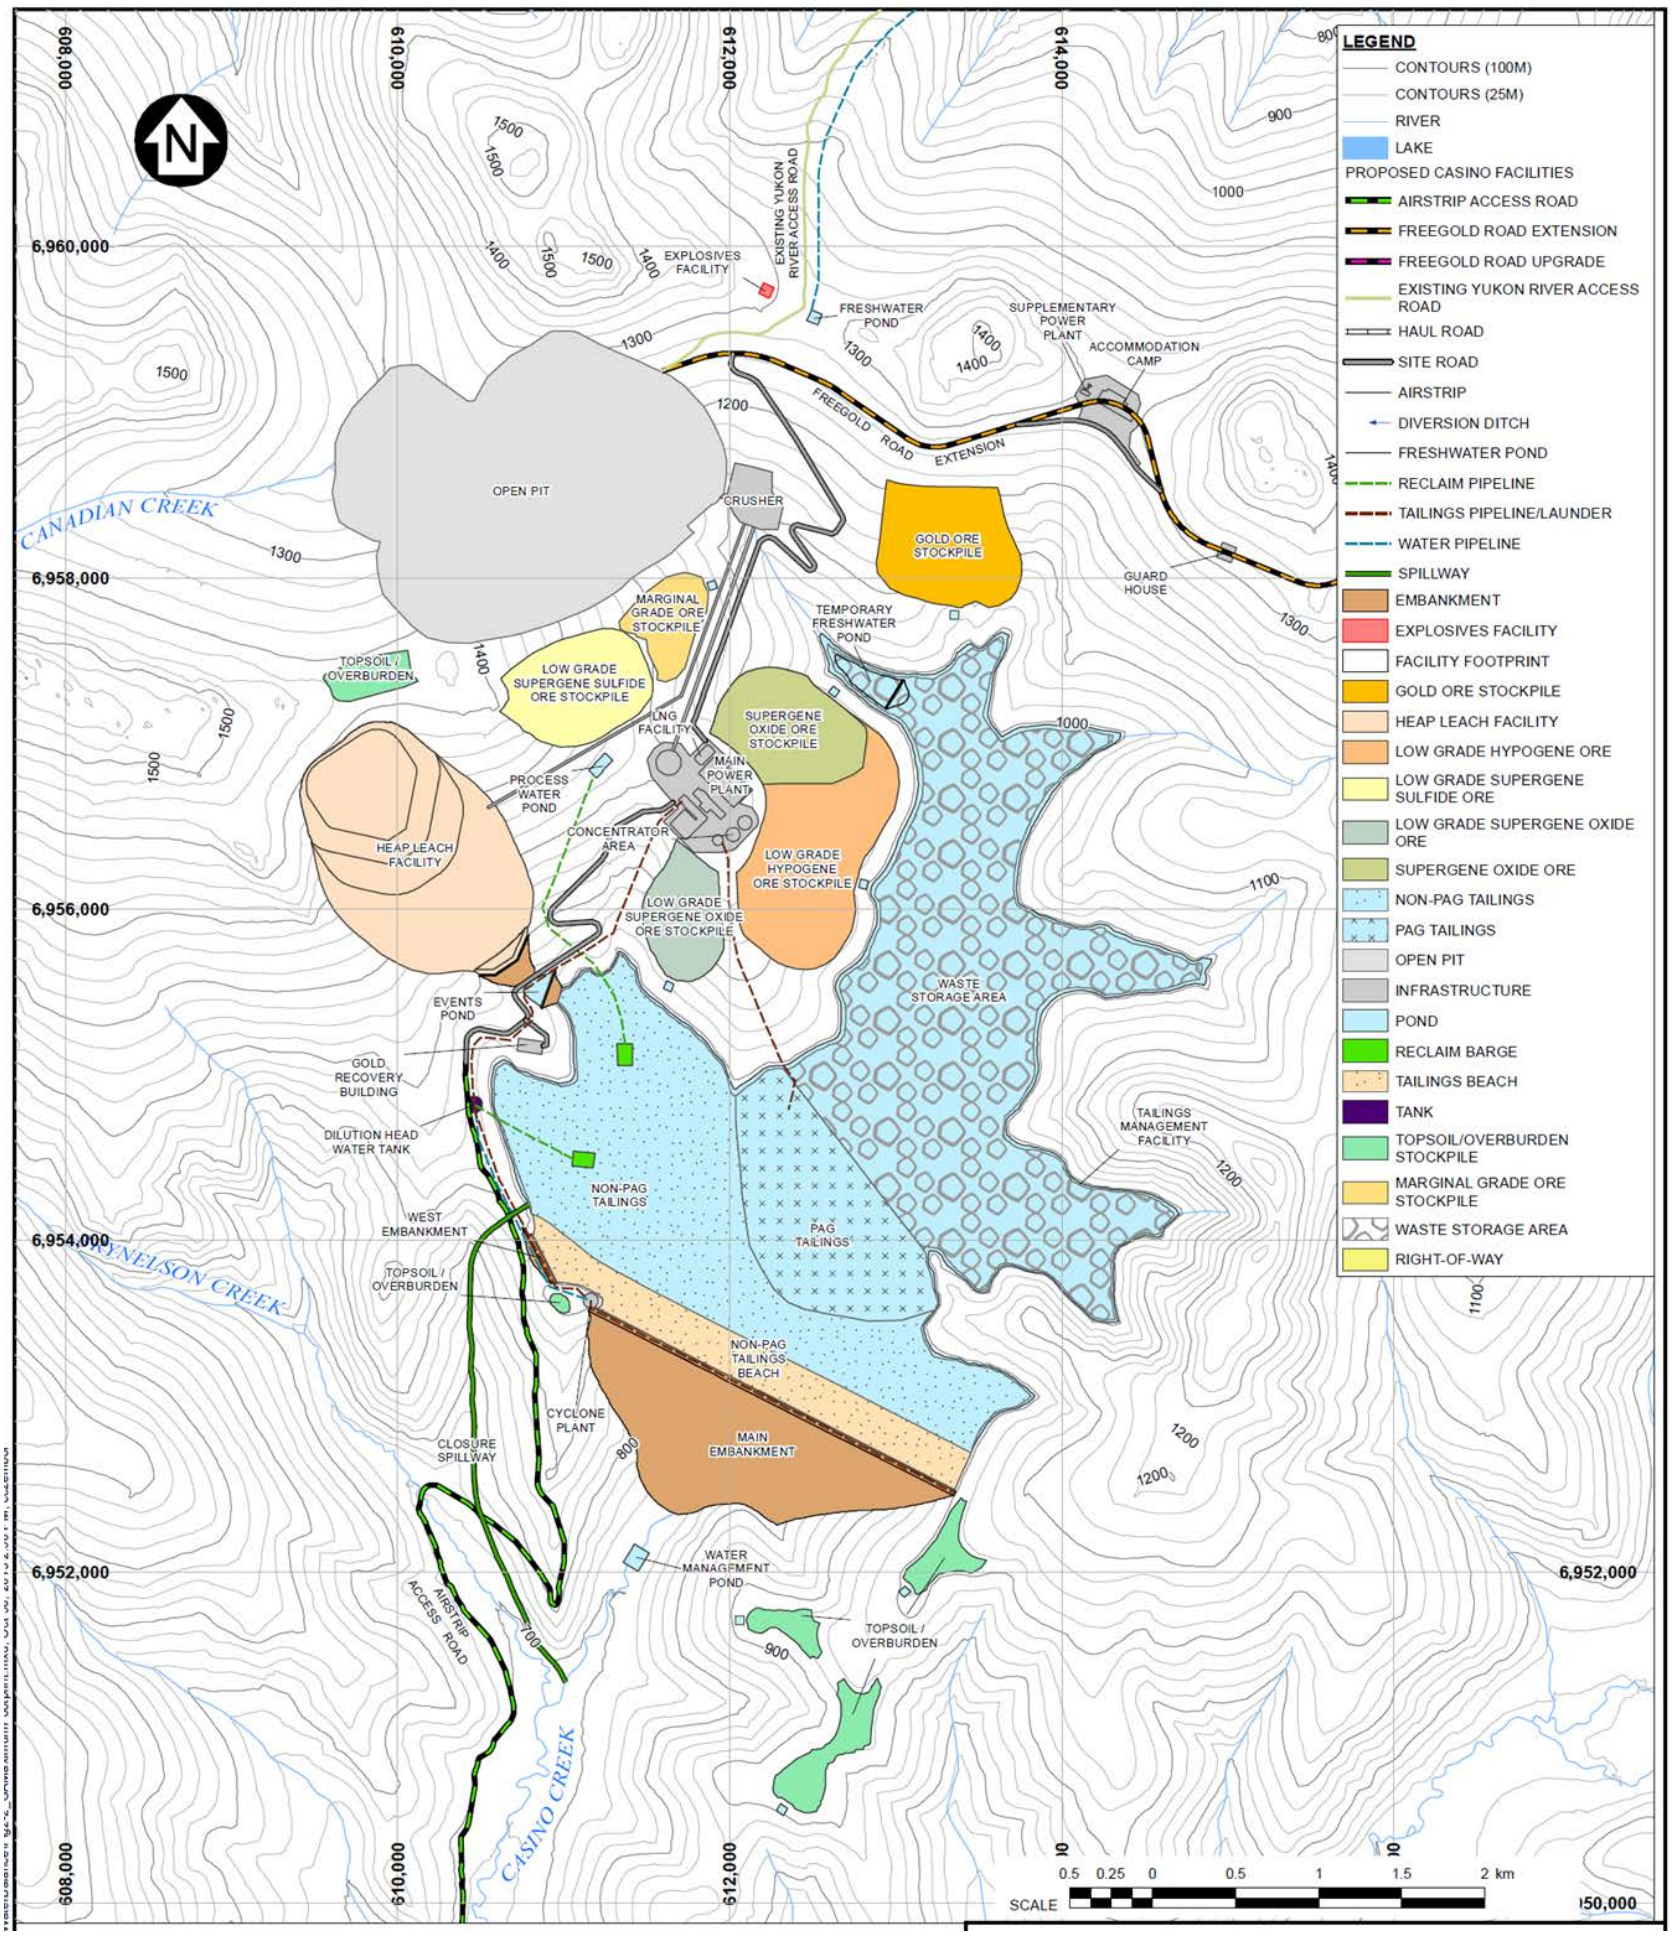
This report presents the methodology and results of the water quality predictions for the TMF Pond model. This report contains all information relevant to the water quality model, and repeats the pertinent information previously provided in the December 2013 report (SEA, 2013). A comparison between the SEA (2013) Pit Lake water quality modelling report and this report is provided Table 1-1.

Table 1-1. Comparison between 2013 and 2015 Modelling Reports

Concept	SEA (2013) Report	Applies to this Report
Water Balance Input Dataset	Average monthly hydrologic conditions (e.g. precipitation, temperature, streamflow, etc.) were used as input for every year of the model simulation.	Inter-annual variation in hydrologic conditions was applied throughout the model simulation. Water balance output flows were calculated from a synthetic, long-term (52 year) input dataset of monthly hydrologic conditions. The synthetic dataset was derived from regional and site data. **Rationale:** Using the range of monthly flows is more conservative (compared to using average annual flows) because realistic wet and dry periods can be simulated.
Estimation of Wet and Dry Years	n/a - wet and dry years were not simulated.	1-in-10 year wet and dry years were identified in the water quality output time-series plots. **Rationale:** To illustrate how the water quality management system will perform as a results of infrequent wet/dry periods.
Monte-Carlo Analysis (Stochastic Modelling)	Stochastic modelling was not carried out.	Model simulations included 52 unique input hydrology datasets. A statistical summary was generated from the water quality model output for the 52 realizations. **Rationale:** To account for all possible water balance flow scenarios that could result from the input hydrology dataset.
Project Phase Start Dates for TMF Discharge Phase and Pit Discharge Phase	Project dates were based on KPL (2013) water balance model output.	Project dates were based on KPL (2015) water balance model results.
TMF Seepage Cut-Off System	The TMF seepage cut-off system was to be constructed after Operations. As a result, during Operations, the WMP was assumed to have a 90% capture efficiency with 10% seepage by-pass to Casino Creek. Following Operations, the seepage cut-off system was to be constructed, resulting in 100% seepage capture efficiency (i.e. 0% by-pass).	The seepage cut-off system will be constructed prior to Operations. The seepage collection system was assumed to have 100% capture efficiency during Operations and for all subsequent mine phases. **Rationale**: Reduce the potential for seepage water to enter Casino Creek during Operations.

Concept	SEA (2013) Report	Applies to this Report
WMP Pumping to the Open Pit (Wetland Construction Phase)	During the Wetland Construction Phase, the WMP was assumed to be pumped to the TMF Pond.	During the wetland construction phase, the WMP will be pumped to the Open Pit. **Rationale:** Mass load from the WMP by-passes the TMF Pond by pumping directly to the Open Pit.
TMF Pond Release to Casino Creek	TMF Pond was allowed to naturally overflow seasonally with no control of the flow rate.	The TMF pond will be released in a controlled manner. The ratio of TMF pond release to WMP release will be set between 1.2 to 2.5, depending on the Project Phase and the month. The ratio increases when there is little flow in Brynelson to provide dilution of the seepage released. **Rationale**: The available dilution in Brynelson is utilized by tying the release of WMP to the natural hydrograph.
CoC List	7 CoCs were reported. The CoC list did not include fluoride.	Fluoride was added as a CoC, so 8 CoCs are reported. **Rationale**: Fluoride was added as it exceeded a generic water quality guideline in Casino and Dip Creeks.

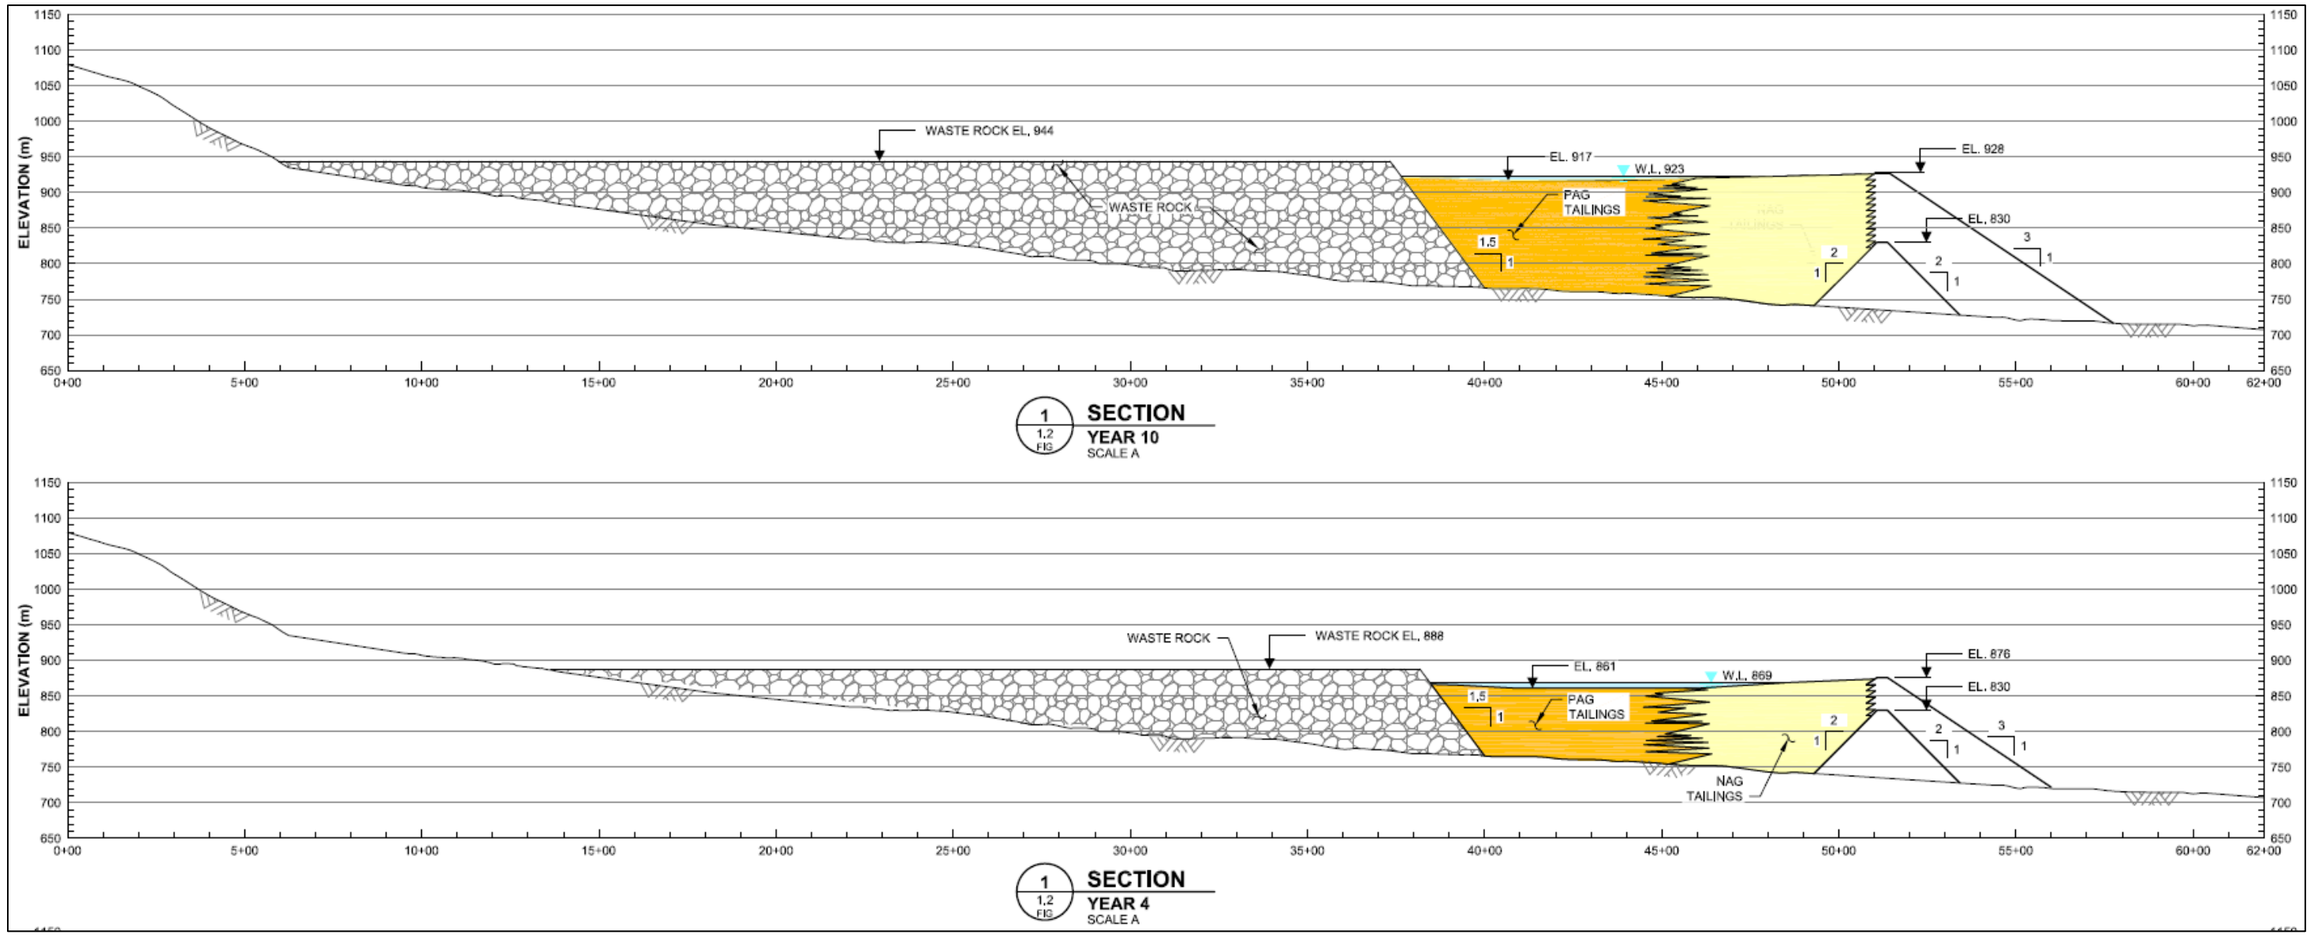
2 Casino Project Water Management Phases



For the purposes of water quality modeling, the Casino Project has been sub-divided into five water management phases. Project years are described in years relative to the beginning of milling operations. For example, Year -2 refers to the second year before Operations begins, and Year 2 refers to the second year of Operations.

Water management phases and relevant project activities related to water quality modeling are provided in Table 2-1. Layout of the Project site is illustrated in Figure 2-1 for Operations. Development of the TMF during Operations is provided in Figure 2-2. Long-term site conditions following mine closure are shown on Figure 2-3.

Table 2-1. Water Management Phases



Water Management Phase	Project Year	Water Management Activities
Construction	-4 to -1	• TMF starter embankment construction. • Construction of TMF Water Management Pond (WMP) downstream from the embankments to recover seepage and embankment runoff. • Open Pit construction. • Construction of the Fresh Water Supply Pond (FWSP) at the north end of the TMF to be used as an interim source of fresh water. • Construction of the freshwater supply pipeline to draw fresh water from the Yukon River.
Operations	1 to 22	• Mill operations. • Tailings discharge to the TMF. Approximately 80% of the total tailings produced will be non-acid generating (NAG) material, and 20% will be potentially acid generating (PAG). • Waste Rock placed at the north end of TMF. • Some of the NAG tailings will be processed in the Cyclone Sand Plant to produce embankment construction material. • Runoff from the ore stockpiles and mill site will be directed into the TMF Pond. • Water recovered in WMP will be pumped to TMF Pond. • TMF Pond water will be reclaimed to the mill. • Makeup water will be supplied to the mill from the Yukon River via the freshwater supply pipeline. • No interaction between Heap Leach Facility (HLF) water management system and TMF water management system throughout Operations.
Wetland Construction	23 to 34	• Seepage collected in the WMP will be pumped to the Open Pit. • Year 23 to Year 28 – TMF Pond water will be pumped to Pit Lake. • North TMF Wetland and South TMF Wetland will be constructed and commissioned.

Water Management Phase	Project Year	Water Management Activities
		• Any unprocessed low or marginal grade ore will be placed in the Pit Lake. • Following wetland construction, the TMF Pond will be allowed to fill through natural recharge. • The tailings beach, stockpile areas, HLF, mill site, and other disturbed surfaces will be covered and re-vegetated. • Year 29 (and beyond) – drainage from reclaimed HLF will be directed into the TMF Pond.
TMF Discharge	35 to 109	• Assuming acceptable water quality, the TMF Pond will discharge to Casino Creek via an engineered spillway, following treatment in the South TMF wetland. • Seepage recovered downstream from the TMF embankments will be stored in the WMP through the low-flow months of the year (winter), and release during with warmer months when the TMF Pond water discharges via the Closure Spillway.
Pit Discharge	>109	• Pit Lake will discharge to the North TMF Wetland treatment system. Treated effluent from the wetland will discharge to the TMF Pond. • WMP will continue to operate as in the TMF Discharge Phase.

3 Model Overview

A site-wide water balance model was developed by KPL and was used as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim. SEA combined the water balance flows with mine loading source terms (Lorax, 2013), and background water quality to predict water quality in the TMF Pond for 27 water quality parameters.

A 52-year model input dataset of monthly weather conditions was developed by KPL in order to simulate the natural variability in hydrologic conditions (i.e. wet and dry periods) that can be expected at the site. The model was run over a time-frame from beginning of Pit Lake formation, to 200 years after the beginning of Operations. Because the model was run over a simulation period of ~200 years, the 52-year input dataset repeated approximately four times during a given simulation.

The model results are presented in two ways in this report:

1) Single Model Realization

   Results generated when one realization of the input hydrology dataset was run with the model. Single realization results provide a time-series of model output which shows a representation of water quality that would result from a realistic range in hydrological conditions at the site. The output provides an indication of how high (or low) water quality concentrations may get, and how often those results are expected to occur. Time-series plots and summary tables of water quality results for a single realization are presented throughout this report.

2) Monte-Carlo Summary (52 Realizations)

   The model was run 52 times. Each model run used a unique input hydrology dataset. The combined output from the 52 model runs (i.e. realizations) represents the range in all possible model outputs resulting from all the possible permutations of the input hydrology dataset. Average annual water balance results presented in this report were generated from the Monte-Carlo Summary results.

Project timelines for activities relevant to TMF Pond water management are provided in Table 3-1. Schematics are provided to illustrate the mass transport pathways associated with the TMF Pond during Operations (Figure 3-1) and long term conditions following mine closure (i.e. Pit Discharge Phase - Figure 3-2). Tables of model input and output values are provided for each modelled water quality parameter in Appendix IV - A (model input) and Appendix IV - B (model results).

Table 3-1. Project Timeline

Project Year	Project Activity
-4	start of construction
-3	Start of mining the Open Pit
1	start of milling (start of Operations Phase)
18	final year of Open Pit Mining
19	Open Pit dewatering stops, Pit Lake begins to form
19	end of waste rock placement in TMF and begin covering waste rock with tailings layer
22	final year of milling (end of Operations Phase)
23	start of pumping TMF Pond to Open Pit (start Wetland Construction Phase)
23	start of pumping WMP to Open Pit
24	end of HLF rinsing and start of HLF drain down (pump to Open Pit)
27	end of pumping TMF to Open Pit
28	start of TMF filling by natural recharge
29	HLF drainage directed to TMF Pond
35	initial discharge of TMF Pond and WMP to Casino Creek
35	end of pumping WMP to Open Pit and initial discharge of WMP to Casino Creek
109	initial discharge of Pit Lake to TMF (into North TMF Wetland)

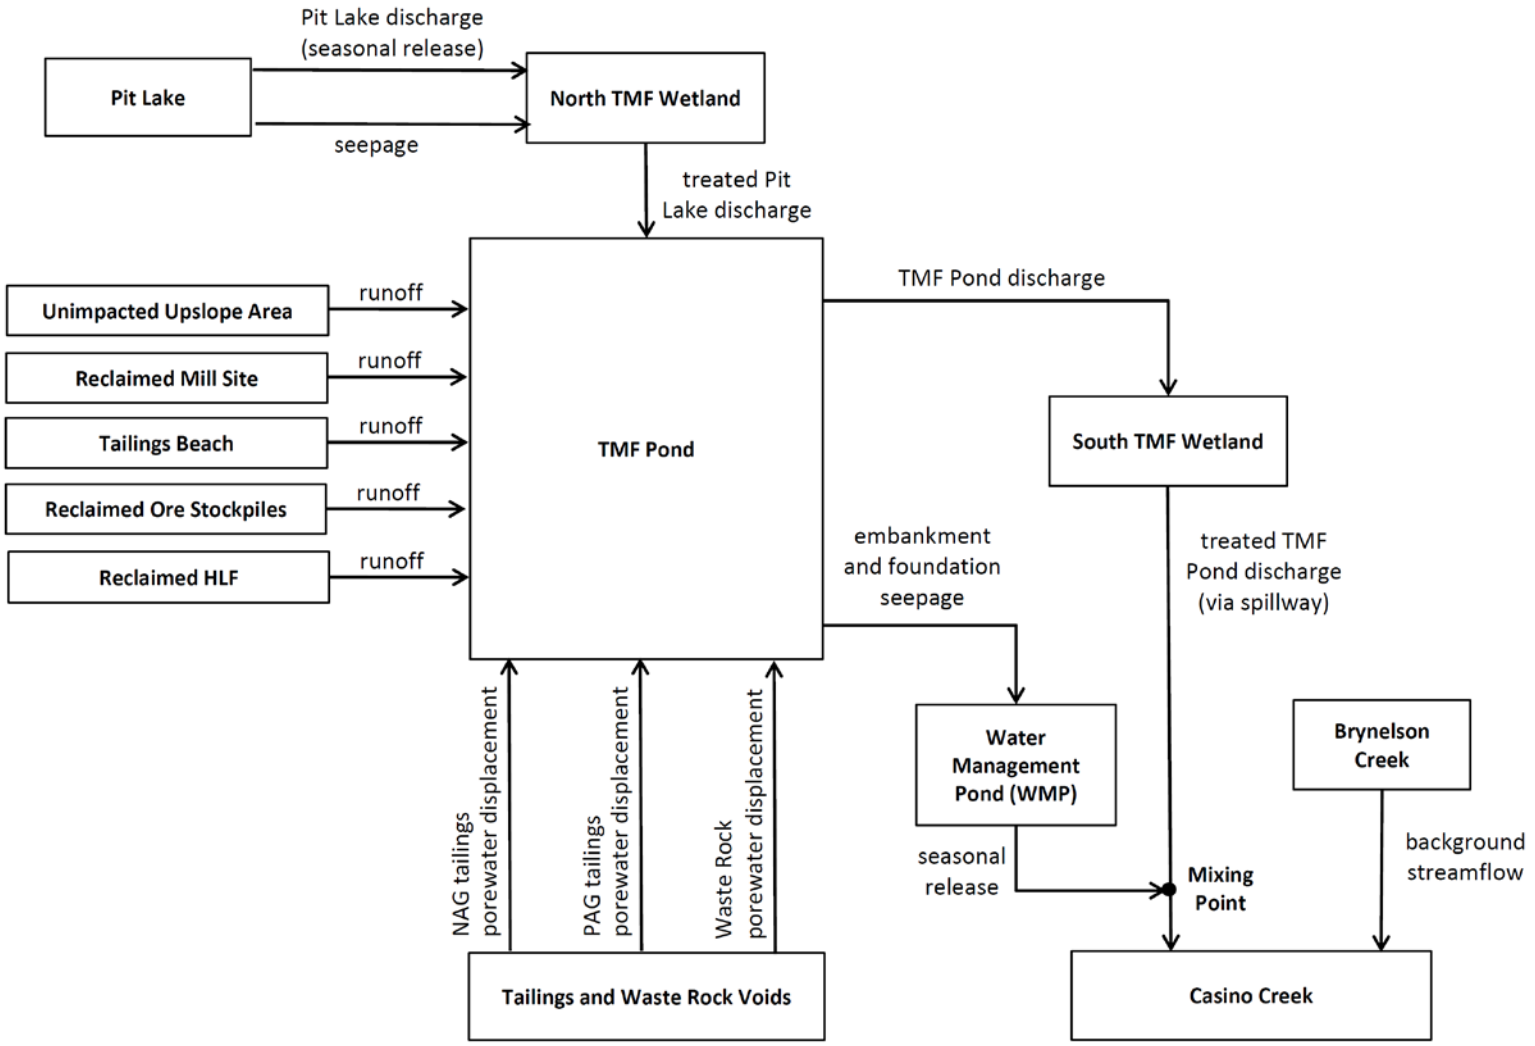

Figure 3-2. Mass Transport Flow Paths through the TMF Pond (Pit Discharge Phase)

4 Water Balance Model

The KPL (2015) water balance model was developed to estimate the TMF Pond inflow and outflow rates for water quality modelling, water management and waste deposition planning. A summary of water balance assumptions and results are provided in the following section.

The TMF Pond will not discharge to the receiving environment during Operations or the Wetland Construction Phase. During the Wetland Construction Phase, the TMF Pond will be pumped to the Pit Lake for five years (Year 23 to Year 27), then will be allowed to fill by natural recharge. The TMF Discharge Phase will begin when the TMF Pond fills to its maximum storage capacity and then discharges to Casino Creek via the engineered closure spillway.

The water balance (KPL, 2015) simulation showed that the TMF will fill to its storage capacity and discharge to Casino Creek about 10 to 15 years following the end of Operations. KP established Year 35 as the best estimate of the beginning of the TMF Discharge Phase. The beginning of the TMF Discharge Phase differs slightly from those reported in the SEA (2013) report. The reason for this difference comes from a revision to WMP pump-out during the Wetland Construction Phase. In the 2013 version, the WMP was assumed to be pumped to the TMF Pond. In the 2015 revision, the WMP was assumed to be pumped to the Open Pit. As a result, reduced inflow to the TMF Pond led to a slightly longer time until filling and initial discharge of the TMF Pond. The 2013 version reported initial TMF Pond discharge to be at Year 31, where the 2015 version has initial discharge occurring in Year 35.

Conversely, the increased inflow to the Open Pit led to a slightly shorter time to pit filling. The 2013 version reported initial Pit Lake discharge after Year 113, where the 2015 version has initial discharge occurring after Year 109. Additional information related to the Pit Lake water balance and water quality model is provided in Appendix I (Open Pit Water Quality Modelling).

Inflow and outflow of water to the TMF Pond from the KPL (2015) water balance model are summarized in Table IV - A 1 to illustrate the average annual conditions over the duration of the water quality model.

5 Water Quality Model

This section provides a description of the modelling methodology that was used for the prediction of mass transport of substances through the TMF Pond and the resulting water quality. Relevant water balance components are discussed where applicable to the water quality modelling calculations. Tables of model input for each modelled water quality parameter are provided in Appendix IV - A.

5.1 TMF Pond Inflows

5.1.1 Precipitation on TMF Pond Surface

The monthly inflow of water to the TMF Pond by precipitation was calculated as the top surface area of the TMF Pond for a given time-step, multiplied by the monthly depth of precipitation. Consequently, calculated inflows from precipitation increased throughout Operations as pond surface area increased. Modelled pond area remained more or less constant following the beginning of the TMF Discharge Phase.

While precipitation was accounted for in the water balance, no load was associated with precipitation in the water quality model.

5.1.2 Background Runoff

Areas not disturbed by mining activities will contribute a load (i.e. background load) to the TMF Pond via overland runoff. The mass loading rate into the TMF Pond from overland runoff was calculated as the monthly rate of runoff, multiplied by the average annual water quality concentrations of the overland runoff.

Water quality monitoring data was available for Casino Creek (monitoring stations W12, W8, and W11) within the drainage basin of the TMF Pond (Figure 5-1). However, the water quality at those sites has been impacted by drainage from Proctor Gulch, where groundwater comes into contact with the Casino ore body (PECG, 2013). During Operations the ore body will be mined out and overland runoff will no longer be impacted by the presence of the ore body. Therefore, the Casino Creek water quality stations do not provide an appropriate representation of background runoff after the open pit excavation is complete.

The Meloy Creek (W13) water quality dataset was selected by SEA to represent background water quality to the TMF Pond because it was the nearest watercourse to the TMF Pond that is not impacted by the presence of the Casino ore body. The median values from 12 water quality

samples collected between 2008 and 2012 at W13 were used to represent average annual overland runoff water quality. Median water quality at W13 is presented in Appendix IV - A (Table IV - A 2).

Meloy Creek (W13) water quality data may be somewhat impacted by the presence of a historical adit. The adit, from lead/zinc/silver exploration between 1965 and 1980 was partially sealed by CMC in 2008. What remains today is a pipe that discharges at surface in upper Meloy Creek watershed. This water (site W43) was included in the 2008-2012 baseline studies (PEGC, 2013). Discharge occurs only during the spring and summer months and is frozen from October to April. At the point of discharge, it travels down the watershed for roughly two kilometres before joining Meloy Creek. Because the flow rate from the adit is relatively low compared to total stream flow at Meloy Creek, the loading from the adit is quite small at W13 for most parameters. However, cadmium (Cd), barium (Ba), lead (Pb), silver (Ag) and zinc (Zn) in the W13 data appeared to be mildly elevated and may result in a slight over-prediction of long-term concentrations in background runoff entering the TMF Pond.

Runoff from the mill site (approximately 0.3 km^2) during operations will be affected by the land disturbance created by the construction of the mill. However, the potential load from the disturbed area is considered by SEA to be negligible compared to major sources of loading to the TMF Pond during Operations (e.g., waste rock, tailings slurry, ore stockpiles, etc.). Therefore, drainage from the mill site was assumed by SEA to have background runoff water quality (from W13) for modelling.

5.1.3 Surplus Fresh Water Supply Pond Discharge

The Fresh Water Supply Pond (FWSP) will be constructed in upper Casino Creek and used during Construction and early Operations. During that time, upper Casino Creek will feed the pond and surplus FWSP water not required for processing will discharge to the TMF Pond (once the TMF has been constructed). Average annual discharge from the FWSP to the TMF Pond is presented in Table IV - A 1.

Proctor Gulch will still be in place during Construction (i.e. it will not have been mined out by the Open Pit by that time) and will therefore still contribute mass loading to Casino Creek. Water quality data from Casino Creek at W8 (median of 13 samples collected between 2008 and 2012) were selected to represent FWSP discharge in the modelling and is presented in Appendix IV - A (Table IV - A 2).

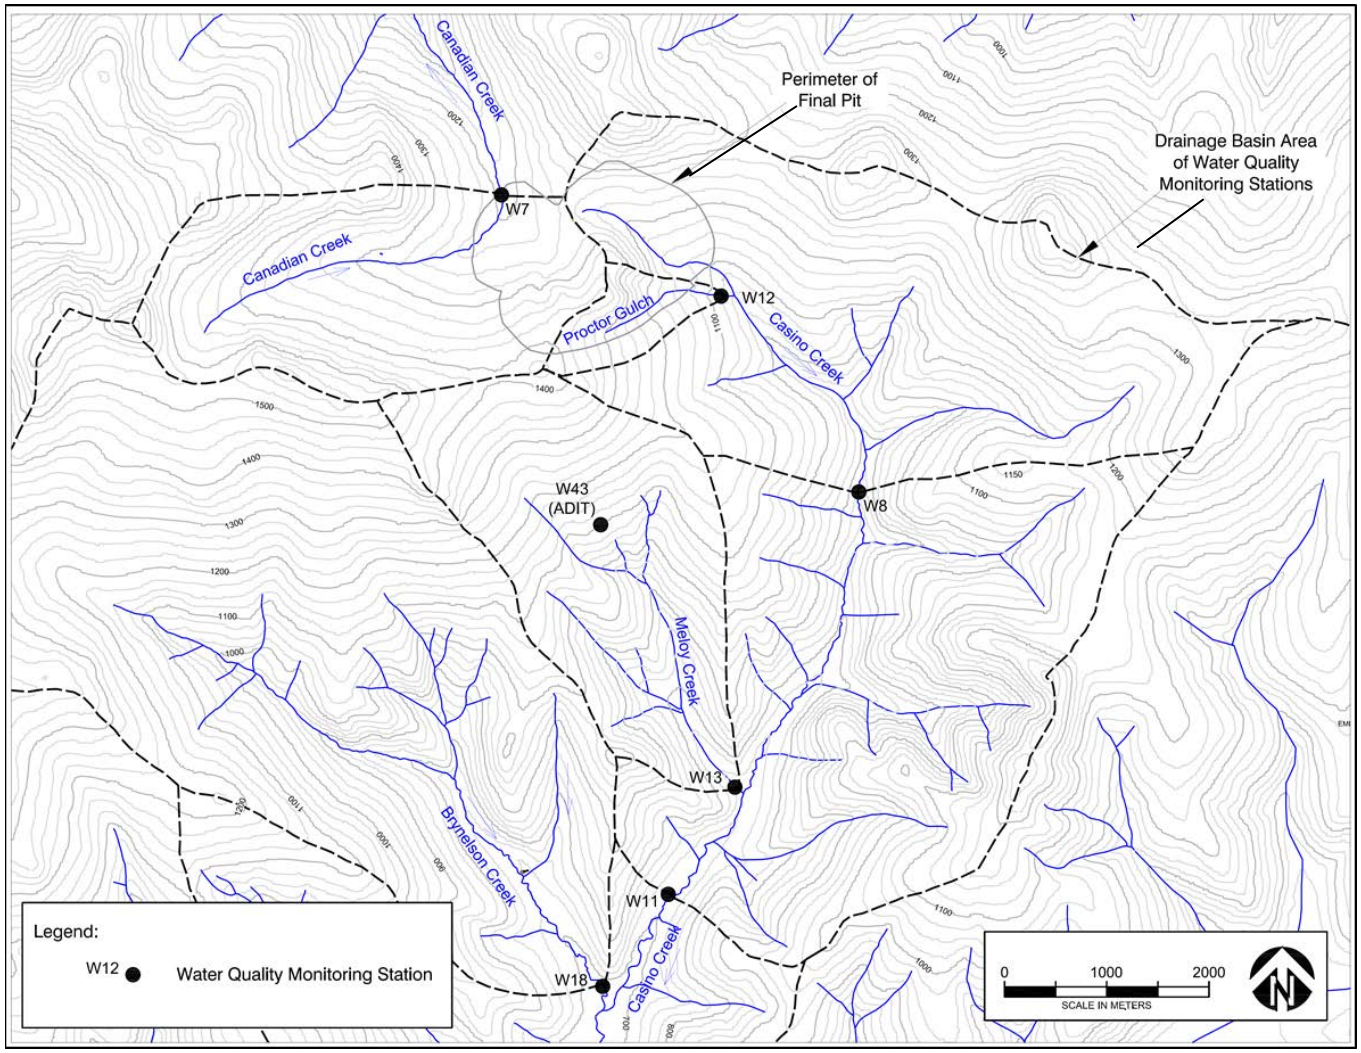

Figure 5-1. Water Quality Monitoring Stations in the Vicinity of the TMF

5.1.4 Treated Domestic Wastewater

Treated domestic wastewater from the water treatment plant will discharge to the TMF Pond during Operations. Mass loading was calculated as the flow rate multiplied by the water quality of the effluent. The average effluent discharge rate was 1.3 L/s in the KPL (2014) water balance.

Prior to its use for domestic purposes, the water supply will be suitable for human consumption and will not contain significant levels of heavy metals. SEA assumed the treated wastewater quality to be equal to the background runoff water quality. The impact of this simplifying assumption on water quality model results is considered by SEA to be negligible.

5.1.5 Ore Stockpile Runoff and Seepage

While the ore stockpiles are present during Operations, contact water (from rainfall and snowmelt) will drain from the rock as runoff or infiltration to groundwater. Runoff from the stockpiles will be captured by the TMF Pond.

Hydrogeological modelling results (KPL, 2013c) indicated that depending on the stockpile location, infiltrated contact water will flow to one or more of the following receptors: the TMF Pond, Open Pit, TMF Embankment (towards the WMP) or TMF Foundation bedrock (towards Casino Creek). SEA estimated an average travel time from a range of travel times provided by KPL (2013c) and assumed that the mass load associated with the stockpile seepage will report to the TMF Pond after a lag-time equal to the seepage travel time (Table 5-1). Methodology of the travel time estimate is provided in Appendix II (Ore Stockpile Water Quality Modelling).

Table 5-1. Seepage Travel Time from Stockpiles to TMF Pond

Stockpile	Seepage Travel time to TMF Pond (years)
Gold Ore	1.8
Marginal Grade Ore	33.2
Supergene Oxide Ore	3.8
Low Grade Supergene Oxide Ore	9.2
Low Grade Supergene Sulphide Ore	33.2
Low Grade Hypogene Ore	3.8

Seepage and runoff concentrations into the TMF Pond were calculated by combining the seepage flow rates with mass loading rates, and mass of rock in the stockpiles. Calculation methodology of stockpile mass loading is described in Appendix II (Ore Stockpile Water Quality Modelling).

During the Wetland Construction Phase, any residual stockpile rock will be placed in the pit, and the stockpile areas will be reclaimed (covered with overburden and re-vegetated). Loading from the reclaimed stockpile areas during the Wetland Construction Phase and beyond were calculated by multiplying the monthly overland runoff by background overland runoff water quality.

5.1.6 Drainage from Unsubmerged Waste Rock

Waste rock will be placed at the north end of the TMF. When the waste rock is placed during Operations, the top surface will be maintained above the normal operating pond level of the supernatant pond to provide a dry, stable placement surface for machine access and waste rock deposition.

Drainage water from the unsubmerged portion of waste rock will carry a mass load into the TMF Pond. Total drainage from the waste rock area to the TMF Pond will increase proportionally with the footprint area throughout operations, with the ultimate waste rock footprint area achieved in Year 17. After that time, waste rock drainage will decrease as the waste rock is covered with tailings, beginning in Year 19. The waste rock and tailings will be submerged after Operations and waste rock runoff will no longer be a source of mass load to the TMF Pond.

Lorax (2013) provided loading rates to calculate mass loading from the unsubmerged waste rock during a given time step. The mass load was calculated by multiplying the mass of unsubmerged waste rock (tonnes) from the KPL water balance, by the loading rates. Total mass load and volume of runoff water were combined at each time step to calculate contact water concentration.

Lorax provided maximum allowable concentrations for the waste rock drainage water to take into consideration water availability and solubility constraints. If the calculated waste rock runoff water quality exceeded the maximum allowable concentrations, waste rock drainage water quality was set equal to the maximum allowable concentrations for that time step.

Loading rates and maximum allowable concentrations are provided in Appendix IV - A (Table IV – A 3).

5.1.7 Tailings Beach Runoff

The footprint area of the tailings beach will increase from 0 km^2 to 0.7 km^2 during Operations. After that time, the tailings beach area will remain constant at 0.7 km^2. Average annual tailings beach runoff rates (from the KPL water balance) are provided in Table IV - A 1.

Runoff from the tailings beach will contribute a mass load to the TMF Pond in Operations and will continue into Post-Closure. Mass loading into the TMF Pond was calculated as the runoff flow rate multiplied by the tailings beach runoff water quality.

Lorax (2013) developed two sets of runoff concentrations for the tailings beach. The first was intended to be used for Operations and the second for Post-Closure conditions (Wetland Construction Phase and beyond). Concentrations in the runoff are expected to be lowest after Operations because by then, the tailings slurry (process) water will have been flushed out and the tailings beach will also be covered and vegetated. Tailings beach runoff water quality values are presented in Appendix IV - A (Table IV - A 2).

5.1.8 Surplus Heap Leach Facility Discharge

The Heap Leach Facility (HLF) will process oxide gold ore by leaching it with an aqueous cyanide solution. The HLF will be situated upslope from the TMF, but will operate independently from the TMF during Operations. That is, there will be no interaction of water or waste between the TMF Pond and the HLF throughout Operations.

During rinsing (Year 19 to Year 23) and drain-down (Year 24 to Year 28) of the HLF, surplus water will be directed to the Pit Lake. Following drain down, the final slopes of the HLF will be graded, covered, and re-vegetated. The water quality model assumes that 20% of surplus water (i.e. 20% of net precipitation) infiltrates and becomes seepage at the toe of the HLF while the remaining 80% of surplus water is non-contact runoff. Both the toe seepage and the surface runoff from the HLF will be directed downslope to the TMF Pond. The average annual flow from the HLF to the TMF Pond was estimated by KPL (2013a) to be 13 L/s. This flow combines the non-contact runoff and the HLF toe seepage.

Lorax (2013) provided a source term for three time periods; 1) rinsing and drain-down, 2) 10 years following drain-down and 3) long-term. The first set of source terms was applied during the drain down period and this loading was allocated to the pit lake (as described in Appendix I). The second set was applied for ten years following drain down (Year 29 to Year 38) while the water quality stabilizes to long-term conditions. Long-term water quality was applied for Year 39 and beyond.

Mass loading from the HLF to the TMF Pond was accounted for in the water quality modelling by multiplying the estimated HLF toe seepage flow rate by the estimated water quality. HLF drainage water quality values are presented in Appendix IV - A (Table IV - A 2).

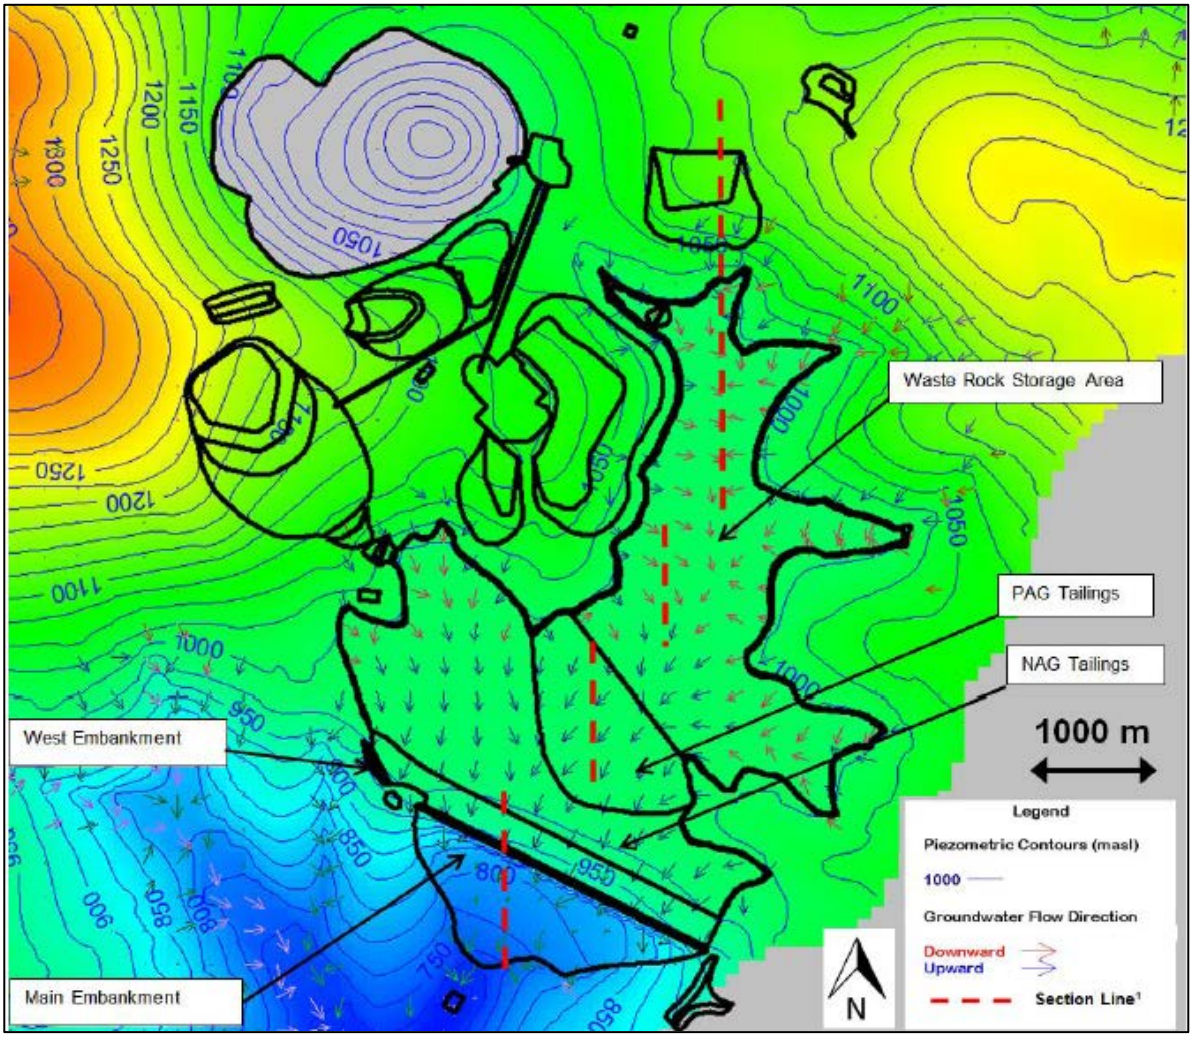
5.1.9 Tailings Slurry Water

NAG and PAG tailings will be transported from the Mill to the TMF as slurry. A portion of the NAG tailings slurry will be conveyed to the Cyclone Sand Plant. Overflow from the sand plant will be discharged to the TMF Pond. The water content that drains from the upstream side of the embankment construction sand (i.e. Sand Plant underflow slurry water) will also report to the TMF Pond. The sand plant will also draw water from the TMF Pond as supplemental feed water. The sand plant process will not introduce additional mass load or water to the TMF Pond system. Average annual inflow rates of slurry water inflow (Table IV - A 1) represent the net rate of slurry water inflow to the TMF Pond (i.e. tailings slurry + sand plant overflow + upstream embankment construction water, minus sand plant feed water).

The water component of the tailings slurry will be process water from the Mill. Slurry water quality was estimated by Lorax (2013). Loading into the TMF Pond was calculated as the concentration in the slurry water multiplied by the total slurry water inflow rate.

TMF Pond water will be reclaimed to the Mill for re-use. Certain water quality parameters are expected to accumulate within the process water over time as the TMF Pond water is recirculated through the mill. Loading rates were provided by Lorax (2013) for those parameters (Sb, As, Mo, Se and U) as g/tonne (i.e., gram of loading per tonne of ore processed). In the water quality model, an incremental mass of those accumulating substances was added to the slurry water quality at each time step based on the mine production schedule (approximately 120,000 tonne/day) from the KPL (2013a) water balance. Slurry water source terms are provided in Appendix IV - A (Table IV - A 2).

5.1.10 Tailings and Waste Rock Porewater Displacement



KPL (2013c) predicted that there will be upward groundwater flow from a portion of the saturated PAG tailings into the TMF Pond. The majority of the waste rock is also expected to have upward groundwater flow (Figure 5-2).

Inflow to the TMF Pond from tailings pore water will be highest during Operations due to tailings consolidation, and will gradually reduce following Operations as the tailings consolidation process slows. When tailings consolidation stops, the on-going tailings and waste rock pore water displacement will be the result of groundwater flow through the tailings and waste rock voids. Average annual flow from the tailings and waste rock into the TMF Pond are summarized in Table IV - A 1.

The KPL water balance provided the total flow rate of tailings pore water displacement which was the sum of groundwater flow and tailings consolidation flow from the combined NAG and PAG tailings. SEA subdivided the total flow into NAG and PAG components. KPL (2013c, Table 5.1) provided estimates of groundwater seepage from the tailings to the TMF Pond for various snapshots in time. The relative proportions of NAG and PAG seepage were adopted by SEA and used to sub-divide the total seepage flow rates. Relative proportions of PAG and NAG seepage are presented in Table 5-2.

Table 5-2. Components of Total Tailings Porewater to the TMF Pond

Year	Fraction of Total Tailings Pore Water Flow from Tailings to TMF Pond (%)	
	PAG	NAG
4	11	89
10	12	88
19	5	95
22	4	96
>22	4	96

Source: KPL (2013c)

Figure 5-2. Numerical Hydrogeological Model of TMF, Hydraulic Gradients

Lorax (2013) estimated the porewater quality of the Waste Rock, NAG Tailings and PAG Tailings (provided in Appendix IV - A, Table IV - A 4). Mass loading into the TMF Pond was calculated in the water quality model by multiplying the water quality by the flow rate for the given time steps. Water quality for years not provided by Lorax were assumed by SEA to be equal to the nearest later year (i.e., years 0-3 were equal to year 4, years 5-9 were equal to year 10, etc.). During operations, it would be reasonable to assume the tailings consolidation portion of the porewater would be similar to tailings slurry water, or pond water (for subaqueously deposited tailings (e.g., PAG tailings)) however, once mill operations cease, all tailings pore water would be expected to be of the characteristics assigned by Lorax and included in the water quality model. This simplifying assumption does not have an effect on long term TMF pond water quality – i.e., once the TMF commences discharge.

Following Operations, the North TMF Wetland will be constructed over the waste rock. A portion of the total upward flow of pore water from the waste rock will enter the North TMF Wetland. Some mass load will be removed in the North TMF Wetland prior to entering the TMF Pond via the wetland discharge. However, as it is not possible to predict what fraction of the upward flow will be treated, the total mass load associated with the upward flow through waste rock was conservatively assumed to enter the TMF Pond rather than part of it entering the North TMF Wetland for treatment.

A layer of tailings (approximately 3 m thick) will be placed over waste rock in the last few years of Operations and will act as a growth medium for the wetland and an attenuation barrier for metals transport from waste rock. The attenuation associated with this tailings layer was not accounted for in the development of the source terms or in the water quality model input assumptions.

5.1.11 Water Management Pond

The Water Management Pond (WMP) will be in place downstream from the TMF embankment. The WMP will collect seepage that travels through the TMF embankment and foundation. The WMP will also collect runoff from the downstream (south) faces of the TMF embankments, and water that drains from the embankment sands during embankment construction (i.e., Sand Plant underflow slurry water). During Operations, the WMP water will be recovered by pumping back to the TMF Pond. During the Wetland Construction Phase, the WMP water will be pumped to the Open Pit.

A description of the water balance and water quality model for the WMP is provided in Appendix V (Seepage Pond Water Quality Modelling). Loading from the WMP into the TMF Pond (during Operations) was calculated as the pumping flow rate, multiplied by the water quality in the WMP. Modelled flow rate is presented in Appendix IV – A (Table IV – A 1). Annual water quality of the WMP is presented in Appendix IV - A (Table IV - A 2) for Operations.

5.1.12 Treated Pit Lake Discharge (North TMF Wetland Discharge)

The KPL (2014) water balance simulation showed that the Pit Lake is expected to reach its maximum storage capacity and discharge to the TMF after approximately Year 109. Before entering the TMF Pond, the Pit Lake discharge will be directed to the North TMF Wetland, an engineered wetland located at the northern edge of the TMF (on Figure 2-3). After the pit lake discharge flows through the wetland system, the treated Pit Lake discharge will enter the TMF Pond.

According to the *Conceptual Reclamation and Closure Plan* (BCL, 2013), the total annual Pit Lake overflow volume will be discharged to the TMF wetland at a controlled rate during the warmest months of the year (June through September, inclusive) for optimal operation of the

TMF wetland treatment system. KPL (2014) modelled the discharge as a constant flow of approximately 180 l/s over the four month period. Inflow of water to the wetland system will be composed of direct precipitation, background runoff, Pit Lake discharge, and seepage (up to 11 L/s) from the Pit Lake. Outflow will include evaporation and discharge via the outlet into the TMF Pond. The estimated average annual discharge from the wetland system is provided in Table IV - A 1.

Clear Coast Consultants (2013) provided the maximum expected water quality concentrations in effluent, and 15% removal for sulphate (Table 5-3) from the North TMF Wetland. Water quality was calculated as the balance of inflows and outflows of water and loadings to the North TMF Wetland. If the calculated water quality in the wetland effluent exceeded the maximum effluent concentrations (Table 5-3) then water quality in the effluent was set equal to the maximum effluent concentrations.

Average annual inflow water quality from the North TMF Wetland to the TMF Pond is provided in Appendix IV - A (Table IV - A 2) for initial discharge of the Pit Lake (Year 109), and long-term conditions (Year 200).

Table 5-3. Maximum Effluent Water Quality from the North TMF Wetland

Water Quality Parameter		Maximum Effluent Water Quality (mg/L)
Sulphate	(SO_4)	15% reduction
Cadmium	(Cd)	0.000080
Copper	(Cu)	0.0040
Molybdenum	(Mo)	0.073
Mercury	(Hg)	0.000026
Selenium	(Se)	-
Silver	(Ag)	0.00010
Uranium	(U)	0.015
Zinc	(Zn)	0.030

5.2 TMF Pond Outflows

The rate of mass exiting the TMF Pond for a given pond outflow rate was calculated as the concentration in the TMF Pond, multiplied by the outflow rate of water over a given time-step. TMF Pond outflows are summarized in the following section.

5.2.1 Evaporation

The monthly outflow of water from the TMF Pond due to evaporation was calculated for a given time step as the pond area, multiplied by the monthly depth of evaporation. Calculated losses to evaporation increased throughout Operations and Wetland Construction Phases as pond surface area increased. Modelled evaporation rates are presented in Table IV - A 1.

While evaporation was accounted for in the water balance, no outflow of mass load was associated with evaporation in the water quality model.

5.2.2 Tailings and Waste Rock Void Entrainment

When tailings and waste rock are deposited in the TMF, the pond water will become entrained in the voids of the deposited solids. Losses to voids will only take place during Operations, because waste rock and tailings will be saturated following Operations. The modelled rate of entrainment is provided in Table IV - A 1.

5.2.3 Mill Reclaim

Water will be reclaimed to the mill for processing during Operations. Average annual reclaim rate from the KP (2014) water balance model is presented in Table IV - A 1.

5.2.4 Pumping to Open Pit

Water from the TMF pond will be pumped to the Open Pit from Year 23 to Year 28 during the Wetland Construction Phase to provide suitable working conditions for wetland construction. The mass load pumped from the TMF Pond was accounted for in the Pit Lake water quality model (Appendix I - Open Pit Water Quality Modelling).

5.2.5 Foundation and Embankment Seepage

KPL (2013c) predicted that toward the south end of the TMF, vertical hydraulic gradients within the tailings will be primarily downward (Figure 5-2). That is, water from the TMF supernatant pond will infiltrate the tailings and flow downward into the foundation material and/or the TMF Embankment. Flow rates will increase throughout operations as the height of the embankment increases, and will stabilize following completion of the embankments. Modelled flows from the TMF Pond to the foundation and embankment are summarized in Table IV - A 1.

5.2.6 Spillway Discharge

In the TMF Discharge Phase and beyond, surplus TMF Pond water will discharge through the South TMF Wetland and into Casino Creek via the TMF Spillway. The South TMF Wetland will be an engineered wetland for the removal of some contaminants. The wetland layout was designed by BCL (2013) and is illustrated on Figure 2-3. South TMF Wetland water quality is described in Section 5.4.

5.3 Calculation of TMF Pond Water Quality

Water quality in the TMF Pond was calculated as the cumulative mass of a given substance in the pond water, divided by the free water volume stored in the pond over a given time step interval.

The TMF Pond mixing model output concentrations were assessed for solubility controls at each time step of the model simulation by coupling GoldSim and PHREEQC. PHREEQC is a geochemical modelling software developed by the United States Geological Survey. To predict pH, all water quality inputs to PHREEQC were charge balanced, and the residual balance was placed on either chloride or sodium. During each timestep, GoldSim ran PHREEQC and the resulting concentrations returned from PHREEQC were linked to the South TMF wetland. Input assumptions are provided in Table 5-4.

Table 5-4. PHREEQC Assumptions for TMF Pond Water Quality Modelling

PHREEQC Input Assumptions	
Equilibrium Phases (minerals form solid phase - precipitate forms)	$Fe(OH)_3(a)$ $Al(OH)_3(a)$
Database	wateq4f
pH	Charge balance (PHREEQC determines pH of solution and alkalinity)
PE	10 (oxidizing)
Temperature	5°C
Oxygen	Atmospheric conditions
CO_2	Atmospheric conditions

5.4 South TMF Wetland Discharge Water Quality

In the TMF Discharge Phase (and beyond), TMF Pond water will be released through the TMF spillway and into Casino Creek. Prior to discharge to the spillway, the TMF Pond water will travel through the South TMF Wetland, an engineered wetland for the removal of certain contaminants. The wetland layout was designed by BCL (2013) and is illustrated on Figure 2-3.

Clear Coast Consultants (2013) provided maximum water quality concentrations for the South TMF Wetland effluent (Table 5-5), and this treatment was included in the water quality model. 15% removal efficiency was incorporated into the wetland for sulphate. If no treatment was specified, the modelled TMF Pond water quality for that parameter was assumed to report to Casino Creek via the spillway.

Table 5-5. Maximum Effluent Water Quality from the South TMF Wetland

Water Quality Parameter		Maximum Effluent Water Quality (mg/L)
Sulphate	(SO_4)	15% reduction
Cadmium	(Cd)	0.000080
Copper	(Cu)	0.0040
Molybdenum	(Mo)	0.073
Mercury	(Hg)	0.000026
Selenium	(Se)	-
Silver	(Ag)	0.00010
Uranium	(U)	0.015
Zinc	(Zn)	0.030

6 Results and Discussion

6.1 Water Quality Predictions

Average annual TMF Pond water quality for select parameters are provided in Table 6-1 for each water management phase for select water quality parameters. Water quality model results are also provided for the TMF Spillway discharge to illustrate the modelled effects of the treatment wetland on TMF Pond water quality prior to discharge to Casino Creek. Tables of water quality model results are provided for all modelled parameters in Appendix IV - B (Table IV - B 1).

Time series plots for select parameters are provided on Figure 6-1 to Figure 6-8 for a single realization of the model (Realization #1). Wet and dry years with 10 year return period are identified on the plots to help illustrate the effects of inter-annual variation in hydrologic conditions. Because the TMF Pond is a large water body, fluctuations in water and mass loading are well attenuated and the resulting variation in TMF Pond water quality from wet and dry years is relatively small.

PHREEQC results indicated that the TMF Pond will be at near neutral pH during all phases of mining. A time-series plot of TMF Pond pH is presented on Figure 6-9.

Table 6-1. TMF Pond Water Quality Model Results

Water Quality Parameter		TMF Pond Water Quality (mg/L)			
		Operations	Wetland Construction Phase	TMF Discharge Phase	Pit Discharge Phase
pH		6.1	6.8	6.9	6.9
Sulphate	(SO_4)	1,242	695	335	266
Fluoride	(F)	2.1	1.2	0.65	0.63
Cadmium	(Cd)	0.00064	0.00065	0.00034	0.00016
Copper	(Cu)	0.33	0.067	0.11	0.073
Iron	(Fe)	0.0012	0.00030	0.00022	0.00023
Molybdenum	(Mo)	0.37	0.20	0.085	0.066
Selenium	(Se)	0.015	0.0069	0.0043	0.0043
Uranium	(U)	0.018	0.033	0.048	0.042
Water Quality Parameter		**TMF Spillway Water Quality (mg/L)**			
		Operations	**Wetland Construction Phase**	**Initial TMF Pond Discharge**	**Pit Discharge Phase**
pH		-	-	6.9	6.9
Sulphate	(SO_4)	-	-	283	225
Fluoride	(F)	-	-	0.65	0.63
Cadmium	(Cd)	-	-	0.000080	0.000080
Copper	(Cu)	-	-	0.0040	0.0040
Iron	(Fe)	-	-	0.00022	0.00023
Molybdenum	(Mo)	-	-	0.085	0.066
Selenium	(Se)	-	-	0.0043	0.0043
Uranium	(U)	-	-	0.015	0.015

1. Values represent average water quality results over the duration of each mining phase for a single model realization (Realization #1).
2. TMF Spillway will have zero discharge during the Operations and Wetland Discharge Phases.

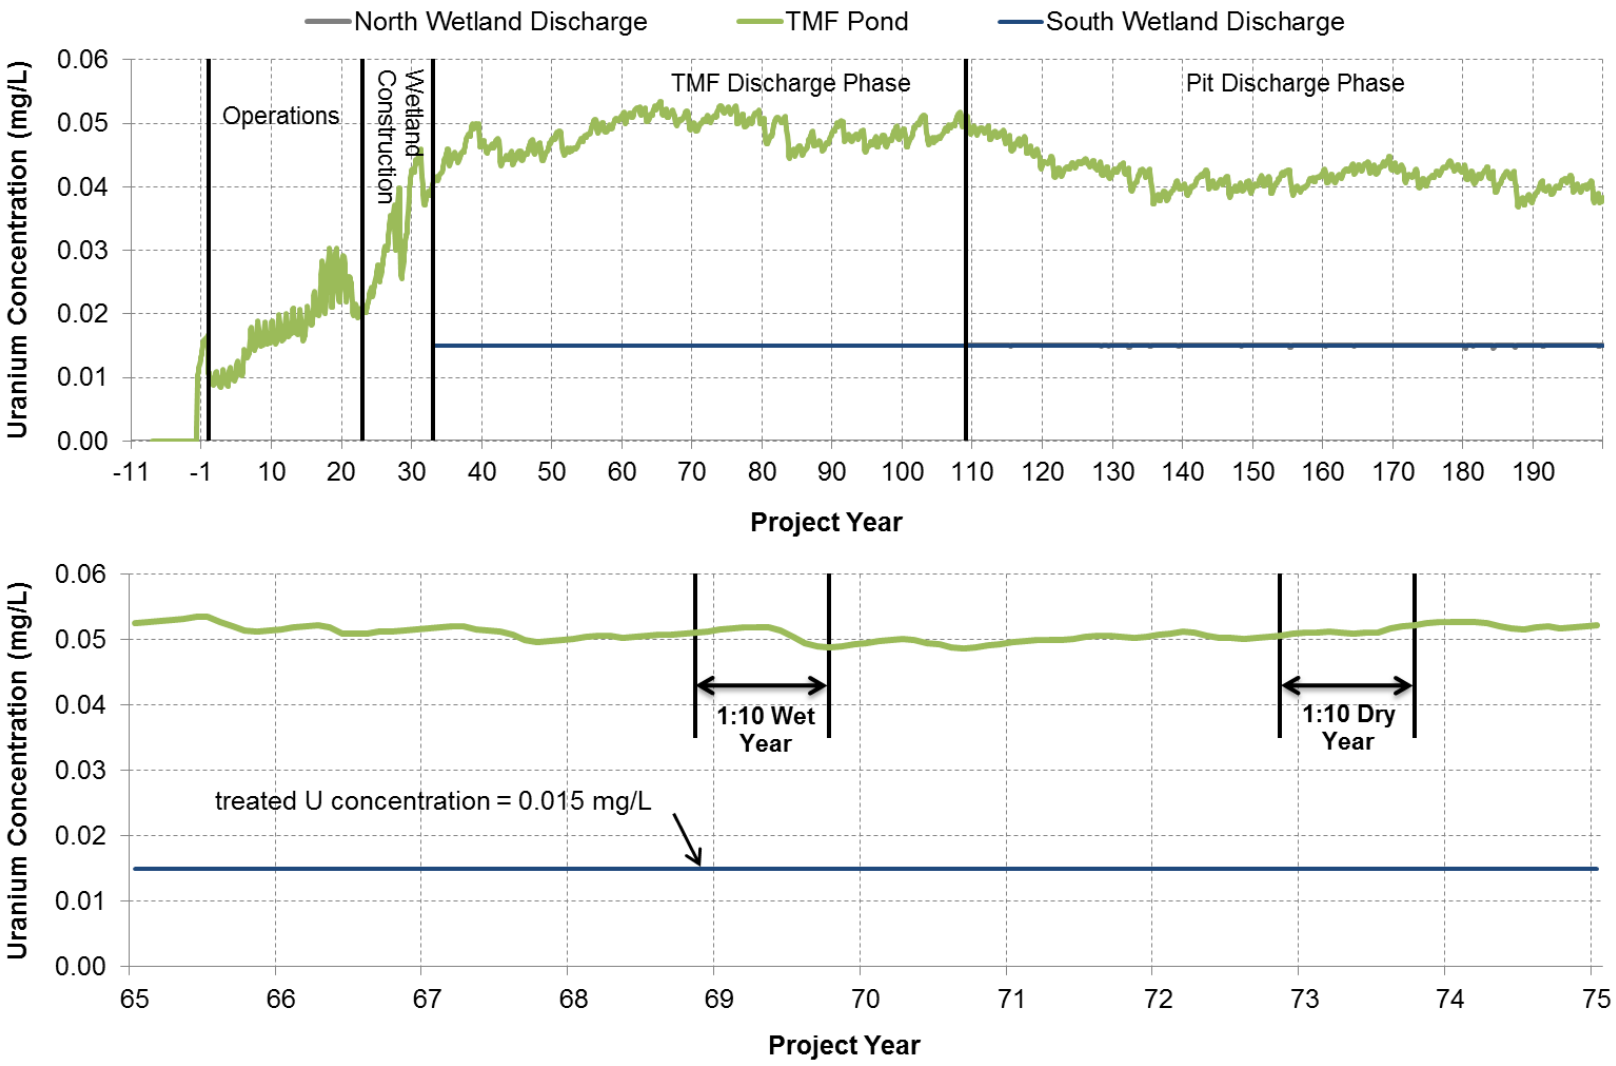

Figure 6-8. Modelled Uranium Water Quality in the TMF Pond and Wetlands

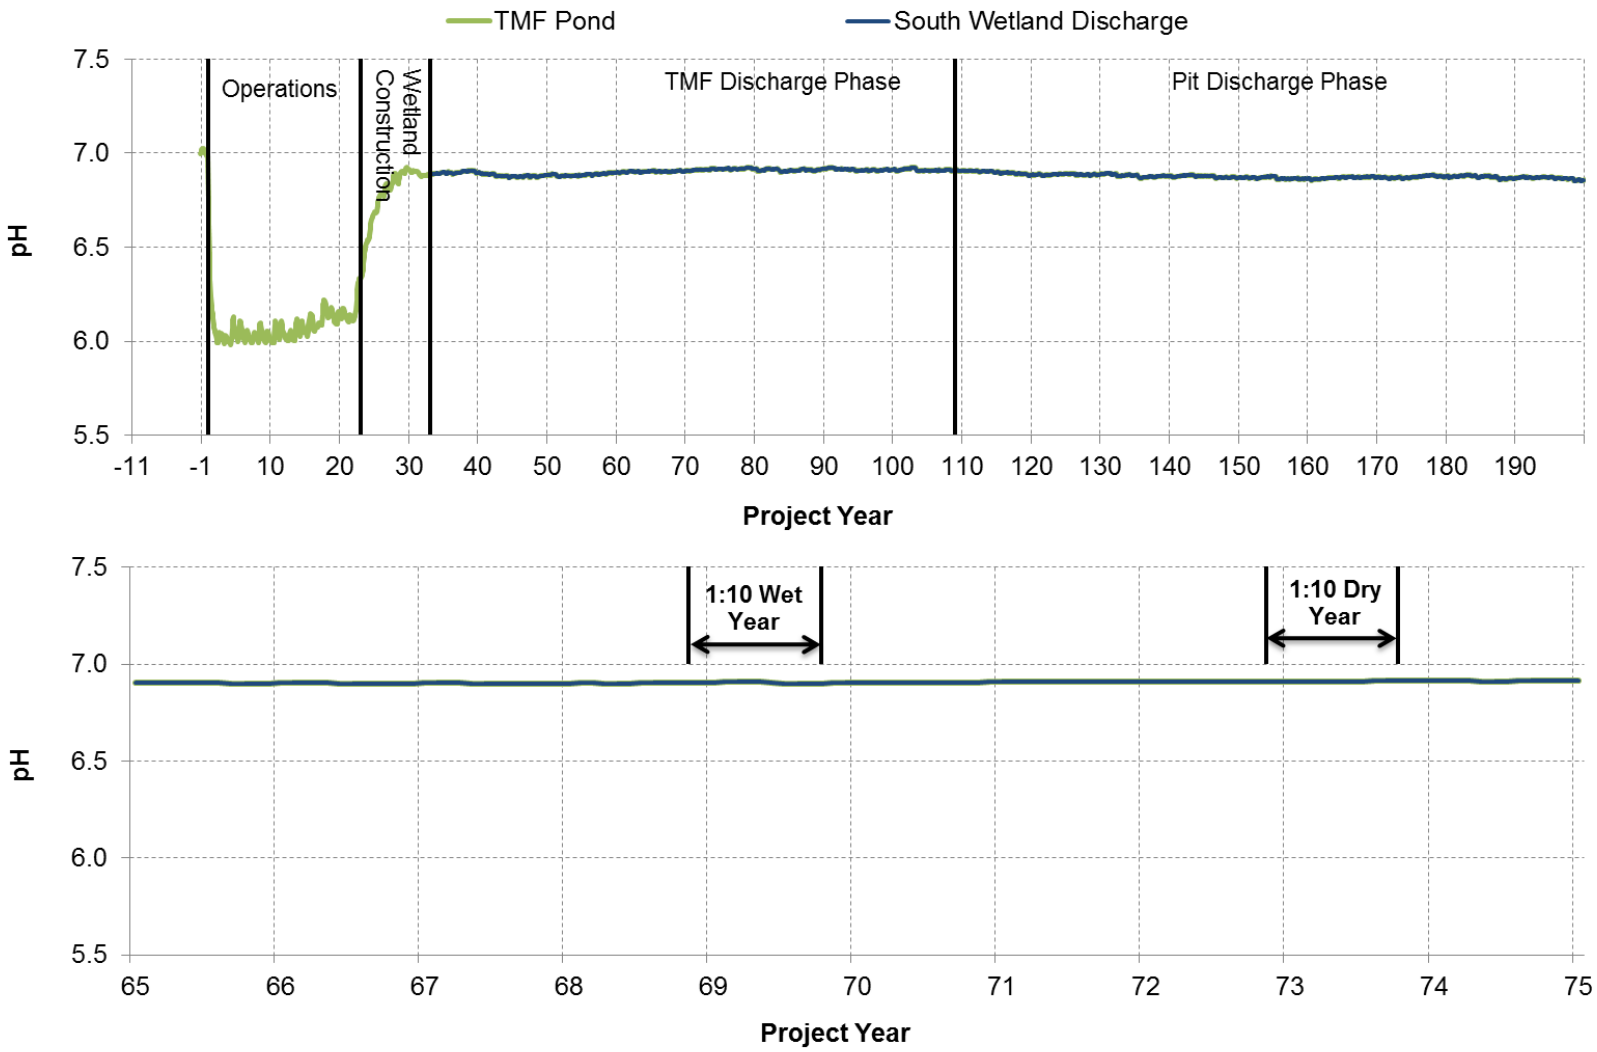

Figure 6-9. Modelled pH of the TMF Pond

Figure 6-10 shows an example of the accumulation of selenium in the process water quality for a single model realization to illustrate the influence of the process water on the TMF Pond water quality. The blue line is the process water quality and the green line is the TMF Pond water quality. Because the TMF pond experiences seasonal dilution, the reclaim water concentration also varies, and thus so will the process water.

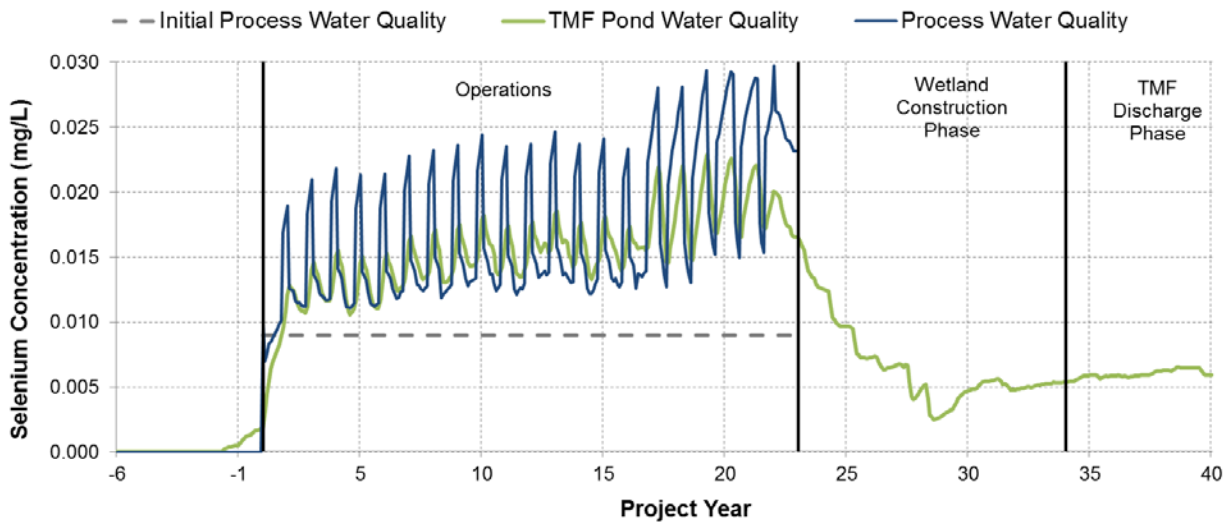

Figure 6-10. Example of Process Water Quality and TMF Pond Quality for Selenium

6.2 Individual Contributions of Mass Loading Sources to the TMF

Individual contributions of each mass loading source are presented in Table 6-2 (Operations), Table 6-3 (Wetland Construction Phase), Table 6-4 (TMF Discharge Phase), and Table 6-5 (Pit Discharge Phase). Individual contributions of mass loading sources are provided in Appendix IV – B (Table IV-B2 to Table IV-B5) for all modelled water quality parameters.

In general, during TMF Discharge, upward fluxes of CoCs in the porewater from the tailings and waste rock are the dominant loads to the TMF Pond. Once the Pit Discharge Phase begins (via the North TMF Wetland), this source is a large proportion of the overall load to the TMF Pond for some water quality parameters.

Table 6-2. Loading Source Contributions to the TMF Pond (Operations)

Source of Loading	Fraction Contributing (%)							
	SO_4	F	Cd	Cu	Fe	Mo	Se	U
Background Runoff	0	0	1	0	0	0	0	3
Stockpile (runoff + seepage)	1	3	44	93	20	2	9	20
Waste Rock Runoff	0	0	7	1	0	0	5	4

1. Includes domestic wastewater treatment plant effluent (average rate = 1.3 L/s during Operations) and mill site runoff
2. Following Operations, runoff from the reclaimed stockpile areas was accounted for as “Background Runoff” in the water balance.
3. Includes sand plant overflow, embankment construction water from the upstream face, minus the sand plant make-up water.
4. Porewater displacement from NAG Tailings, PAG Tailings, and Waste Rock includes tailings consolidation seepage (tailings only) and seepage from ore stockpiles.
5. Values reported in this table represent average model results from 52 model realizations.

Table IV - A 2 Source Terms for Inflows to the TMF Pond

Water Quality Model Parameter		Background Runoff (W13) [1] (mg/L)	FWSP Inflow (W8) [1] (mg/L)	Tailngs Beach Runoff		HLF Drainage		WMP Pumping [2] (mg/L)	Tailings Slurry Water [3]		N TMF Wetland [4] Pit Discharge Phase (mg/L)

1. Median water quality from water quality data collected at W13 and W8.
2. Average water quality during the Operations Phase.
3. Represents the water quality of the slurry water. For parameters where a “mass accumulation” source term was provided, the “water quality” value represents the initial water quality in the slurry water at the beginning of the model simulation.
4. Average water quality during the Pit Discharge Phase.

Table IV - A 3 **Source Terms for Inflows to the TMF Pond - Loading Rates and Maximum Concentrations for Unsubmerged Waste Rock in the TMF during Operations**

Water Quality Parameter	Mass Loading Rate (mg/tonne/year)			Maximum Concentration (mg/L)		
	Year -3 to Year 4	Year 5 to Year 14	Year 15 to Year 20	Year -3 to Year 4	Year 5 to Year 14	Year 15 to Year 20

1. Average of all years during the Operations Phase, calculated from output from model Realization #1.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

1 Introduction

The Casino Project (the Project) is a proposed mining project in the west-central Yukon. The deposit will be mined using open pit methods, with a nominal mill throughput of approximately 120,000 tonnes/day of ore over a 22 year operating life. Milling operations will produce molybdenum and copper concentrates through conventional flotation circuit milling and gold and silver doré will be produced by cyanide heap leaching.

Seepage water and runoff from the TMF embankment and foundation will be collected by an underdrain system and a surface ditch system that discharge into a Water Management Pond (WMP) located downstream of the TMF main embankment (KPL, 2012). Additionally, the WMP will collect hydrocyclone underflow from the tailings sand used to construct the TMF Embankment. All water collected in the WMP will be pumped back to the TMF Pond during Operations.

Following mine closure, seepage recovered downstream from the TMF embankments will be stored in the WMP through the low flow months of the year (winter), and released during months when Casino Creek flows are higher (spring, summer, and fall) when the seepage water can mix with the TMF Spillway discharge prior to entering Casino Creek.

A water quality model was developed to predict mine drainage water quality and the potential for effects on the receiving environment of the proposed Casino Mine. A site-wide water balance was developed by Knight Piésold Limited (KPL) and was used by Source Environmental Associates Inc. (SEA) as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim.

A water balance model was initially developed by KPL in 2013 (and is described in KP. 2013a). The 2013 water balance was run using average annual estimates for hydrologic conditions at the site. Water quality modelling for the average annual water balance was carried out by SEA. Modelling methodology and results were reported in SEA (2013).

In 2014, a climate variability water balance model was developed by KPL (and is described in KPL, 2015) to account for the expected variability in hydrological conditions (i.e. wet and dry periods) from year to year. SEA used the climate variability water balance as the basis for the water quality model that is described herein.

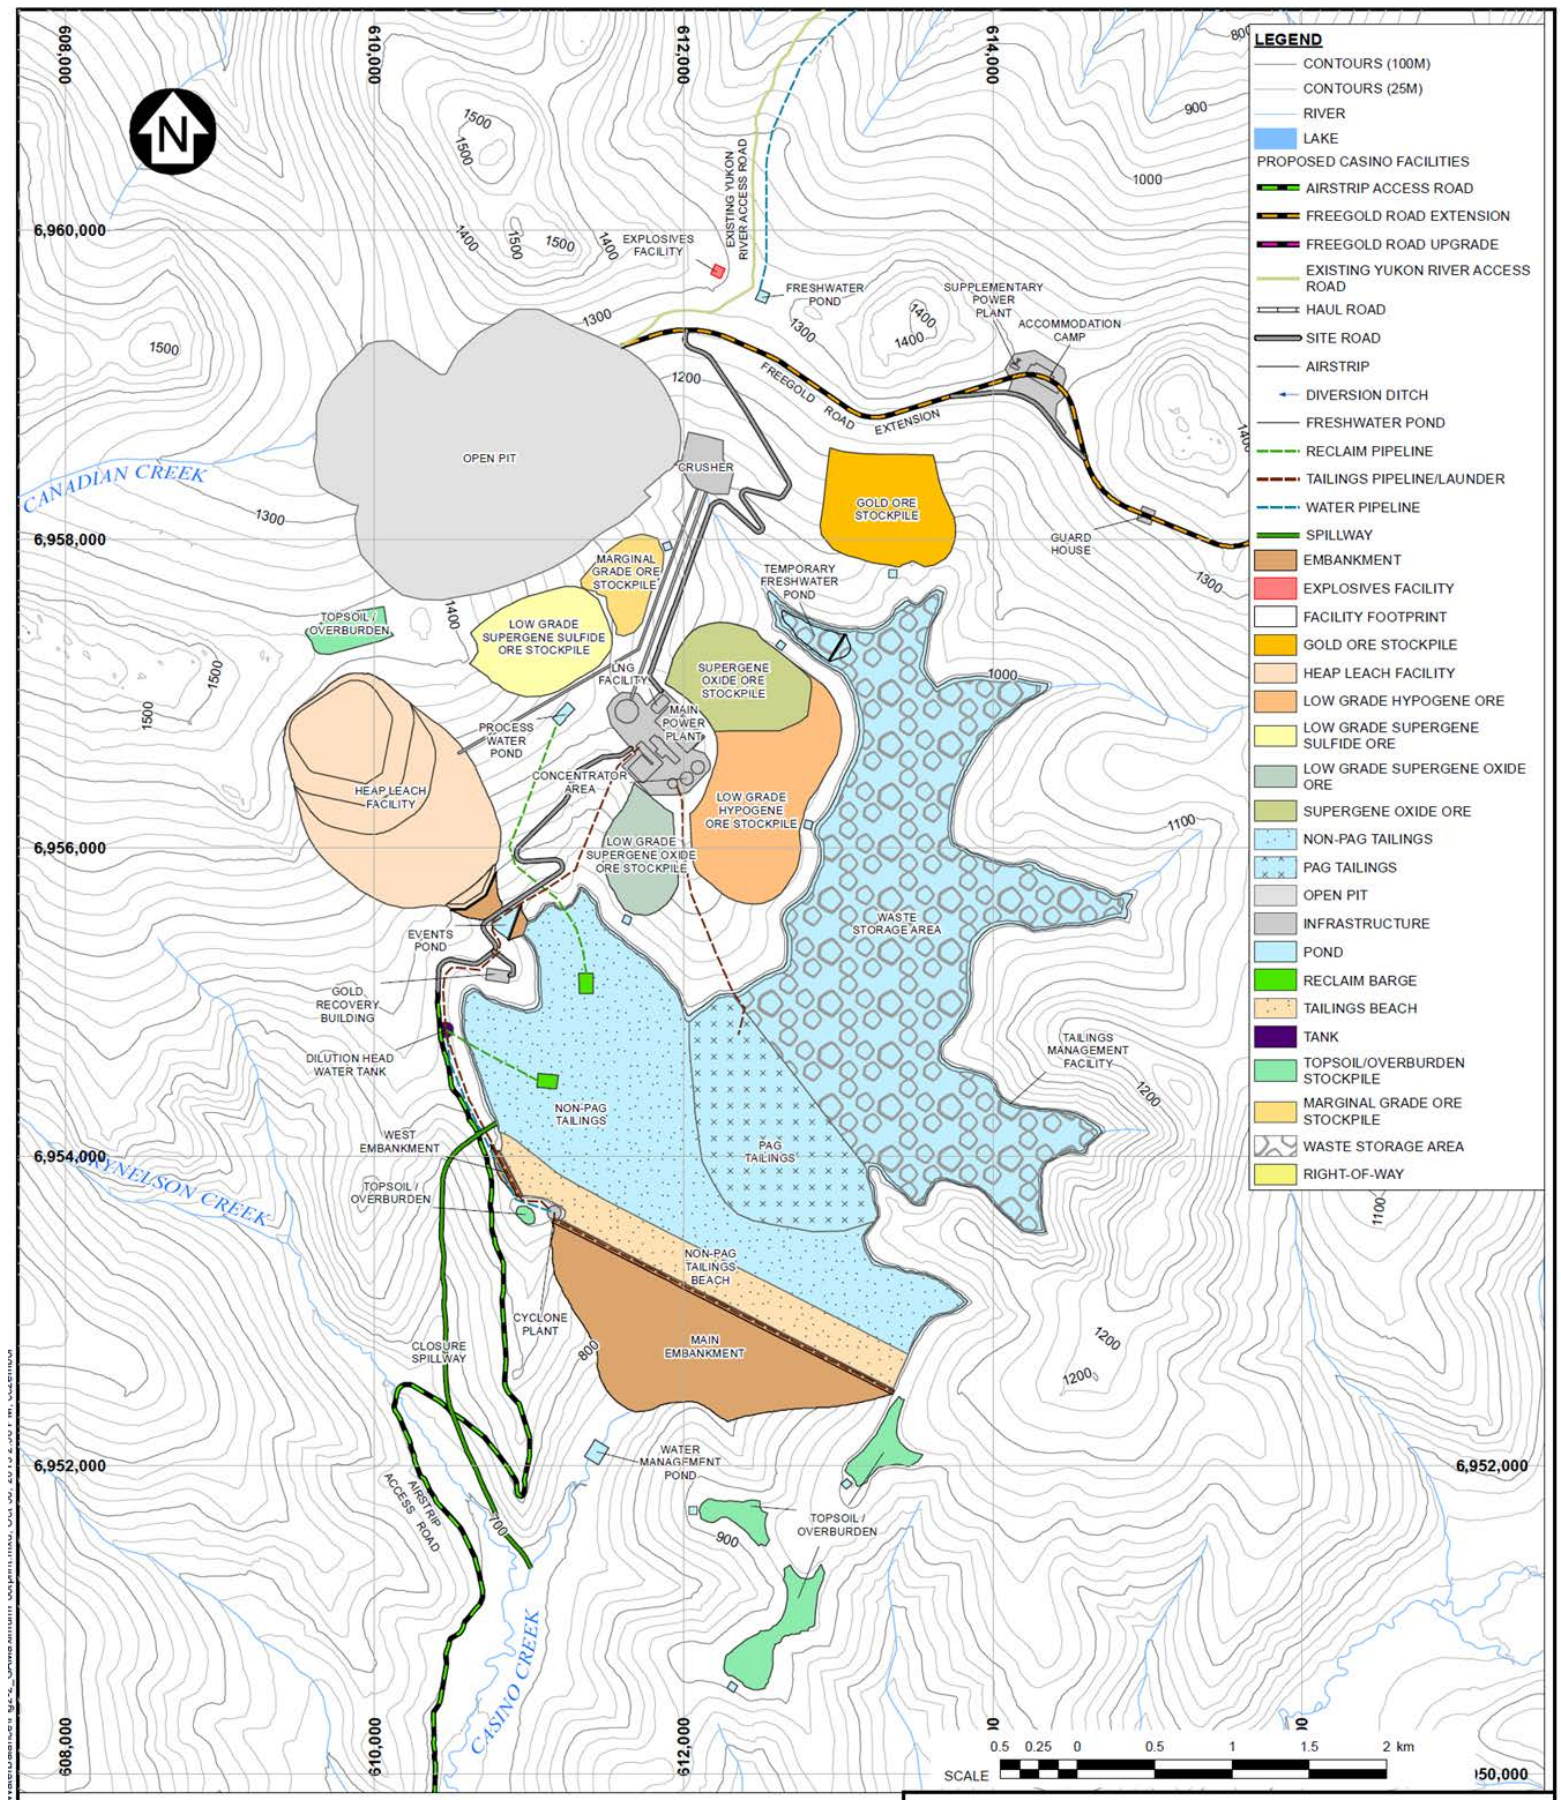
This report presents the methodology and results of the water quality predictions for the WMP model. This report contains all information relevant to the water quality model, and repeats the pertinent information previously provided in the December 2013 report (SEA, 2013). A comparison between the SEA (2013) Pit Lake water quality modelling report and this report is provided in Table 1-1.

Table 1-1. Comparison between 2013 and 2015 Modelling Reports

Concept	SEA (2013) Report	Applies to this Report
Water Balance Input Dataset	Average monthly hydrologic conditions (e.g. precipitation, temperature, streamflow, etc.) were used as input for every year of the model simulation.	Inter-annual variation in hydrologic conditions was applied throughout the model simulation. Water balance output flows were calculated from a synthetic, long-term (52 year) input dataset of monthly hydrologic conditions. The synthetic dataset was derived from regional and site data. **Rationale:** Using the range of monthly flows is more conservative (compared to using average annual flows) because realistic wet and dry periods can be simulated.
Estimation of Wet and Dry Years	n/a - wet and dry years were not simulated.	1-in-10 year wet and dry years were identified in the water quality output time-series plots. **Rationale:** To illustrate how the water quality management system will perform as a results of infrequent wet/dry periods.
Monte-Carlo Analysis (Stochastic Modelling)	Stochastic modelling was not carried out.	Model simulations included 52 unique input hydrology datasets. A statistical summary was generated from the water quality model output for the 52 realizations. **Rationale:** To account for all possible water balance flow scenarios that could result from the input hydrology dataset.
Project Phase Start Dates for TMF Discharge Phase and Pit Discharge Phase	Project dates were based on KPL (2013) water balance model output.	Project dates were based on KPL (2015) water balance model results.
TMF Seepage Cut-Off System	The TMF seepage cut-off system was to be constructed after Operations. As a result, during Operations, the WMP was assumed to have a 90% capture efficiency with 10% seepage by-pass to Casino Creek. Following Operations, the seepage cut-off system was to be constructed, resulting in 100% seepage capture efficiency (i.e. 0% by-pass).	The seepage cut-off system will be constructed prior to Operations. The seepage collection system was assumed to have 100% capture efficiency during Operations and for all subsequent mine phases. **Rationale**: Reduce the potential for seepage water to enter Casino Creek during Operations.

Concept	SEA (2013) Report	Applies to this Report
Water Management Pond (WMP) / Winter Seepage Mitigation Pond (WSMP)	WMP was to be online for seepage collection during Operations. Following operations, the WSMP was to be used for seepage collection in winter and release during summer. Both facilities were essentially situated in the same location.	For all phases, the seepage collection pond(s) will be referred to as the WMP. **Rationale**: Simplification of terminology.
WMP Pumping to the Open Pit (Wetland Construction Phase)	During the Wetland Construction Phase, the WMP was assumed to be pumped to the TMF Pond.	During the wetland construction phase, the WMP will be pumped to the Open Pit. **Rationale:** Mass load from the WMP by-passes the TMF Pond by pumping directly to the Open Pit.
WMP Release to Casino Creek	Release from the seepage pond was set at a constant rate of 130 L/s from May to August with flows gradually reduced to 50 L/s by November.	Release of WMP was set to 0.8 times flow in Brynelson for typical conditions. To ensure sufficient seepage storage capacity for the following winter an increased release rate (above 0.8 times Brynelson flow) will be used during exceptionally dry periods, to drain-down the WMP. **Rationale:** The available dilution in Brynelson will be utilized by proportioning the release of WMP to the natural hydrograph.
TMF Pond Release to Casino Creek	TMF Pond was allowed to naturally overflow seasonally with no control of the flow rate.	The TMF pond will be released in a controlled manner. The ratio of TMF pond release to WMP release will be set between 1.2 to 2.5, depending on the Project Phase and the month. The ratio increases when there is little flow in Brynelson to provide dilution of the seepage released. **Rationale**: The available dilution in Brynelson is utilized by tying the release of WMP to the natural hydrograph.

Concept	SEA (2013) Report	Applies to this Report
Location of GoldSim-PHREEQC modelling nodes Embedded in the Water Quality Model	Solubility limits were calculated (using PHREEQC) for the following nodes: • Open Pit • TMF Pond • "Mixing Point" (upstream from H18 – where TMF Pond and WMP water mix)	Solubility limits were calculated (using PHREEQC) for the following nodes: • Open Pit • TMF Pond • WMP **Rationale:** Contact of WMP seepage with atmospheric conditions will occur in the WMP and chemical precipitation is more likely to occur in the WMP, rather than at the mixing point.
pH Prediction	pH was calculated for mine contact water (TMF Pond, WMP, Open Pit) using PHREEQC. pH was not calculated for Casino and Dip Creeks.	pH was calculated (using PHREEQC) for mine contact water, Casino Creek and Dip Creek modelling points.
CoC List	7 CoCs were reported. The CoC list did not include fluoride.	Fluoride was added as a CoC, so 8 CoCs are reported. **Rationale**: Fluoride was added as it exceeded a generic water quality guideline



2 Casino Project Water Management Phases

For the purposes of water quality modeling, the Casino Project was sub-divided into five water management phases in (Table 2-1). Project years are described in years relative to the beginning of milling operations. For example, Year -2 refers to the second year before Operations begins, and Year 2 refers to the second year of Operations.

Layout of the Project site is illustrated in Figure 2-1 for Operations. Long-term conditions following mine closure are shown on Figure 2-2.

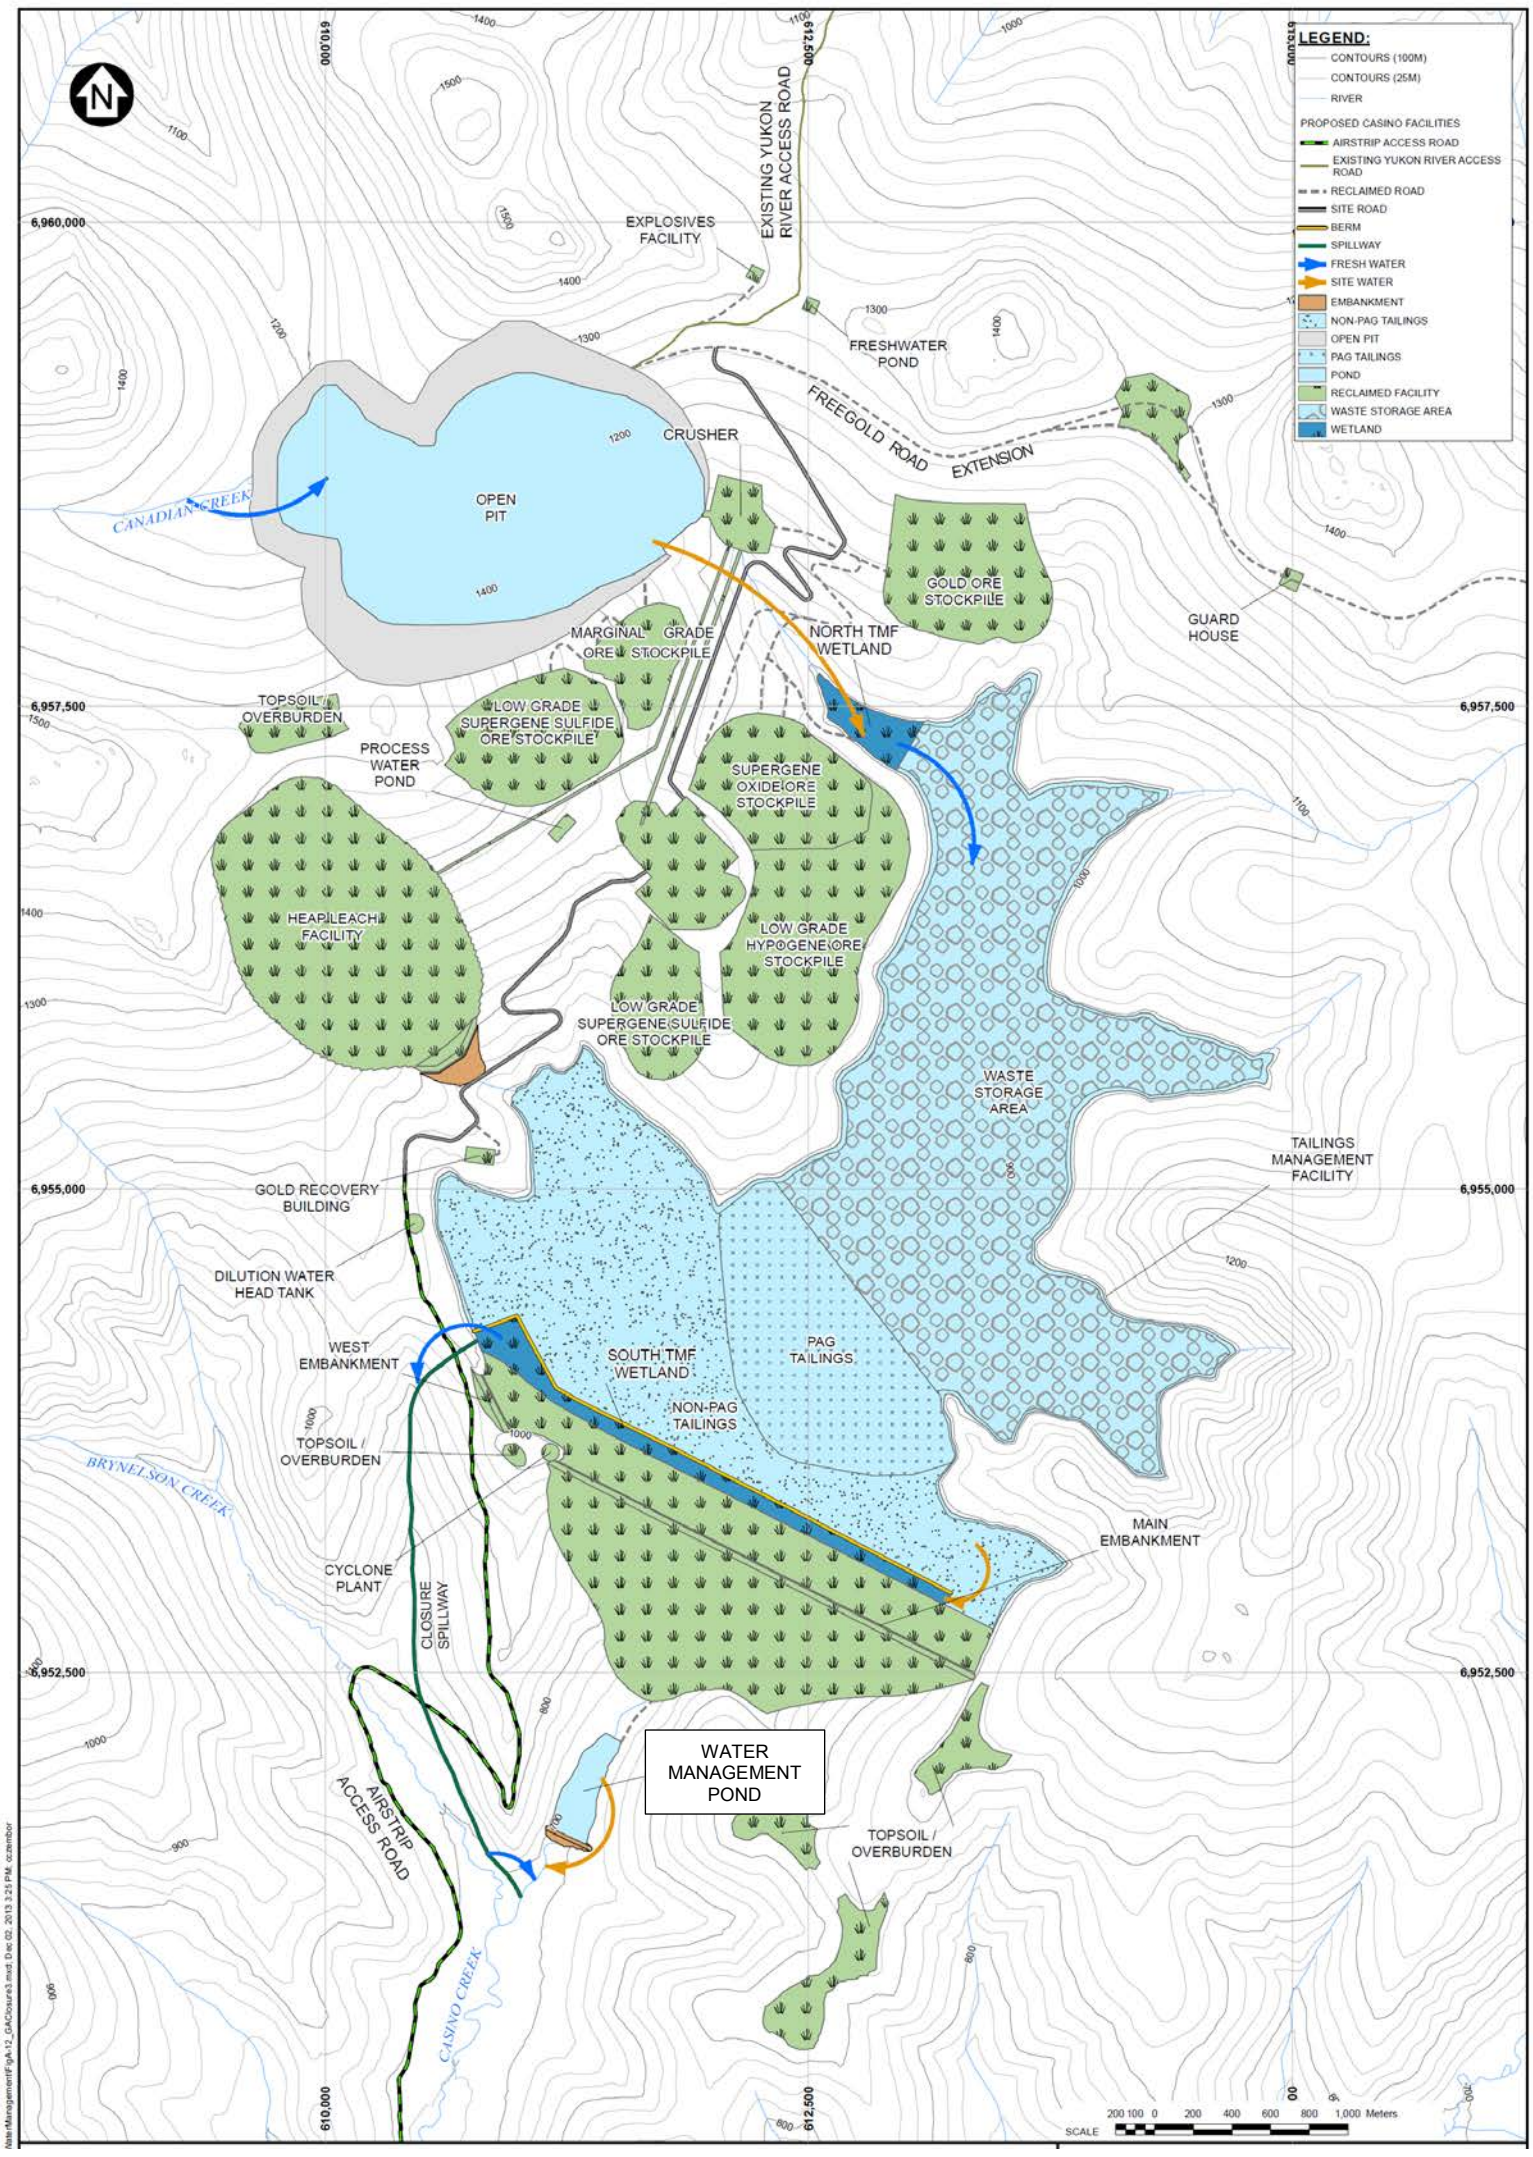


Table 2-1. Water Management Phases

Water Management Phase	Project Year	Project Activities Relevant to WMP and WSMP
Construction	-4 to -1	• Construction of the TMF and associated mining infrastructure. • WMP constructed downstream of the TMF to control sediment and detain runoff from disturbed areas. • Water collected in WMP pumped to TMF Pond.
Operations	1 to 22	• Mining and processing of ore. • Water from TMF embankment and foundation seepage, surface runoff, and embankment construction water collected in the WMP and pumped back to the TMF Pond.
Wetland Construction	23 to 34	• Cessation of milling. • Pump back from the WMP the Open Pit. • Re-vegetation of the TMF Embankment.
TMF Discharge	35 to 109	• Storage of recovered seepage downstream from the TMF embankments in the WMP through the low flow months of the year (winter) and release to Casino Creek during the open water season.
Pit Discharge	> 109

Figure 2-2. Casino Project Overview (Pit Discharge Phase)

3 Model Overview

A site-wide water balance model was developed by KPL and was used as the basis for the water quality model. The water balance and the water quality models were fully integrated in GoldSim. SEA combined the water balance flows with mine loading source terms (Lorax, 2013), and background water quality to predict water quality in the WMP for 27 water quality parameters.

A 52-year model input dataset of monthly weather conditions was developed by KPL in order to simulate the natural variability in hydrologic conditions (i.e. wet and dry periods) that can be expected at the site. The model was run over a time-frame from beginning of Pit Lake formation, to 200 years after the beginning of Operations. Because the model was run over a simulation period of ~200 years, the 52-year input dataset repeated approximately four times during a given simulation.

The model results are presented in two ways in this report:

1) Single Model Realization

   Results generated when one realization of the input hydrology dataset was run with the model. Single realization results provide a time-series of model output which shows a representation of water quality that would result from a realistic range in hydrological conditions at the site. The output provides an indication of how high (or low) water quality concentrations may get, and how often those results are expected to occur. Time-series plots and summary tables of water quality results for a single realization are presented throughout this report.

2) Monte-Carlo Summary (52 Realizations)

   The model was run 52 times. Each model run used a unique input hydrology dataset. The combined output from the 52 model runs (i.e. realizations) represents the range in all possible model outputs resulting from all the possible permutations of the input hydrology dataset. Average annual water balance results presented in this report were generated from the Monte-Carlo Summary results.

Schematics are provided to illustrate the mass transport pathways associated with the WMP during Operations (Figure 3-1), Wetland Construction Phase (Figure 3-2), and the TMF and Pit Discharge Phases (Figure 3-3). Tables of model input and output values are provided for each modelled water quality parameter in Appendix V - A (model input) and Appendix V - B (model results).

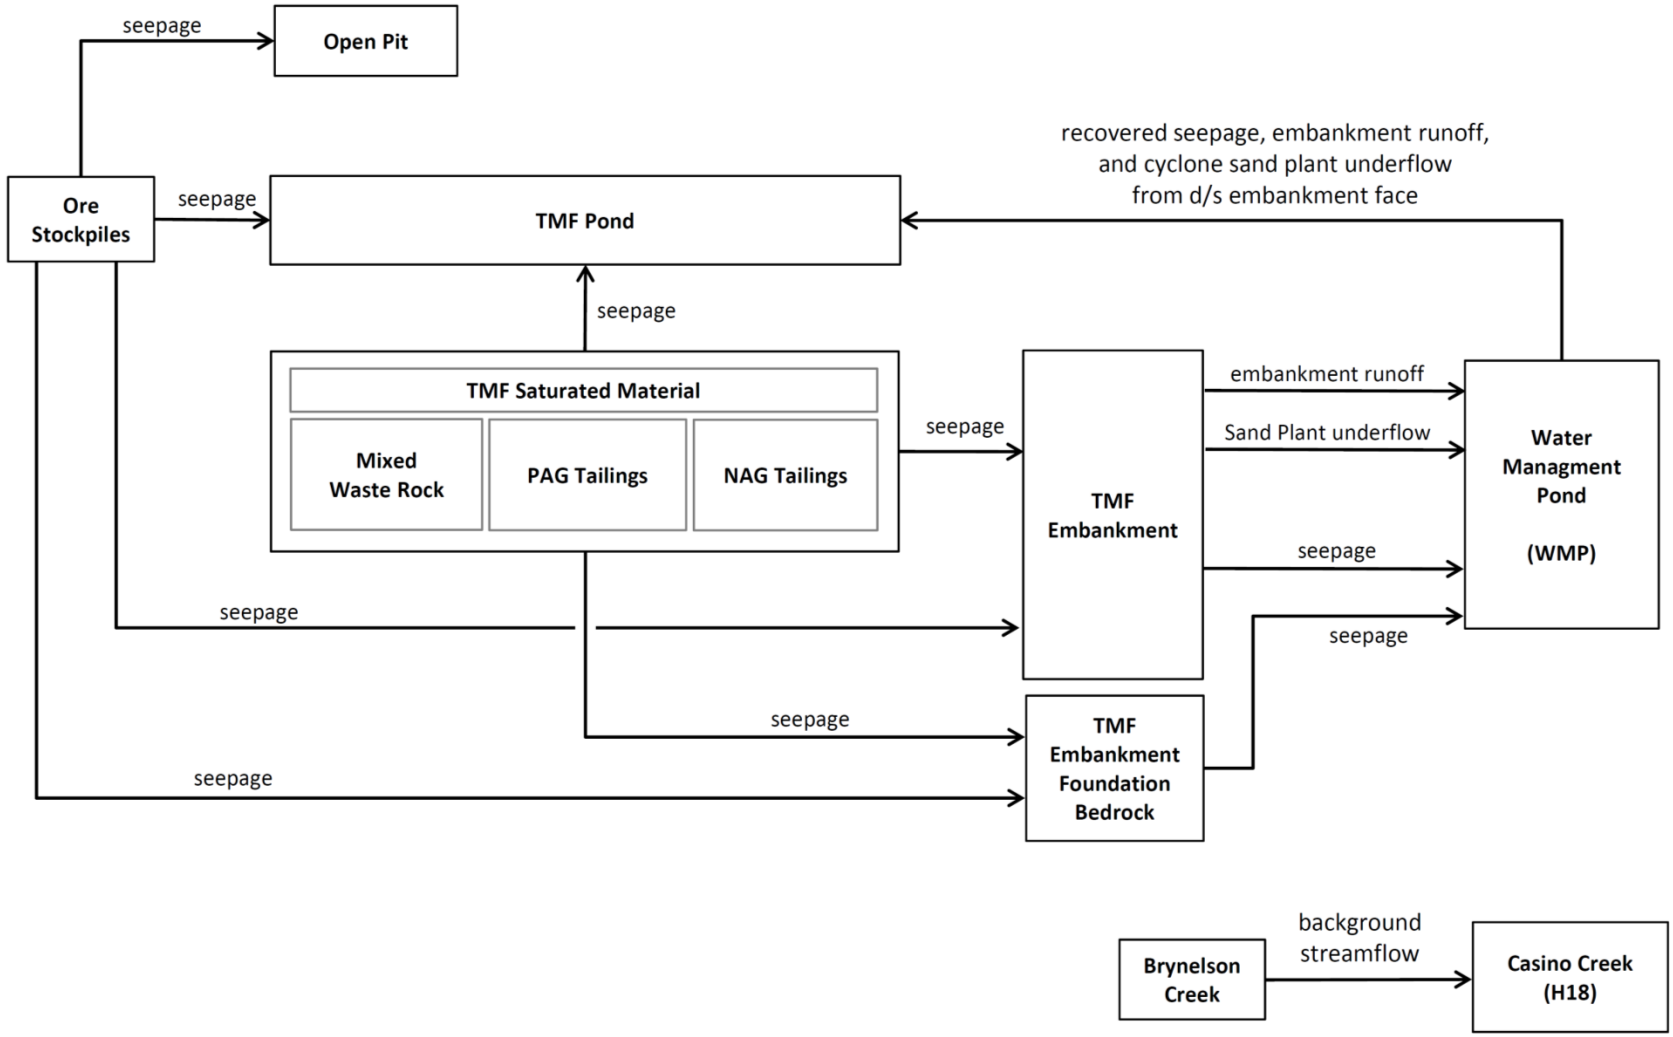

Figure 3-1. Mass Transport Flow Paths Associated with the WMP (Operations Phase)

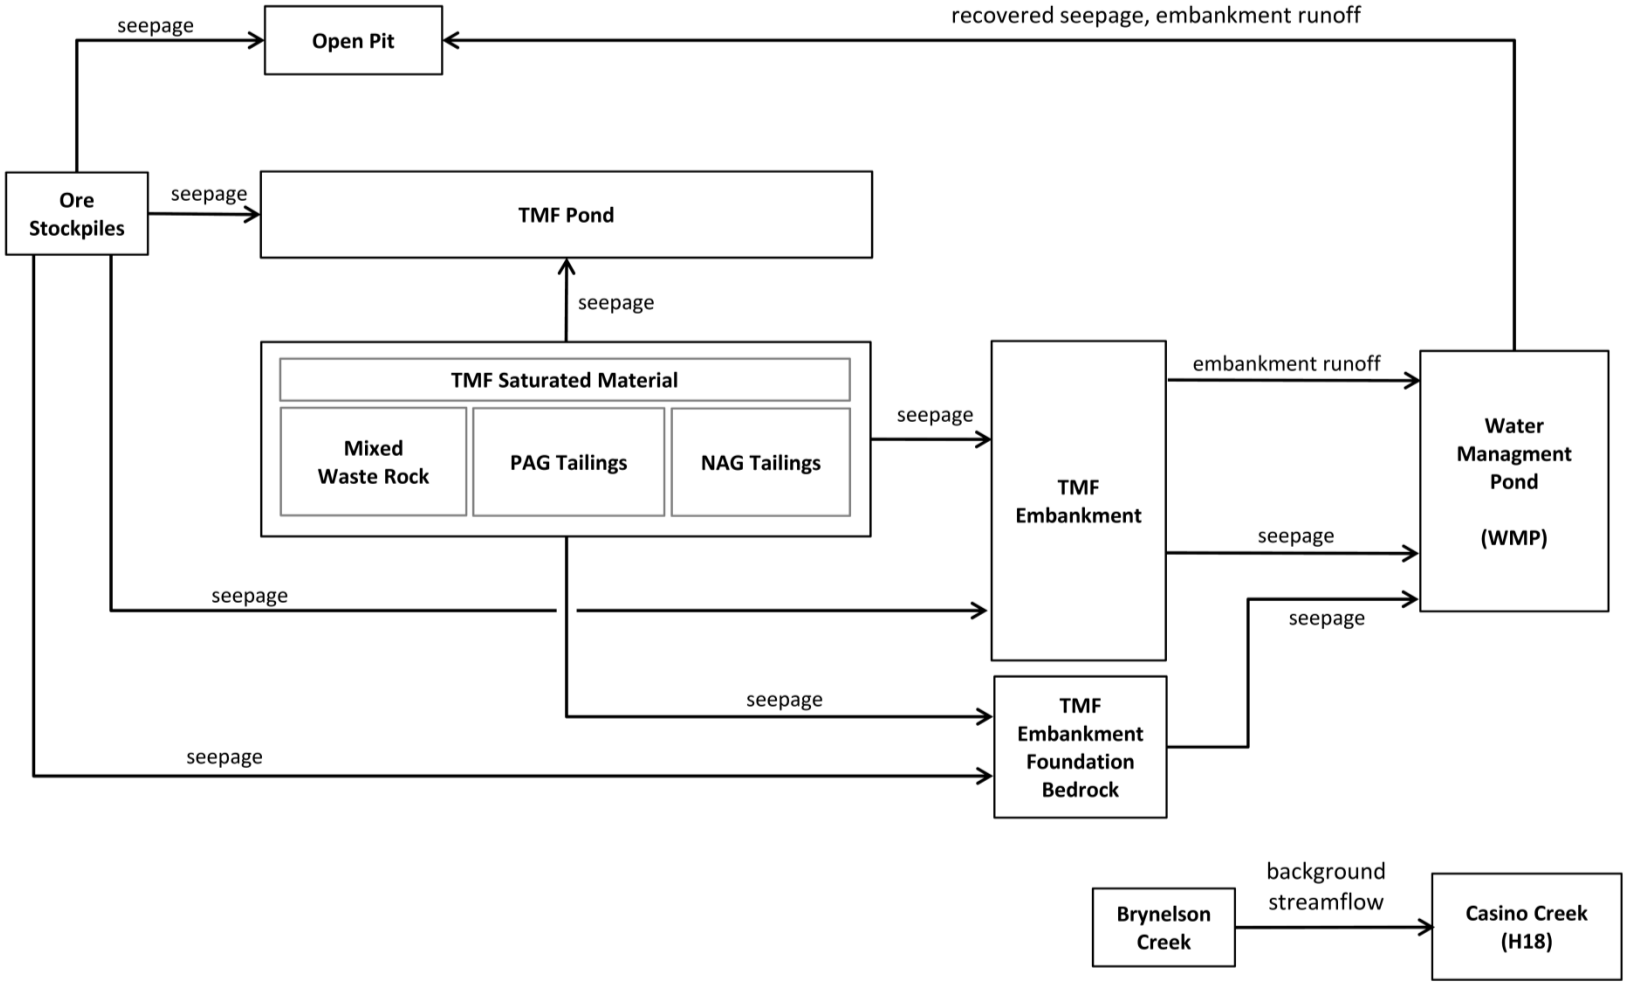

Figure 3-2. Mass Transport Flow Paths Associated with the WMP (Wetland Construction Phase)

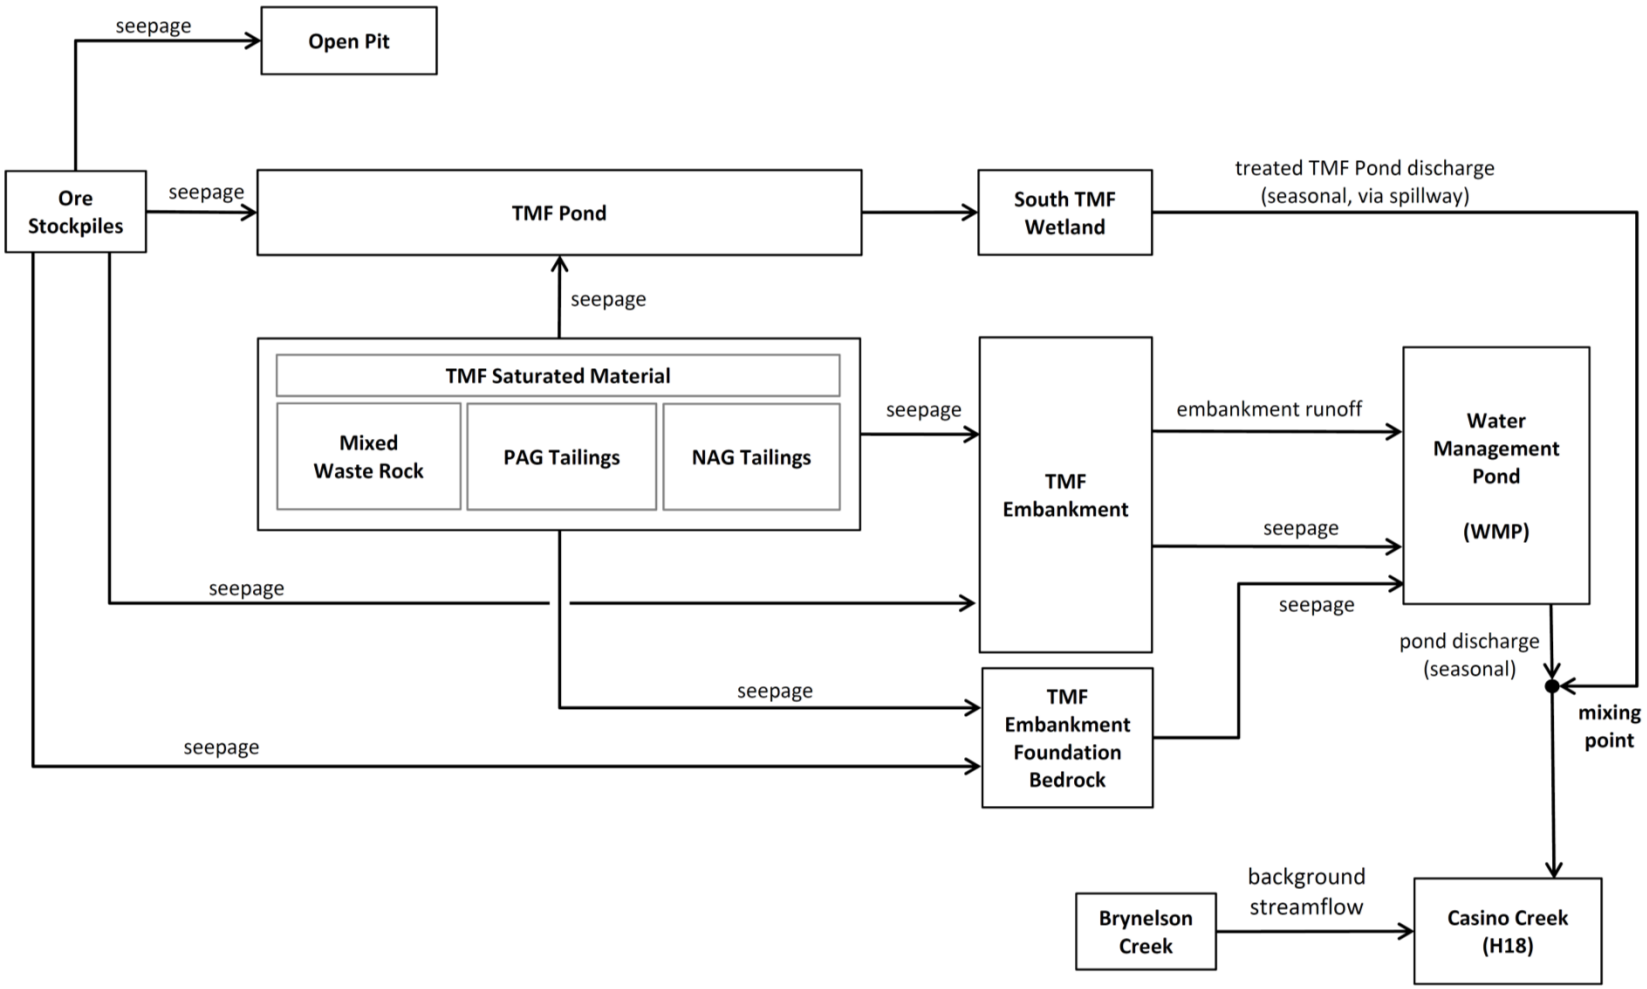

Figure 3-3. Mass Transport Flow Paths Associated with the WMP (TMF Discharge and Pit Discharge Phases)

4 Water Balance Model

WMP inflow and outflow rates from the KPL water balance (2015) are summarized by SEA in Table 4-1 to illustrate the annual flow rates over the duration of the water quality model. The results represent the average results between 52 model realizations.

Foundation and embankment seepage are expected to increase with the size of the TMF embankment. Seepage rates through the embankment and foundation were predicted by KPL (2013b) using numerical groundwater modelling, and were accounted for by KPL in their water balance model (KPL 2015).

In the TMF Discharge Phase (and beyond), seepage recovered downstream from the TMF embankments will be stored in the WMP through the low flow months of the year (winter), and seepage will be released concurrently with the TMF Spillway discharge. Withdrawal and discharge from the WMP pond will occur May to November through the following controls:

- In May, once Brynelson Creek is discharging at 20 L/s or more, the WMP will discharge at a ratio of 0.8 times the Brynelson Creek Flow. From June to November under typical conditions in Brynelson, the WMP will discharge at this ratio until the WMP is empty and water is released as it comes in (minimum flow expected to be 36 L/s of TMF seepage). However, for years with exceptionally low flow in Brynelson, the WMP will need to be discharged at a rate of up to 200 L/s to drain down stored water in the WMP in order to ensure there is storage capacity available for the following winter months.

- The release of the TMF pond will be controlled to further mitigate water quality in Casino Creek. This is especially important for drier periods when there is little-to-no water in Brynelson Creek. The ratio of TMF pond release to WMP release is set at 1.2 for June to November and 2.0 for May for the TMF Discharge Phase. These ratios were determined to avoid excess draw-down in the TMF pond and provide for a sufficient water cover over waste rock and tailings. The ratio of TMF pond release to WMP release varies from 1.2 to 2.5 for the Pit Discharge Phase as there is more water available in the TMF once the pit starts to discharge.

Table 4-1. WMP Water Balance Results

Water Management Phase	Project Year	Average Annual Inflow (L/s) [1]						Outflow (L/s) [1]

1. Flow rates reported in this table are average results from 52 model realizations over the duration of each water management phase.

5 Water Quality Model

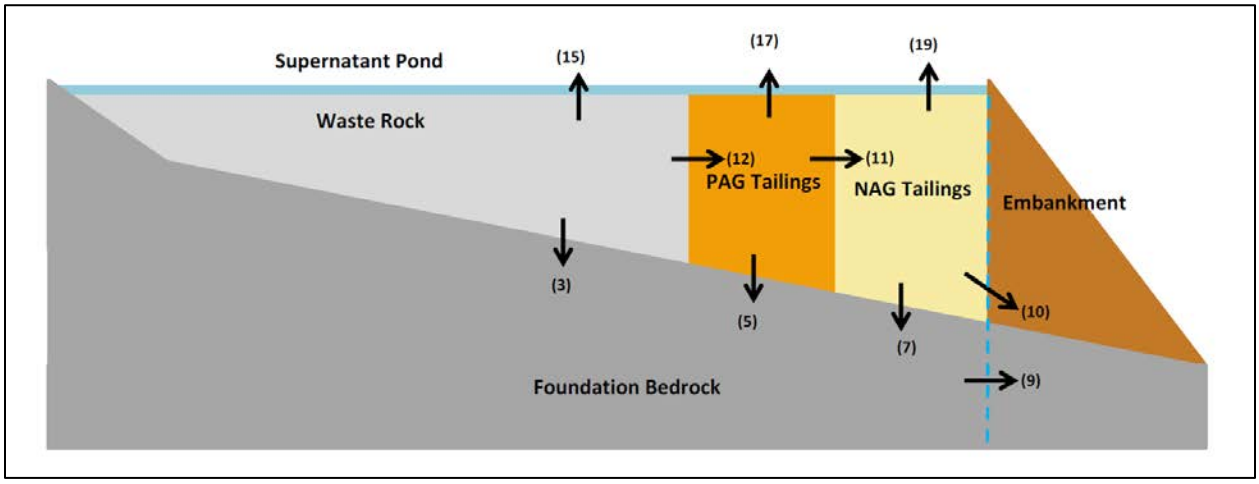
This section provides a description of the modelling methodology that was used for the prediction of mass transport of substances to the WMP and the resulting water quality. Relevant water balance components are discussed where applicable to the water quality modelling calculations.

5.1 WMP Inflows

Inflows to the WMP include: overland runoff; TMF embankment runoff; TMF embankment and foundation seepage collected by the seepage collection system; Cyclone Sand Plant underflow water; and, groundwater impacted by ore stockpile seepage.

5.1.1 Background Overland Runoff

Runoff from the undisturbed upslope area (i.e. background runoff) of the WMP will be collected in the pond. Mean annual runoff into the WMP is presented in Table 4-1. Median annual water quality from baseline sampling station at Brynelson Creek (W18) was used to calculate the mass loading to the WMP. Input water quality values are provided in Appendix V - A (Table V - A 1).



5.1.2 TMF Embankment Runoff

NAG tailings will be used for the production of cyclone sand for construction of the TMF Embankments (KPL, 2012). According to KPL (2013a), the final drainage area of the embankments will be 1.2 km^2. Runoff from the downstream face of the embankments will be intercepted by collection ditches and directed to the WMP. Average annual runoff from the embankment is provided in Table 4-1.

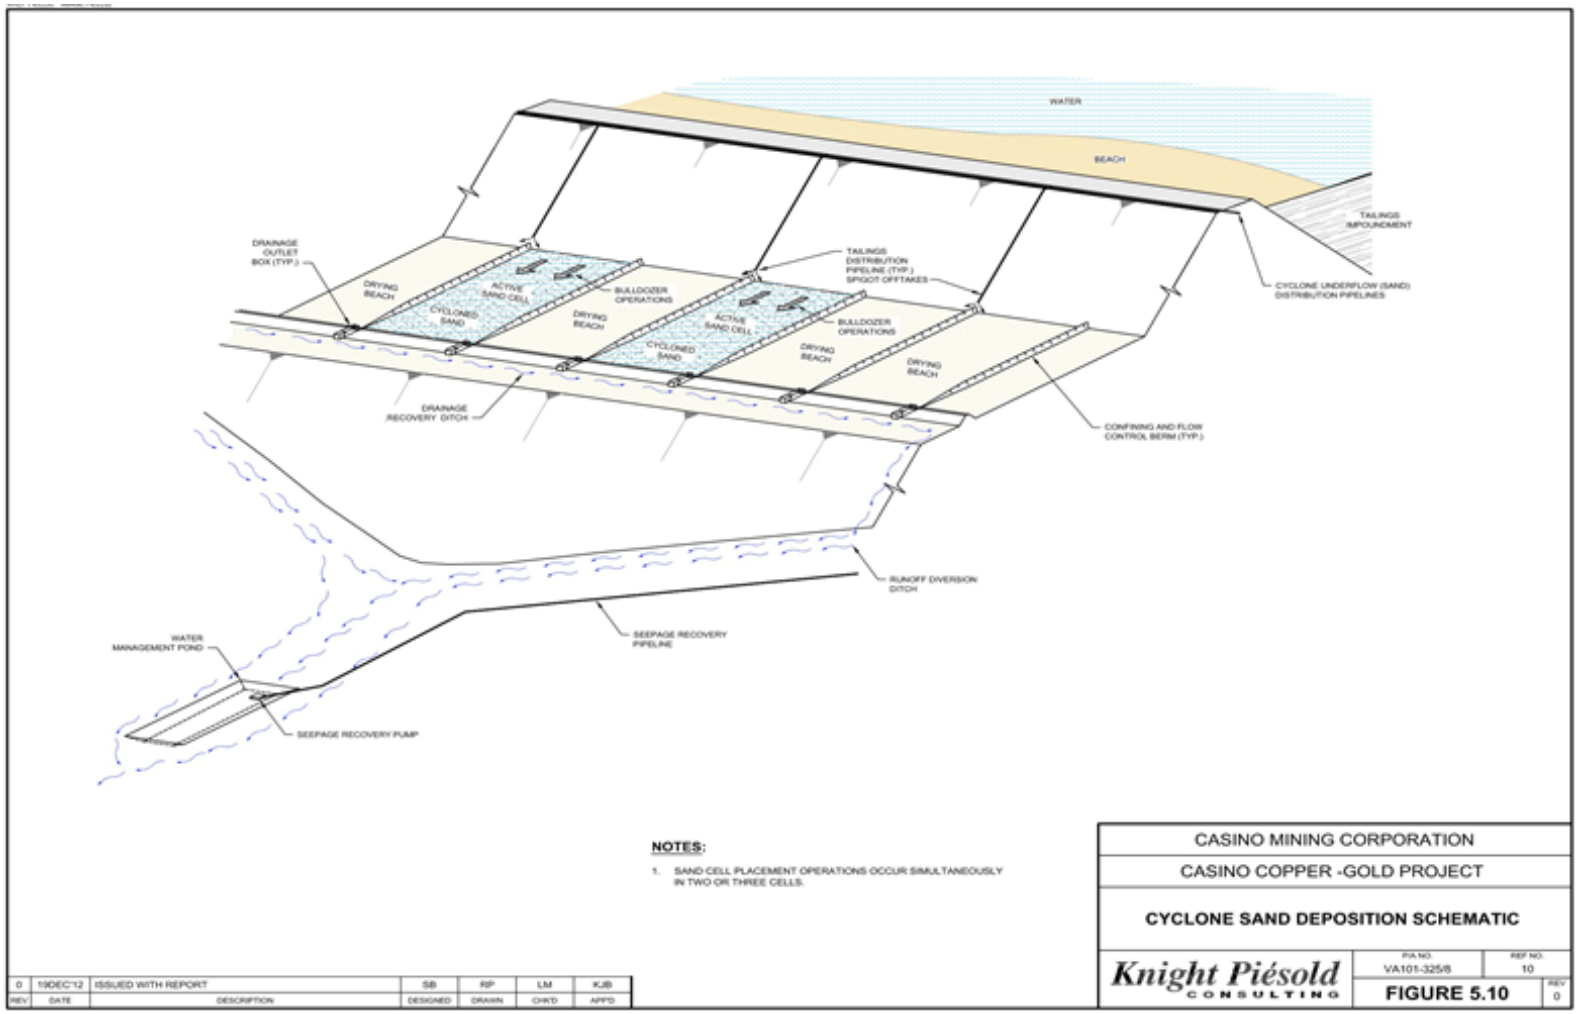
The mass loading rate of the embankment runoff into the WMP was calculated as the monthly flow rate, multiplied by the runoff concentration. The embankment face will be re-vegetated upon mine closure. As a result, metal and sulphate leaching rates are expected to be lower following Operations because the re-vegetation will reduce contact of water with the embankment sand. Lorax (2013) provided runoff concentrations for Operations and for a reclaimed embankment surface (Appendix V-A, Table V - A 1). The reclaimed embankment concentrations were assumed to commence in Year 26, which corresponds to a few years following the end of Operations after vegetation becomes established on the reclaimed surface.

5.1.3 TMF Embankment and Foundation Seepage

Seepage through the TMF foundation and embankment will be collected in the WMP. Lorax provided a schematic of TMF seepage flow paths to illustrate the sources and receptors of TMF seepage (Figure 5-1). Embankment seepage to the WMP is represented by flow path (10), and foundation seepage to the WMP is represented by flow path (9). The foundation and embankment seepage flow rates are expected to increase with the size of the TMF facility and embankment footprint. Average annual seepage rates are provided in Table 4-1.

Source: Lorax (2013), Figure 7-2

Figure 5-1. TMF Seepage Flow Paths



According to Lorax (2013), the seepage water quality will change throughout Operations because it will be affected by the quantity of the waste rock and tailings deposited in the TMF. Lorax provided source terms for the following stages of TMF Development: Year 4, 9, 19, 22, and >22 (Appendix V - A, Table V - A 1). Mass loading into the WMP was calculated by multiplying the seepage water quality by the seepage flow rate over a given time step. Seepage concentrations for years not explicitly provided by Lorax were assumed to be equal to the nearest later year (i.e., Years 0-4 were equal to Year 4, Years 5-9 were equal to Year 9, etc.).

TMF seepage was assumed to travel instantaneously from the source to receptor (i.e. through the embankment and through the foundation).

5.1.4 Cyclone Sand Plant Underflow (Embankment Construction Water)

During Operations, cyclone sand will be produced from bulk NAG tailings and discharged to the embankment for construction. Water expelled from the sand will be collected in the WMP (Figure 5-2).

Mill process (tailings slurry) water was used to represent the water quality of the embankment construction water. Loading into the WMP Pond was calculated as the concentration in the slurry water multiplied by the total slurry water inflow rate. Tailings slurry water quality changes over time for certain parameters, as discussed in Appendix IV – TMF Pond Water Quality Modelling.

Source: KPL (2012)

Figure 5-2. Cyclone Sand Deposition Schematic

5.1.5 Ore Stockpile Seepage

While the ore stockpiles are present during Operations, contact water (from rainfall and snowmelt) will drain from the rock as runoff or infiltration to groundwater. Runoff from the stockpiles will be captured by the TMF Pond.

Hydrogeological modelling (KPL, 2013b) indicated that depending on the stockpile location, infiltrated contact water will flow to one or more of the following receptors: the TMF Pond; Open Pit; TMF Embankment (towards the WMP); or TMF Foundation bedrock (towards the WMP). SEA estimated an average travel time from a range of seepage travel times provided by KPL (2013b) and assumed that the mass load associated with the stockpile seepage will report to the WMP after a lag-time equal to the seepage travel time (Table 5-1).

Table 5-1. Seepage Travel Time from Stockpiles to WMP

Stockpile	Seepage Travel time to WMP via TMF Embankment [1] (years)	Seepage Travel time to WMP via TMF Foundation [1] (years)
Gold Ore	(note 2)	(note 2)
Marginal Grade Ore	(note 2)	(note 2)
Supergene Oxide Ore	8.3	(note 2)
Low Grade Supergene Oxide Ore[3]	7.7	28
Low Grade Supergene Sulphide Ore	(note 2)	(note 2)
Low Grade Hypogene Ore	8.3	15

1. Average estimated travel time from KPL (2013b) hydrogeological modelling assessment.
2. Not expected to report to the TMF Embankment or Foundation
3. Seepage interception at the source (with 90% efficiency) is planned for this pile

Seepage and runoff concentrations into the groundwater were calculated by combining the seepage flow rates with mass loading rates. Calculation methodology of stockpile mass loading is described in Appendix II - Ore Stockpile Water Quality Modelling.

5.2 WMP Outflow

5.2.1 WMP Pump-back (Operations and Wetland Construction Phases)

KPL (2015) assumed that 100% of water collected in the WMP will be pumped back to the TMF during Operations and to the Open Pit during the Wetland Construction Phase. Average annual flow is presented in Table 4-1. Water quality in the WMP was multiplied by the monthly pumping rate to calculate mass loading from the WMP to the TMF Pond and Open Pit.

5.2.2 WMP Seasonal Release to Casino Creek (TMF Discharge and Pit Discharge Phases)

The KPL (2015) water balance simulated the release of water from WMP to Casino Creek from May to November (inclusive), and flow rate would be proportional to the flow rate in Brynelson Creek, the main tributary to Casino Creek immediately downstream from the Project site. The WMP will collect seepage (i.e. no discharge to Casino Creek) from December to April. Logic used in the water balance for release of WMP water is described in Section 4 (Water Balance). WMP water quality was multiplied by the monthly discharge rate to calculate mass loading into Casino Creek during a given time-step.

5.3 Calculation of Water Quality in the WMP

Water quality in the WMP was calculated in GoldSim with a cell pathway. The WMP Pond mixing model output concentrations were assessed for solubility controls at each time step of the model simulation by coupling GoldSim and PHREEQC. PHREEQC is a geochemical modelling software developed by the United States Geological Survey. To accurately predict pH, all water quality inputs to PHREEQC were charge balanced, and the residual balance was placed on either chloride or sodium. During each timestep, Goldsim ran PHREEQC and the resulting concentrations returned from PHREEQC were linked to the WMP water quality. Input assumptions are provided in Table 5-2.

Table 5-2. PHREEQC Assumptions used in the WMP Model

PHREEQC Input Assumptions	
Equilibrium Phases (minerals form solid phase - precipitate forms)	$Fe(OH)_3(a)$, $Al(OH)_3(a)$
Database	wateq4f
pH	Charge balance (PHREEQC determines pH of solution and alkalinity)
PE	10 (oxidizing)
Temperature	5^0C
Oxygen	atmospheric conditions
CO2	atmospheric conditions

6 Results and Discussion

WMP water quality results are provided for select parameters in Table 6-1 and for the full set of modelled parameters in Appendix V - B (Table V – B1).

Time series plots for select parameters are provided on Figure 6-1 to Figure 6-9 for a single realization of the model. Wet and dry years with 10 year return periods are identified on the plots to help illustrate the effects of inter-annual variation in hydrologic conditions on water quality. The model results show that wet and dry hydrologic conditions result in minimal inter-annual variation in WMP water quality during the TMF Discharge Phase and the Pit Discharge Phase. WMP water quality is dominated by seepage water which was modelled as a constant, year-round flow rate (i.e. it does not vary during wet and dry periods).

Seasonal variation in WMP water quality is most noticeable in the model results because seepage water inflow is constant, and surface water only enters during the warmer months. In general (following Operations), concentrations increase throughout the winter months when seepage alone enters the WMP, and concentrations reduce through the open water season as surface water enters the WMP and water is released to Casino Creek.

The WMP water quality is higher for some parameters such as cadmium (Figure 6-36-4) and molybdenum (Figure 6-7) during the first few years following Operations. This is a result of the source terms that were applied to represent embankment runoff water quality. The post-closure source term for embankment runoff was applied beginning in Year 26. Prior to that, the Operations source term was applied. Source terms are presented in Appendix V - B (Table V-A1).

The pH of the WMP was determined with PHREEQC to be near neutral. A time-series plot of modelled pH is provided in Figure 6-10.

Table 6-1. Water Quality Model Results for the WMP

Water Quality Model Parameter	WMP Quality (mg/L)		
	Recovered to TMF (Operations Phase)	Recovered to Pit (Wetland Construction Phase)	Released to Casino Creek (TMF Discharge and Pit Discharge Phases)
pH	6.2	6.4	6.4
Sulphate (SO_4)	1,137	954	979
Fluoride (F)	1.9	1.8	1.8
Cadmium (Cd)	0.00063	0.0014	0.0012
Copper (Cu)	0.021	0.043	0.038
Iron (Fe)	0.0011	0.00057	0.00059
Molybdenum (Mo)	0.27	0.30	0.24
Selenium (Se)	0.0075	0.0073	0.0072
Uranium (U)	0.0095	0.036	0.036

1. Values represent average water quality results over the duration of each mining phase for a single model realization (Realization #1).

Individual contributions of mass loading sources are presented for select parameters during Operations (Table 6-2) and TMF Discharge and Pit Discharge Phases (Table 6-3). The mass loading contributions for all model parameters are presented in Appendix V - B. During Operations, the majority of the loadings to the WMP come from seepage or the sand plant underflow. During TMF Discharge and Pit Discharge phases, seepage is generally the highest contributor to mass loading to the WMP, with embankment runoff providing the majority of the remaining load.

Table 6-2. Loading Contributions to the WMP (Operations)

Source of Loading	Fraction Contributing (%)							
	SO_4	F	Cd	Cu	Fe	Mo	Se	U
Background Runoff	0	0	0	1	1	0	0	5
Embankment Runoff	1	1	48	14	0	22	2	25
Stockpile Seepage	0	0	1	17	0	0	0	1
Tailings and Waste Rock Seepage	13	12	42	38	92	12	13	34
Sand Plant Slurry Underflow	86	86	8	31	7	66	85	36
Total	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**

1. Average of all years during Operations, calculated from output from model Realization #1.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

Table 6-3. Loading Contributions to the WMP (TMF Discharge / Pit Discharge Phases)

Source of Loading	Fraction Contributing (%)							
	SO_4	F	Cd	Cu	Fe	Mo	Se	U
Background Runoff	1	0	0	1	0	0	0	2
Embankment Runoff	4	26	20	13	0	30	13	47
Stockpile Seepage	0	0	0	1	0	0	0	0
Tailings and Waste Rock Seepage	96	73	80	86	100	70	87	51
Sand Plant Slurry Underflow	0	0	0	0	0	0	0	0
Total	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**

1. Average of all years during TMF Discharge and Pit Discharge Phases, calculated from output from model Realization #1.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

1. Average of all years during TMF Discharge and Pit Discharge Phases, calculated from output from model Realization #1.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded to the nearest 1 and the total of individual values may not add to exactly 100.

1. CCME Guidelines for protection of aquatic life are shown for reference. The BC Water Quality Guideline for sulphate was used because CCME guidelines are not available.
2. Water quality guidelines for SO4, Cd, Cu, Pb, and Ni are hardness dependent. Values presented in this table were calculated using the median baseline hardness of Brynelson Creek at W18 (74 mg/L as $CaCO_3$).

Table VI-2 Baseline Water Quality in Casino Creek (W4)

Water Quality Model Parameter	CCME Guideline (mg/L)	W4 Median Water Quality (mg/L)			
		All Data	Winter	Spring	Summer
Hardness (as $CaCO_3$)		111	162	64	111
Alkalinity (as $CaCO_3$)		79	110	44	79
Sulphate (SO_4)	309	41	60	20	41
Chloride (Cl)	640	0.25	0.25	1.1	0.25

Zinc (Zn)	0.50	-	0.019	0.022

1. Results in this table were generated from model output of a single model realization (Realization #1).
2. Zero discharge of mine derived water into Casino Creek during Operations, and Wetland Construction Phases.
3. Average of months when TMF and WMP water is released to Casino Creek (May to November). Average calculated from all years during each of the TMF Discharge and Pit Discharge Phases.

Table VI-6 Water Quality Predictions for Casino Creek (H18) – Single Model Realization

Water Quality Model Parameter		CCME Guideline (mg/L) [4,5]	Operations and Wetland Construction Phase (mg/L)				TMF Discharge Phase (mg/L)				Pit Discharge Phase (mg/L)

1. Results presented in this table were generated from model output of a single model realization (Realization #1).
2. Results presented in this table represent average water quality for all years (or seasons) that fall within each phase of mining.
3. Shaded cells are modelled concentrations that exceed the CCME Guidelines for the protection of freshwater aquatic life. Water quality limits have not been established and the CCME guidelines are provided as a point of reference only.
4. BC Water Quality guideline for sulphate was used because CCME guidelines are not available.
5. Water quality guidelines for SO_4, Cd, Cu, Pb, and Ni are hardness dependent. Values presented in this table were calculated using the median baseline hardness of Casino Creek at W4 (111 mg/L as $CaCO_3$).

Table VI-7 Water Quality Predictions for Casino Creek (W4) – Single Model Realization

1. Average of all years during each phase, calculated from output from model Realization #1.
2. Shaded cells are for sources that contribute >10% to the overall load.
3. Values are rounded and the total of individual values may not add to exactly 100.

Model Results

Monte-Carlo Summary
(52 Realizations)

Table VI-11 Water Quality Predictions for Dip Creek (H18) – Median (P50) from 52 Model Realizations

1. Results were generated from median water quality model results from 52 model realizations. Median values were averaged by mine phase.
2. Shaded cells are modelled concentrations that exceed the CCME Guidelines for the protection of freshwater aquatic life. Water quality limits have not been established and the CCME guidelines are provided as a point of reference only.
3. BC Water Quality guideline for sulphate was used because CCME guidelines are not available.
4. Water quality guidelines for SO4, Cd, Cu, Pb, and Ni are hardness dependent. Values presented in this table were calculated using the median baseline hardness of Dip Creek at W4 (111 mg/L as $CaCO_3$).

1. Results were generated from median water quality model results from 52 model realizations. Median values were averaged by mine phase.
2. Shaded cells are modelled concentrations that exceed the CCME Guidelines for the protection of freshwater aquatic life. Water quality limits have not been established and the CCME guidelines are provided as a point of reference only.
3. BC Water Quality guideline for sulphate was used because CCME guidelines are not available.
4. Water quality guidelines for SO4, Cd, Cu, Pb, and Ni are hardness dependent. Values presented in this table were calculated using the median baseline hardness of Dip Creek at W5 (90 mg/L as $CaCO_3$).

APPENDIX A.7C: Potential Effects of Climate Change on the Variability Water Balance

February 5, 2015

Dear Mary,

Re: Casino Project – Potential Effects of Climate Change on the YESAB Water Balance

1 – INTRODUCTION

The water balance submitted to the Yukon Environmental and Socio-Economic Assessment Board (YESAB) for the Casino Project (the project) has been updated to consider potential climate change effects. The objective of the water balance was to evaluate the quantity of water flowing in the ground, in the streams, and in various mine facilities, as well as provide a platform for development of the water quality model. The water balance submitted as part of the YESAB Proposal (the Proposal) in December 2013 was based on mean monthly climate conditions and was subsequently updated in January 2015 to include climate variability. The details of the climate variability water balance and results are described in the Knight Piésold (KP) letter "Casino Project – YESAB Water Balance to Include Climate Variability" (2015). For the purposes of this letter, the climate variability water balance model will be used as the "base case" water balance to provide a means of comparison for the projected climate change effects on estimates of flow quantity for the project.

The purposes of this letter are to outline changes to inputs and assumptions in the base case water balance that were made in order to model projected climate change effects, and to present the flow quantity results of the modelling. Based on the climate change model results, it was determined that the projected climate change effects on flow quantity were within the range of conditions already predicted by the base case water balance for which mitigation measures have been developed (KP, 2015). Therefore, climate change is not expected to adversely affect the water quality impact of the project. The results of the water quality modelling for the base case model are discussed separately in Section A.7 of the Supplementary Information Report (SIR).

2 – CLIMATE CHANGE ASSUMPTIONS

The base case water balance was developed using the net precipitation values produced by the calibrated watershed model (KP, 2013a). Net precipitation is defined as the water available for groundwater recharge and runoff from the total amount of precipitation (rainfall and snowmelt) after considering losses to the environment (e.g. evapotranspiration and soil moisture losses). The watershed model net precipitation results were developed using climatic inputs based on a 52 year long-term baseline monthly record (precipitation and temperature) developed for the project site (KP, 2013b).

In order to develop the projected climate change net precipitation inputs for the base case water balance, the long-term baseline monthly temperature and precipitation series used in the watershed model were adjusted to be representative of conditions in 2025, 2055 and 2085. The adjustments were determined on the basis of projected future annual and seasonal temperature values using the ClimateWNA program (CFCG, 2014) developed by the Department of Forest Sciences at the University of British Columbia. This program

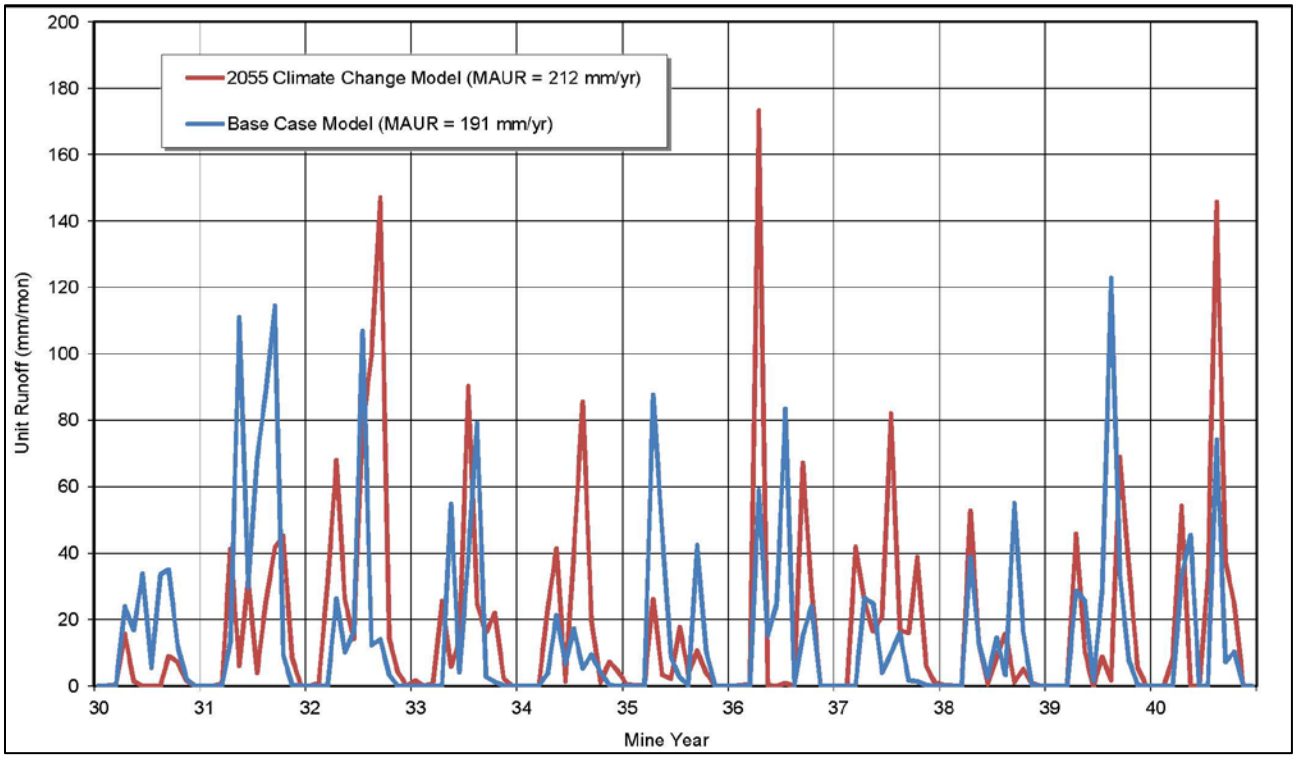
downscales and integrates historical datasets (1901-2009) and future climate datasets (2020s, 2050s and 2080s) generated by various global circulation models.

Values were calculated for the CanEWM2_RCP85 model scenario, which appears to have the most substantial climate change effects of all the scenarios offered by the program. The magnitudes of the projected changes are shown in Table 1, which are shown relative to the climate normal for the reference period 1961-1990 used by the ClimateWNA program (CFCG, 2014). For example, differences between the 1961-1990 climate normal temperature and precipitation values and the projected 2055 values equate to +5.2 °C for temperature and +18% for precipitation. Adjusting the model input values of temperature and precipitation results in changes to the other components of the water cycle in the watershed model, as summarized in Table 2 for the reference elevation of 1200 m. A general increase in temperature and precipitation corresponds to greater rainfall but less snowfall, greater evapotranspiration but less sublimation, and higher annual runoff. Based on the three climate scenarios (2025, 2055, 2085), the 2055 scenario was projected to generate the largest increases in resulting runoff; therefore, the 2055 conditions were chosen as the representative scenario for evaluating the effects of climate change on the updated water balance model.

Table 1 Projected Climate Change Scenarios

	Climate Change Scenario	Temperature (°C)					Precipitation (mm)				
		Annual	Winter	Spring	Summer	Fall	Annual	Winter	Spring	Summer	Fall
Change Relative to 1961-1990	2025	2.7	2.5	2.6	2.9	3.1	8%	0%	16%	9%	7%
	2055	5.2	6.5	4.6	4.9	5.0	18%	15%	23%	11%	26%
	2085	8.0	9.4	7.1	7.8	7.7	20%	34%	41%	5%	22%

Table 2 Climate Change Effects Summary (elevation 1200 m)



Parameter	Watershed Model Scenario			
	Base Case	2025	2055	2085
Mean Annual Precipitation (mm)	461	499	538	546
Mean Annual Rainfall (mm)	305	352	385	399
Mean Annual Snowfall (mm)	156	147	153	147
Mean Annual Sublimation (mm)	61	56	52	47
Mean Annual Actual Evapotranspiration (mm)	204	230	251	281
Mean Annual Unit Runoff (mm)	184	199	220	203

3 – CLIMATE CHANGE MODEL INPUTS

3.1 NET PRECIPITATION INPUTS

The water balance timeline includes four years of baseline conditions (Year -8 to Year -5), four years of pre-production (Year -4 to Year -1), 22 years of operations (Year 1 to Year 22), 91 years of closure (Year 23 to Year 113), and 87 years of post-closure (Year 114 to Year 200). The 52 years of net precipitation values therefore had to be repeated four times to produce a time series long enough for the simulated 208 year timeline. The watershed model produced a 52 year time series record of net precipitation for each model node; the resulting 2055 climate change scenario monthly values for each baseline watershed node and mine facility node are presented in Appendices A and B, respectively.

Figure 1 presents a comparison of the resulting baseline runoff values for the 2055 climate change scenario and base case models for model node W4 (Lower Casino Creek), for an example 11-year period (Years 30 to 40 of the model simulation). Based on this 11-year period, the mean annual unit runoff (MAUR) for the climate change scenario is approximately 11% higher than for the base case scenario. However, on a monthly basis there appears to be no consistent difference between the high flows for the base case and climate change scenarios, both in terms of timing and magnitude. In some years the base case scenario has higher flows (Years 30, 31, 35, 38 and 39) and in other years the climate change scenario has higher flows (Years 32, 33, 34, 36, 37 and 40).

NOTES

1. MAUR (mm/yr) = MEAN ANNUAL UNIT RUNOFF.
2. THE MAUR VALUES PRESENTED ON THE FIGURE FOR EACH MODEL ARE BASED ON THE AVERAGE OF THE 10 YEAR PERIOD PRESENTED FROM YEAR 30 TO YEAR 40.

Figure 1 **Climate Change Water Balance Model – Comparison of Monthly Runoff at W4**

3.2 LAKE EVAPORATION

The monthly long term temperature time series for the 52 years of record was adjusted based on the 2055 climate change scenario and then used as input to the Thornthwaite equation to estimate lake evaporation for the project site. The resulting 52 years of monthly lake evaporation values for the TMF pond and the Pit Lake at the assumed elevation of 1400 m are shown in Table C.1 in Appendix C. The mean average annual lake evaporation for the climate change scenario was estimated to be 397 mm, which is only a 3% increase from the base case scenario value of 387 mm. The negligible increase in the lake evaporation values as a result of the 2055 climate change scenario, coupled with the larger increase in precipitation values, is likely why the corresponding runoff for this scenario is more substantial compared to the other projected climate change scenarios.

4 – WATER BALANCE RESULTS

4.1 OVERVIEW

Using the climate variability approach, 52 unique sets of water balance results were developed for each node in the model. The following sections present detailed water balance results over the life of the model for the TMF, Open Pit, Water Management Pond (WMP) and Heap Leach Facility (HLF). The climate change model results are presented as monthly and annual median values (50^{th} percentile) for comparison with the base case model results.

4.2 TAILINGS MANAGEMENT FACILITY

The water balance was used to determine the likelihood of having a surplus or deficit condition during mill operations. The TMF pond was assumed to be maintained at a minimum pond volume of 15 Mm^3 (approximately 3 months of slurry water requirements) in all months throughout operations. A deficit condition was defined when the TMF pond volume was at the minimum volume of 15 Mm^3 and the TMF and surrounding catchments were not able to supply enough process water to meet the mill process water needs. Figure 2 presents the range of possible cumulative TMF pond volumes for the base case and climate change models, as defined by the median results. The climate change model shows a larger accumulated pond volume initially prior to operations and in some years during operations. Overall, the climate change scenario pond volumes during operations are projected to be ~4% greater on a monthly basis, which is due to the higher runoff values generated by the projected climate change scenarios compared to the base case scenario.

The TMF operates in a deficit condition during the entire operation period (Years 1 to 22), with the exception of Year 22. There is no makeup water required under all scenarios for Year 22 since the TMF is in a surplus condition and can supply all the required process water required by the mill. Makeup water from the Yukon River will be used to supplement the mill process water during deficit conditions when the mill is operating. The annual makeup flow requirements during operations are summarized in Table 3. Comparison of the annual makeup water requirements for the baseline and climate change models indicate that climate change conditions result in 10% to 50% less makeup water being required on an annual basis to support mill operations. The lower makeup water requirements are due to the projections of greater precipitation in the future and associated increases in water available to satisfy the mill requirements.

Similarly, under climate change conditions less makeup water is required from the Yukon River to supplement the TMF pond prior to operations to establish the minimum pond volume. The median start-up water requirements from the Yukon River are 6.4 Mm^3 and 9.0 Mm^3 for the climate change and base case scenarios, respectively.

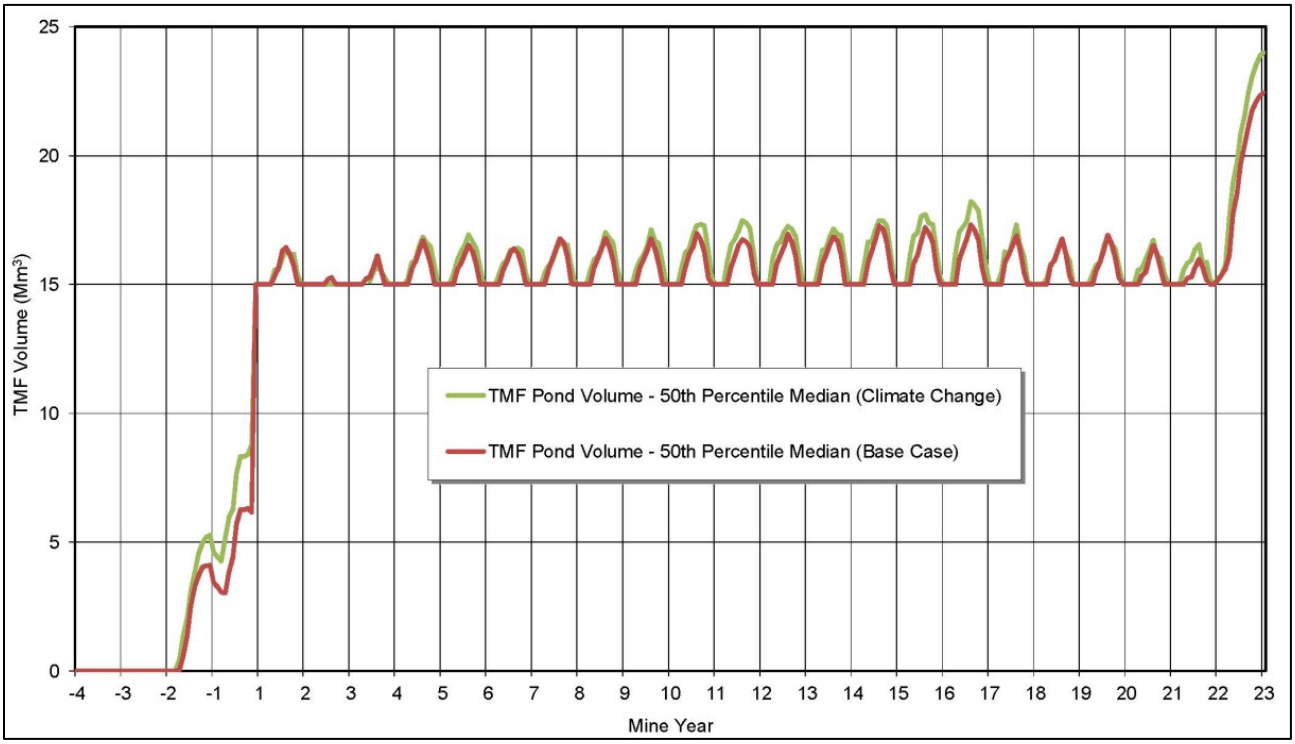


Figure 2: Tailings Management Facility Simulated Pond Volumes for Operations

Following the cessation of milling activities, the TMF pond will be pumped to the Open Pit to allow for the construction of the North and South TMF wetlands. The TMF median pond water depth for the climate change scenario, with pumping, is projected to be 1.7 m, compared to a median TMF pond water depth of 1.0 m for the base case scenario. Therefore, an increased pumping rate would be required for the climate change condition to maintain the desired water level for wetland development.

Following the wetland establishment, the TMF pond will be allowed to fill at its natural inflow rate until it begins to spill. The median results of the climate change model indicate that it takes approximately 10 years for the TMF pond to begin spilling following the end of operations, compared to 12 years for the base case model. Discharge from the TMF pond in closure will be via the constructed TMF spillway to Casino Creek downstream of the WMP. The discharge from the TMF pond will be a combination of the water released through the low-level outlet in the spillway plus any excess flow that discharges through the main spillway during wet periods. The total combined flow (low-level + main spillway) discharges through the TMF spillway are summarized in Table 6 for both models, for Years 60 and 120. These two years represent periods prior to and after filling of the Open Pit; once full, the Pit will spill water into the TMF pond and thereby increase TMF spillway flows. On an annual basis the climate change scenario indicates greater spill volumes than the base case due to overall wetter conditions, but on a monthly basis the relative spill volumes vary greatly due to differences in the hydrologic patterns. For instance, the climate change model predicts much higher spill volumes in April but lower spill volumes in May because of the earlier onset of freshet resulting from warmer temperatures.

Table 3 Annual Mill Process Water Makeup Requirements

Mine Year	Process Water Requirements (m^3/yr)	
	Base Case Model	Climate Change Model
	Median	Median

4.3 OPEN PIT

During closure, the Open Pit will be allowed to fill and become a pit lake. The annual Pit Lake discharge volume will be released to the North TMF Wetland at a controlled rate through a gravity controlled discharge system during the warmest months of the year (June through September). The modelling indicates that the Pit Lake will fill to the spill level 13 years faster for the climate change scenario than for the base case scenario.

Once pit filling is achieved, a controlled release flow averaging 180 L/s (June through September) will be required to maintain lake levels in the Pit at or below an elevation of 1095 masl, based on average climate conditions. Flows in excess of the controlled flow rate will be allowed to spill to the North TMF Wetland. Table 5 summarizes the release rates from the Pit Lake to the North TMF Wetland for Year 110. Results for this year are presented as an example of a "typical" year and indicate that there are expected to be no excess releases under median conditions for both the base case and the climate change scenario. The model results indicate that once full, the open pit will spill flows to the TMF pond (via the North Wetland).

Table 5 Pit Lake Release Rates

4.4 WATER MANAGEMENT POND

Once the TMF begins spilling, flows collected in the water management pond (WMP), which were previously pumped to the Open Pit, will be stored during the low flow months (December through March) and discharged during the spring to coincide with periods of high flows in Brynelson Creek and discharge from TMF spillway (April through November). Discharge from the WMP will continue in Closure Water Management Phase III, once the Open Pit is full and spilling to the TMF pond. The flow releases from the WMP are summarized in Table 6 for median conditions, for both the base case and the climate change scenario. Results are shown for Years 60 and 120, which represent periods prior to and after filling of the Open Pit. The results are very similar for both periods, with the base case and the climate change scenario having similar annual flows, but substantially different monthly distributions. The climate change scenario results indicate a more even monthly distribution of flows, which reflects the change in flow pattern of the receiving waters, with an increase in winter flows and a decrease in freshet flows, resulting from an increase in winter rainfall and snowmelt and a decrease in the spring snowpack melt.

Overall, the water management pond in closure is predicted to empty by the end of each year and provide adequate storage for the winter seepage and runoff, for both the base case and the climate change scenario.

Table 6 Water Management Pond Flow Releases in Closure

		Flow (L/s)												
		Jan	**Feb**	**Mar**	**Apr**	**May**	**Jun**	**Jul**	**Aug**	**Sep**	**Oct**	**Nov**	**Dec**	**Annual**

4.5 HEAP LEACH FACILITY

The results of the updated water balance indicate that the Heap Leach Facility (HLF) operates in a water deficit condition during all months of operations when ore stacking is active (Years -3 to 15). Table 7 summarizes the annual makeup water requirements during operations, which are lower for the climate change scenario because of overall wetter climatic conditions. These wetter conditions result in an increase in the accumulated water in the heap, as indicated on Figure 3. The monthly surplus flow rates for the climate change scenario are generally lower compared to the base case, as presented on Figure 3; however, due to the modified monthly distribution of flows for the climate change scenario, more water is discharged from the heap on an annual basis, as summarized in Table 8.

Table 7 Annual Process Water Makeup Requirements for HLF

5 – SUMMARY

Predicted climate change scenarios for the Casino Project are projected to be both warmer and wetter, resulting in increased annual runoff (~20%) and a more even monthly distribution of runoff. These conditions, in turn, produce the following likely changes in the project operational water balance mine development components, when comparing the median climate change model results with the corresponding base case model results:

- Tailings Management Facility (TMF):
  - Pond volumes during operations are ~ 4% greater.
  - ~ 30% less make-up water from the Yukon River is required for start-up.
  - ~ 10% to 50% less make-up water from the Yukon River is required for operations.
  - A greater pumping rate may be required to facilitate TMF wetland development at closure.
  - After closure, the TMF pond will fill to its spill level approximately 2 years faster (10 years vs. 12 years).
- Open Pit:
  - In closure the Open Pit Lake will fill to the spill level 13 years faster (74 years vs. 87 years).
  - Once full, the Open Pit Lake is projected to spill under the controlled release rate of 180 L/s during June to September without any uncontrolled discharge for median conditions.
- Water Management Pond (WMP):
  - Flows released from the WMP will be very similar on an annual flow basis, but substantially different on a monthly basis. There will be a more even monthly distribution of flows, which reflects the change in flow pattern of the receiving waters, with an increase in winter flows and a decrease in freshet flows resulting from an increase in winter rainfall and snowmelt and a decrease in the spring snowpack melt.
- Heap Leach Facility:
  - Increases in both the surplus water from the heap and accumulated water in the heap.

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness
Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

PALMER ENVIRONMENTAL CONSULTING GROUP INC.

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Gui
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

PALMER ENVIRONMENTAL CONSULTING GROUP INC.

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Gui
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Gui
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

PALMER ENVIRONMENTAL CONSULTING GROUP INC.

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness
Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

PALMER ENVIRONMENTAL CONSULTING GROUP INC.

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness
Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness
Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

PALMER ENVIRONMENTAL CONSULTING GROUP INC.

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness

Note:

1) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
a) Ammonia (NH3) guideline based on ph=8 and temp=20
b) Aluminum (AL-T)= 0.005 mg/L at pH < 6.5: 0.1 mg/L at pH ≥ 6.5
c) Cadmium (Cd) mg/L: 10^(0.86*(log(hardness))-3.2)/1000
d) Copper (Cu) mg/L: (e^0.8545[ln(hardness)]-1.465)*0.2/1000; minimum is 0.002mg/L regardless of water hardness
e) Lead (Pb) mg/L: (e^1.273[ln(hardness)]-4.705)/1000; minimum is 0.001mg/L regardless of water hardness
f) Nickel (Ni) mg/L: (e^0.76[(ln(hardness)]+1.06)/1000; minimum is 0.025mg/L regardless of water hardness
Highlighted cells indicate updates from Project Proposal

"n"	Count
"min"	Minimum Value
"max"	Maximum Value
"sd"	Standard Deviation
"se"	Standard Error
"cov"	Covariance
"<DL"	# of Non-detectable Values
">GL"	# of Exceedances of CCME Guic
"%>GL"	% of Parameters that Exceed CCME Guidelin
"-"	No Data Available

draft for discussion

Dear Dr. West-Sells:

Re: Casino Project: 2008 Environmental Studies Report

AECOM is pleased to submit the attached report describing the studies conducted in 2008 on the atmospheric, aquatic and terrestrial environments of the Casino Project area. If there are any questions or comments on this report, then please contact the undersigned. Thank you for the opportunity to work with you on this project.

Sincerely,
AECOM Canada Ltd.

Revision Log

Revision #	Revised By	Date	Issue / Revision Description

Executive Summary

This report describes the studies conducted in 2008 on the atmospheric, aquatic and terrestrial environments of the Casino Project area. The Casino Project is a proposed porphyry copper-gold-molybdenum mine located at latitude 62° 44'N and longitude 138° 50'W in west-central Yukon, 300 km northwest of the territorial capital of Whitehorse.

On October 3, 2008, the Casino meteorological station was installed on Patton Hill at an elevation of 1,203 m above sea level. The station consists of a 10 m-high, free-standing tower equipped with instrumentation, datalogger, and logger enclosure. It records wind speed and direction, rainfall, air temperature, barometric pressure, relative humidity and snow depth and stores the records in a datalogger powered by a battery charged with a solar panel. The datalogger is equipped with a satellite modem for remotely accessing the data.

Surveys of the aquatic environment were made on May 9, May 20-24, July 7-11, September 9-13 and October 9-11. The objectives were to measure stream flows, to sample water quality, stream sediment quality, periphyton communities, benthic invertebrate communities and fish communities, and to describe fish habitat.

In May 2008, dataloggers were installed at six hydrometric stations to measure water surface elevation (from which stream flows were calculated) and water temperature. A seventh station was added in October. Those data were downloaded on subsequent trips in July, September and October. Stations were winterized in October. In general, manual measurements of discharge and stage were conducted at medium to high flows. Analysis showed fair to strong correlations of discharge and stage. Reconstruction of the hydrographs showed two large peaks of discharge at all stations that were assumed to be initiated by a regional precipitation event. Historic discharge data for 1993 and 1994 were compared to the 2008 flow data at three sites.

A total of 19 sites were chosen for water quality sampling. Water samples were collected from each site in May, July and September and analyzed for the full suite of physical parameters, anions, nutrients and total and dissolved metals. Exceedances of the Canadian Council of Ministers of the Environment (CCME) guidelines for protection of freshwater aquatic life were observed for nine parameters. The number of exceedances was highest for cadmium, copper and aluminum and least for cyanide. Exceedances were most numerous in May, similar between July and September and least numerous in October, indicating a seasonal trend most likely directly related to hydrological factors such as snow melt and stream flow.

Principal components analysis was used to identify the major spatial and temporal trends in water quality. The first component, WQ1, was positively correlated with 16 dissolved and total metals and negatively correlated with total and dissolved molybdenum, and was the geochemical signal of drainage from the adit of the lower camp into the upper reach of Casino Creek.

The second component, WQ2, was positively correlated with ten dissolved and total metals, sulphate, nitrite and ammonia and negatively correlated with pH, alkalinity, barium and nitrate. This “iron-pH” component

reflects the geochemical signature of the surficial geology of Proctor Gulch, the upper Casino Creek and Britannia Creek.

The third component, WQ3, was positively correlated with hardness, conductivity, Total Dissolved Solids (TDS), and 13 total and dissolved metals. These parameters typically reflect the influence of groundwater flows.

The fourth component, WQ4, was positively correlated with 12 dissolved and total metals, Total Suspended Solids (TSS) and Total Kjeldahl Nitrogen (TKN) and negatively correlated with dissolved and total silicon. The scores for this "vanadium-silicon" component were lowest for sites in Casino Creek and in upper Britannia Creek, and highest for sites in Dip Creek, Britannia Creek, Sunshine Creek and the Yukon River. Therefore, WQ4 represents a geochemical signal found at all sites except those in Casino Creek and upper Britannia Creek.

The fifth component, WQ5, was positively correlated with dissolved and total selenium and nickel and turbidity. The scores for this "selenium-nickel-turbidity" component were highest for sites in the Yukon River, hence WQ5 represents a geochemical signal associated with the Yukon River.

Sediment samples were collected from a sub-set of 12 stream sites in September and pH and total metal concentrations were measured. Exceedances of CCME sediment guidelines were identified for five total metals: arsenic, cadmium, copper, lead and zinc. All of those metals except arsenic were also observed to exceed CCME water quality guidelines at some stations on some dates. A PCA of sediment quality variables extracted three components that accounted for 87.7% of the explained variance. SQ1 was highly positively correlated with manganese, cadmium, cobalt, zinc, lead and antimony; SQ2 was highly positively correlated with vanadium, titanium, aluminum, tin, phosphorus, sodium and barium; and SQ3 was highly positively correlated with bismuth, silver and arsenic and highly negatively correlated with pH.

Five samples each of periphyton and benthic invertebrate communities were collected from seven stream sites in September. There were highly significant differences in mean periphyton density among sites with sites P8, P7 and P4 in Casino Creek having significantly higher mean density than other sites. There were no significant differences among sites in the Shannon-Weiner diversity index, but there were highly significant differences among sites in species richness because of higher richness for sites P8, P7 and P4 than for other sites.

Over 95% of the benthic organisms at each site belonged to eight taxa: the insect Orders of Diptera, Plecoptera, Ephemeroptera, Trichoptera, Prostigmata and Collembola plus the worms of Class Oligochaeta and Phylum Nematoda. There were statistically significant differences in mean density and diversity among sites.

Fish communities at 12 stream sites were sampled in July and September with minnow traps, electrofishers and angling. In addition, an aerial survey of Britannia and Canadian creeks was conducted on September 11 to search for Pacific salmon spawners (none were observed).

A total of 40 fish from two species – Arctic grayling (*Thymallus arcticus*) and slimy sculpin (*Cottus cognatus*) – were captured. Apart from one Arctic grayling caught by angling, all were captured by electrofishing. Only Arctic grayling were found in the Britannia Creek Watershed, but both Arctic grayling and slimy sculpin were found in Casino Creek and Dip Creek watersheds. Slimy sculpin made up the majority of the catch (81 to 86%) in those two watersheds, respectively.

Arctic grayling were absent from the study area in September, most likely due to late-summer outmigration in search of overwintering habitat. In contrast, the mean catch-per-unit-effort (CPUE) of slimy sculpin for Casino and Dip Creeks was not significantly different between July and September, indicating that slimy sculpin either did not outmigrate from Casino Creek until after mid-September.

Arctic grayling ranged in length from 173 to 300 mm and in age from two to siz years, indicating the presence of juvenile and adults but not young-of-the-year. Slimy sculpin ranged in length from 29 to 294 mm, indicating the presence of juveniles and adults.

Nine slimy sculpin were collected from Casino and Dip creeks in July and September and subjected to whole-body tissue metals analysis.

Reconnaissance surveys of the terrestrial environment were conducted on July 7-11 and September 8-11, 2008. The objectives were to provide sufficient preliminary information on soils and vegetation to plan a future air photograph interpretation study of vegetation communities, and to document wildlife presence and use of the various plant communities and habitats.

Aerial surveys of vegetation communities and wildlife were conducted in a helicopter that flew slowly at low altitudes. Aerial surveys were followed by ground surveys conducted on foot or with all terrain vehicles. Soil pits were dug, samples of vegetation were collected and animal sighting and signs (claw marks, paw prints, antlers, scat, etc.) were photographed and their GPS co-ordinates recorded.

The surveys showed that the study area is characterized by smooth, rolling topography with moderate to deeply incised valleys. Wildlife habitat consists of a variety of plant communities ranging from sparsely vegetated bare rock, large expanses of heath tundra, wet sedge meadows with tall riparian shrubland and treed slopes dominated by spruce, aspen, birch and willows. Open stands of black spruce and white spruce occur in valleys and lower slopes, with black spruce on wetter sites and white spruce on better drained sites. Willow, shrub birch, Labrador tea, mosses and lichens are principal understory species.

Fifteen species of mammals and ten species of birds were observed or heard during the surveys. Moose were observed along the Yukon River and along Casino and Dip creeks. The area being considered for the proposed Casino Project appears to be a preferred moose wintering area. Caribou were seen and caribou sign (e.g., pellets, shed antlers, trails, etc.) was found on ridge tops. Numerous wolf tracks and scats were observed along Dip Creek, suggesting the presence of a den site. Grizzly bears and black bears were observed and well-developed small mammal trails were observed in some spruce habitat.

Potential summer and winter range, lambing areas and escape terrain for sheep are limited within the survey area. No thinhorn sheep were observed along the Yukon River bank directly across from Britannia Creek.

Acknowledgements

The studies described in this report were carried out by the following AECOM staff:

- Project Management:
  - Rick Palmer, B.Sc., Senior Aquatic Biologist
- Hydrology:
  - Chad Davey, B.A., M.Sc., Environmental Scientist
  - Rolf Aslund, P.Eng., Senior Water Resources Engineer
- Surface Water Quality and Sediment Quality:
  - Kai Woloshyn, B.Sc., Environmental Scientist
  - May Quach, M.Env.Sci., CEPIT, Aquatic Ecologist
- Fish and Fish Habitat:
  - Jennifer Sarchuk, B.Sc., Biologist
  - Genevieve Martin, B.Sc., Environmental Biologist
  - Eric Cleveland, Fish. Wild. Tech., Environmental Technician
- Soils and Vegetation:
  - Sean Bennett, B.Sc., R.P.F., Terrestrial Ecologist
  - Kevin Lloyd, M.Sc., Senior Ecologist
- Wildlife and Wildlife Habitat:
  - Paul Fraser, B.Sc., P.Bio., Senior Wildlife Biologist
  - Laurence Turney, B.Sc., R.P.Bio., Senior Wildlife Ecologist

Climate and air quality was the responsibility of the following RWDI staff: Geoff Doerksen, M.Sc., Project Manager, and Kathy Preston.

1. Introduction

1.1 Overview

This report describes the studies conducted in 2008 on the atmospheric, aquatic and terrestrial environments of the Casino Project area. Studies on hydrogeology (AECOM in preparation) and geochemistry (Lorax 2009) are reported separately. The purpose of these studies was to characterize the pre-development environment in support of the permitting process for the Casino Project.

The Casino Project is a proposed porphyry copper-gold-molybdenum mine located at latitude 62°44'N and longitude 138°50'W in west-central Yukon, 300 km northwest of the territorial capital of Whitehorse. Figure 1 shows the location of the Casino Project, surrounded by the aquatic Regional Study Area (RSA), in relation to the Yukon River – to which all of the streams in the Casino Project area eventually discharge.

In August 2008, a pre-feasibility study of the Casino Project was completed (M3 Engineering 2008). It envisioned a conventional truck-shovel, open pit mine. Waste rock will be stored in three waste rock dumps located south and east of the open pit (Figure 2). Tailings, process water, treated sewage effluent, leachate from the waste rock dumps and surface runoff from the mine site will be stored in a Tailings Impoundment Area (TIA) located in the headwaters of Casino Creek south of the waste rock dumps. The TIA is intended to be a zero discharge operation, hence makeup water will be pumped to the TIA through a pipeline from a site on the Yukon River approximately 17 km to the north. A 187 km-long unpaved access road (see Figures 6a and 6b) will be built from the Alaskan Highway at a point about 48 km northwest of Burwash Landing out to the mine site. It will be used to bring in equipment, supplies and fuel and to truck out metal concentrate.

1.2 Project History

The first known recording of a lode mineral claim in the area was in 1917. Discovery of silverlead veins in the 1930's led to further exploration that eventually led to the discovery in 1969 of the large copper and molybdenum porphyry deposit on Patton Hill. Over the next 23 years, various parties including Brameda Resources, Quintana Minerals, Teck Corporation and Archer, Cathro and Associates Ltd. acquired the property and did more drilling. In 1992, Pacific Sentinel Gold Corp. acquired the property and ran a major drilling program from 1992 to 1995. In addition, they performed a considerable amount of metallurgical, geotechnical and environmental work and completed a scoping study in 1995. Soon thereafter, First Trimark Resources and CRS Copper Resources obtained the property. In 2004, the two firms combined to form Lumina Copper Corporation and in November 2006 Western Copper Corporation acquired Lumina Copper Corporation and the Casino property.

1.3 Historical Sources of Environmental Data

In 1997, Hallam Knight Piésold Ltd. (HKP) completed a data report for Pacific Sentinel Gold Corp. summarizing the results of environmental baseline studies conducted from 1993 to 1995 (Hallam Knight Piésold 1997). The report provided data on meteorology, hydrology, surface water quality, groundwater quality, stream sediment quality, periphyton, benthic invertebrates, fish, soils, terrestrial vegetation and wildlife. Some of that data was compared to that collected in 2008 in this report.

Apart from Hallam Knight Piésold (1997), there are limited data available on the aquatic environment of the Casino area. Fisheries and Oceans Canada (DFO) has conducted surveys of fish and fish habitat in watersheds in the area, including the reaches of the Yukon River adjacent to the Casino property and the lower reaches of Dip Creek and the Klotassin, Donjek and White rivers. These were conducted for the purposes of managing Pacific salmon fisheries in the Yukon River, and for classifying fish habitat in support of the Yukon Placer Authorization (Government of Canada 2000). The results of these surveys are reported in DFO's Fisheries Information Summary System (FISS) (Appendix B10). The sources of the information listed in the FISS reports are Hallam Knight Piésold (1997) and memoranda, letters, personal communications and other relevant information held in the files of DFO's Whitehorse office.

Fish and Wildlife Branch of Yukon Department of Environment has conducted surveys of wildlife in the Casino study area and along its proposed access routes. Some of that data has been published, e.g., Farnell *et al.* (1991), but most of the baseline information on the relative abundance, seasonal distribution, movement and habitat use of wildlife in the Project area has yet to be collated and published. Some Traditional Knowledge of the Project area is available. For example, the current management plan for the Klaza Caribou Herd was derived in part from Traditional Knowledge of behaviour and habitat use provided by the Little Salmon/Carmacks First Nation (Yukon Environment 2004).

1.4 Study Areas

1.4.1 General

Two types of study area were defined for each of the three environmental components: a Local Study Area (LSA) and a Regional Study Area (RSA). The Canadian Environmental Assessment Agency (CEAA) defines a LSA as:

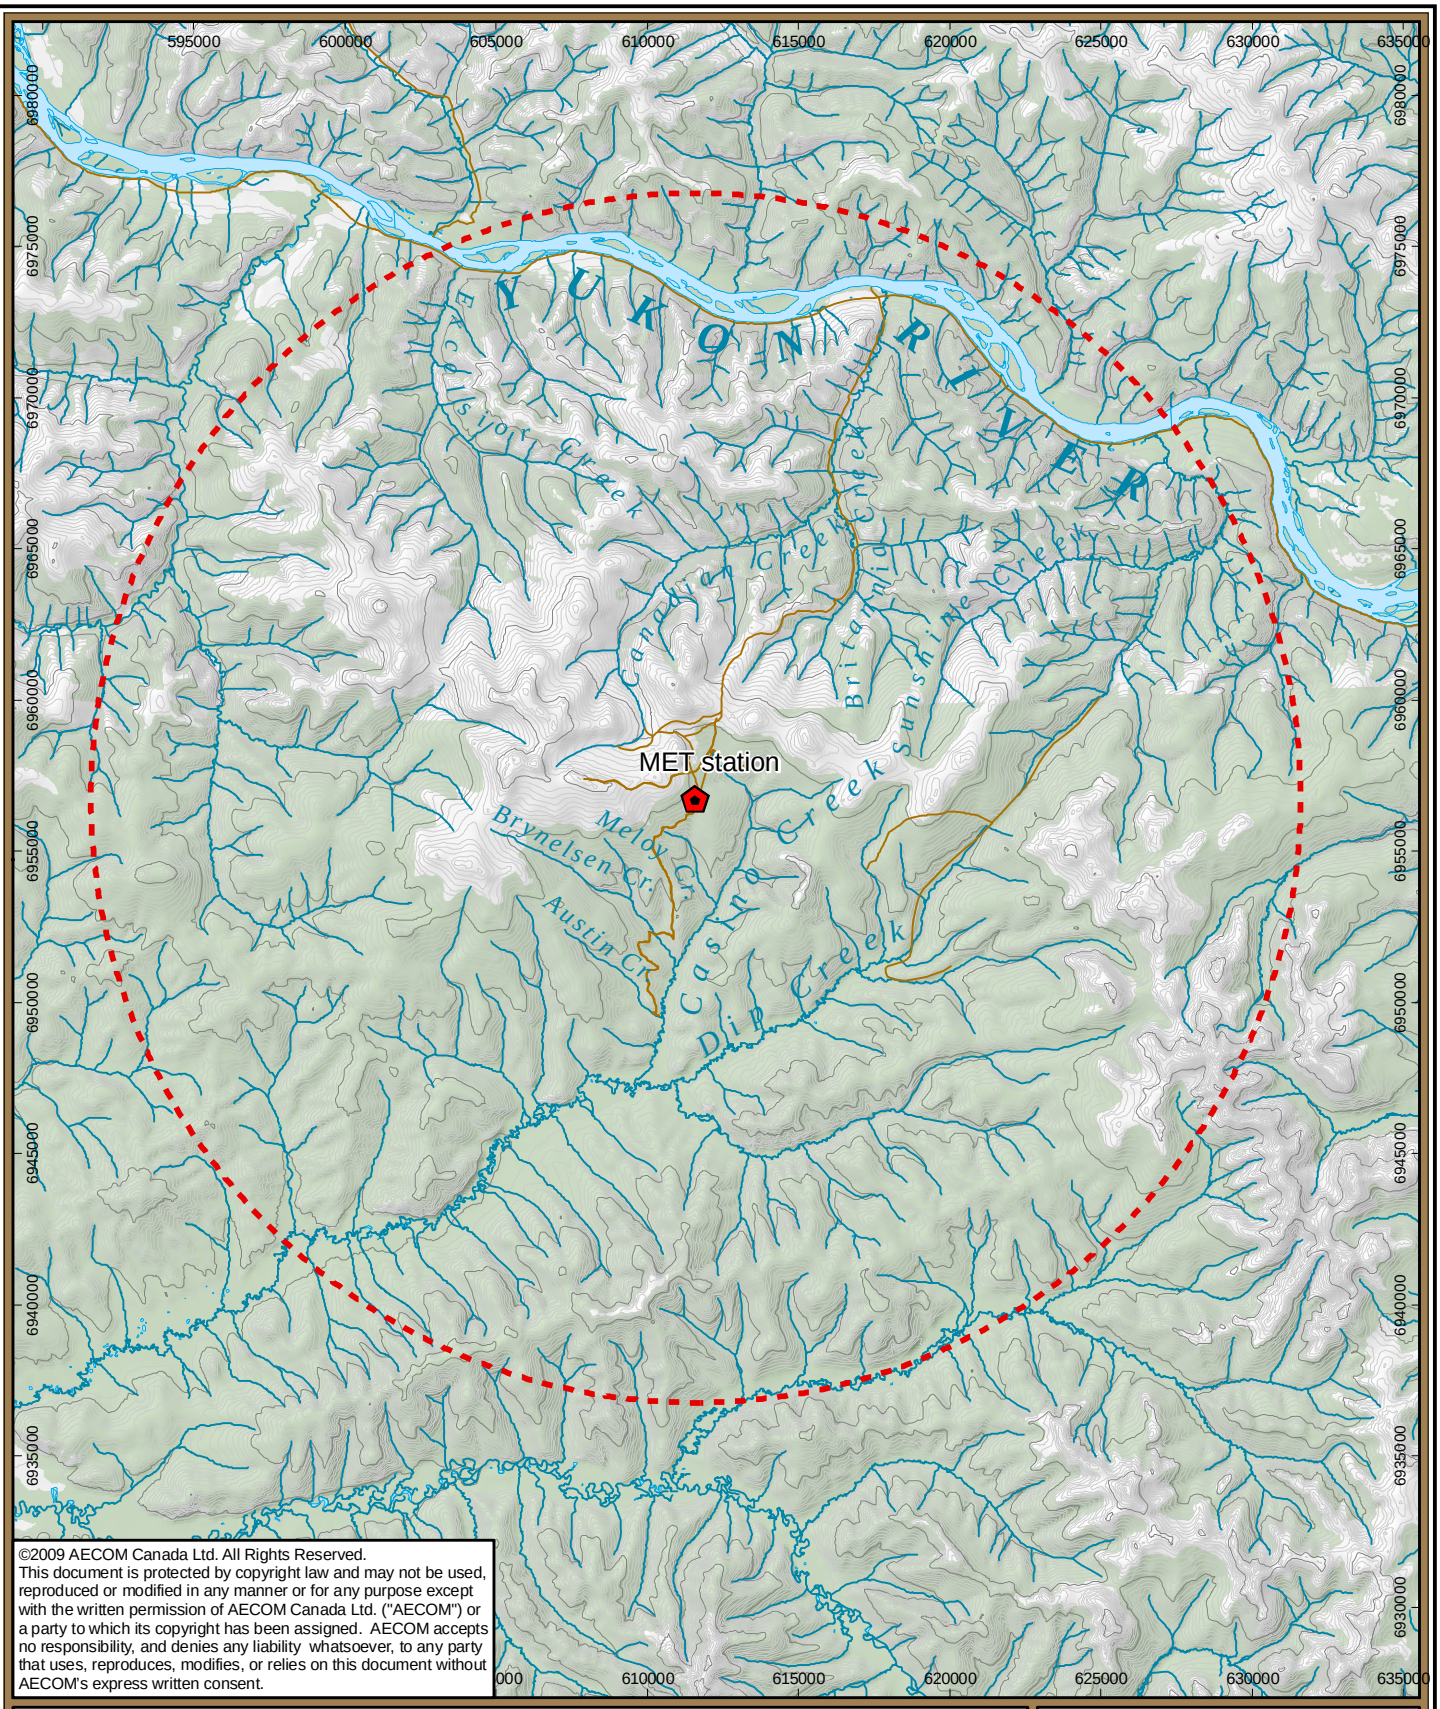
> "The area within which local effects are assessed (i.e., within close proximity to the action where direct effects are anticipated)" (CEAA 2008)

The boundaries of LSAs are defined by topographic features such as watershed boundaries (for aquatics) and slope breaks (for vegetation and wildlife). The LSA is of a size that lends itself to sampling and mapping at high intensity. CEAA (2008) defines a RSA as:

> "The area within which cumulative effects are assessed (i.e., extending a distance from the project footprint in which both direct and indirect effects are anticipated to occur)."

In practice, the RSA encompasses the LSA plus a larger surrounding area that is of sufficient size to evaluate the potential severity of Project-specific effects in combination with other past, present and reasonably foreseeable effects. The RSA may also include reference sampling sites that will be used as controls to assess Project-related effects on the LSA during the operational and post-closure phases of the Project. The RSA is defined by ecological boundaries and it is of a size that lends itself to sampling and mapping at lower intensities than an LSA.

1.4.2 Atmospheric Environment



The atmospheric LSA was based on the assumption that the atmospheric conditions measured at the meteorological station at the mine site are representative of conditions up to 20 km away (Geoff Doerksen, RWDI, personal communication) (Figure 3). The atmospheric RSA has not yet been defined.

1.4.3 Aquatic Environment

The LSA for the aquatic environment was defined by the boundaries of the two watersheds surrounding the Casino deposit: the Britannia Creek Watershed to the north and the Casino Creek Watershed to the south (Figure 4). Most of the proposed mine infrastructure will be in the Casino Creek Watershed, but some (e.g., the northern corner of the open pit) will be in the Britannia Creek Watershed. The northern part of the LSA is drained by Britannia Creek and one of its tributaries, Canadian Creek. Britannia Creek flows into the Yukon River. The northern edge of the LSA includes a 2 km-long reach of the Yukon River. The southern part of the property is drained by Casino Creek which flows south to Dip Creek and thence to the Yukon River via the Klotassin, Donjek and White rivers. The southern edge of the LSA includes a 2 km-long reach of Dip Creek.

The aquatics RSA was defined as the LSA plus four adjacent areas:

- ***Dip Creek Watershed***. The headwaters of Dip Creek are not expected to be affected by Project activities, but the reaches of Dip Creek downstream of the confluence of Dip and Casino creeks will be affected by reduction in flows from Casino Creek caused by the impoundment of its headwaters. The effects of those flow reductions will decrease with downstream distance from the confluence of Dip and Casino creeks. One water quality site (W16) was placed approximately 11 km downstream of the confluence to monitor far-field effects.
- **Sunshine Creek Watershed**. This watershed, located to the east of the Britannia Creek Watershed, is not expected to be affected by Project activities. For that reason a reference water quality station – site W17 – was located on Sunshine Creek upstream of its confluence with the Yukon River.
- ***Excelsior Creek Watershed***. This watershed, located to the west of Britannia Creek Watershed, is also not expected to be affected by Project activities. It was originally intended to be the site of a reference water quality site, but that site (W17) was eventually moved to Sunshine Creek for logistical reasons. This watershed may serve as a location for a reference site in the future.

- ***Yukon River***. This river will be the receiving environment for flows from Britannia Creek. Therefore, water quality sampling stations were placed upstream (W6b – a reference site) and downstream (W6a and W15) of the confluence of Britannia Creek and the Yukon River.

1.4.4 Terrestrial Environment

The terrestrial LSA was defined by the boundaries of the Casino Creek, Britannia Creek and Dip Creek watersheds (Figure 5). It is larger than the aquatics LSA but smaller than the aquatics RSA. The terrestrial RSA has not yet been defined. Figures 6a and 6b show the terrestrial LSA in relation to the proposed road route and the Wildlife Key Areas that have been identified by the Fish and Wildlife Branch of the Yukon Department of Environment.

1.5 Study Objectives

The overall objective of the 2008 environmental studies was to characterize the pre-development atmospheric, aquatic and terrestrial environments of the Casino Project area. The sampling strategy was to use, as much as was possible, the same sampling sites or areas that were monitored by Hallam Knight Piésold Ltd. from 1993 to 1995. This will develop further a multi-year database that will allow assessment of natural inter-annual variability.

The specific objective for the atmospheric studies was to install an automated meteorological station on Patton Hill that was capable of being remotely downloaded and that will record meteorological data continuously from the date of installation to the present. These measurements will provide the necessary observations for air quality modelling.

The specific objectives for the aquatic studies were the following:

- Install hydrometric stations on streams in the LSA that will continuously record stream flows and water temperatures.
- Develop stage-discharge curves for each hydrometric station from manual measurements of stream flow and staff gauge height collected over the open-water season.
- Sample stream water quality at sites in the LSA and RSA throughout the open-water season.
- Sample stream sediment quality at sites in the LSA once in 2008.
- Measure the density and taxonomic composition of the mid-summer periphyton communities in the LSA. Periphyton is the term given to the algal community that grows attached to stream substrates. It is the principal source of primary production for stream ecosystems and, because it is fixed to the substrate, it is useful for assessing mine effects on the aquatic environment.
- Measure the density and taxonomic composition of the stream benthic invertebrate communities in the LSA. Benthic invertebrates are a major source of prey for fish and, because they are attached to the substrate, are useful for assessing mine effects on the aquatic environment. Benthic invertebrates are a required component of the Environmental Effects Monitoring (EEM) guidelines of the Metal Mining Effluent Regulations (MMER) (Environment Canada 2002).

- Identify the fish species present in the LSA, describe their spatial distributions and measure their relative abundance and biological characteristics. Fish are the principal predators of stream communities and are a required component of the EEM guidelines of the MMER.
- Measure the whole-body tissue metal concentrations of slimy sculpin (*Cottus cognatus*) from each of the two watersheds in the LSA. Slimy sculpin were chosen because they are a resident species, hence their tissue metal concentrations will reflect local background metal concentrations in water. Tissue metal concentrations are a required component of the EEM guidelines of the MMER.
- Measure the key physical characteristics of stream fish habitat in the LSA.

The specific objectives of the terrestrial ecosystem studies were to collect sufficient preliminary information on soils and vegetation to plan a future air photograph interpretation study of the vegetation communities of the terrestrial LSA and RSA, and to document wildlife presence and use of the various plant communities and habitats.

2. Methods

2.1 Atmospheric Environment

2.1.1 Location and Setup of Meteorological Station

The geomorphology of the Casino Project area – a ridge from which watersheds descend to the north and south – meant that the atmospheric characteristics of the study area could be adequately monitored with a single meteorological station installed near the top of the ridge. The Casino meteorological station was installed on Patton Hill on October 3, 2008, and has been recording data continuously since that day. The station is located at 62°43'27.837"N and 138°49'0.562"W (UTM co-ordinates of 611,609E and 6,956,775N) at an elevation of 1,203 m above sea level (asl) (Figure 3). Appendix A1 shows the letter report from RWDI Air Inc. that describes the station and its installation.

The station consists of a 10 m-high, free-standing tower equipped with instrumentation, datalogger, and logger enclosure (Photo 1). The station is sited in a transition zone between tree line and alpine with an unobstructed fetch of at least 100 m in all directions. The site is sparsely covered in low brush and trees that are approximately 10 m tall. The station has instrumentation capable of measuring wind speed and direction, rainfall, air temperature, barometric pressure, relative humidity and snow depth. Observations are recorded and stored by a datalogger, which is powered by a battery charged with a solar panel at the station. The datalogger is equipped with a satellite modem for remotely accessing the data.

2.1.2 Quality Assurance/Quality Control (QA/QC)

Because the meteorological station was installed late in 2008, too few data have been collected from that station to be presented and analyzed in this report. However, the data that are being collected will be processed according to the following QA/QC protocols.

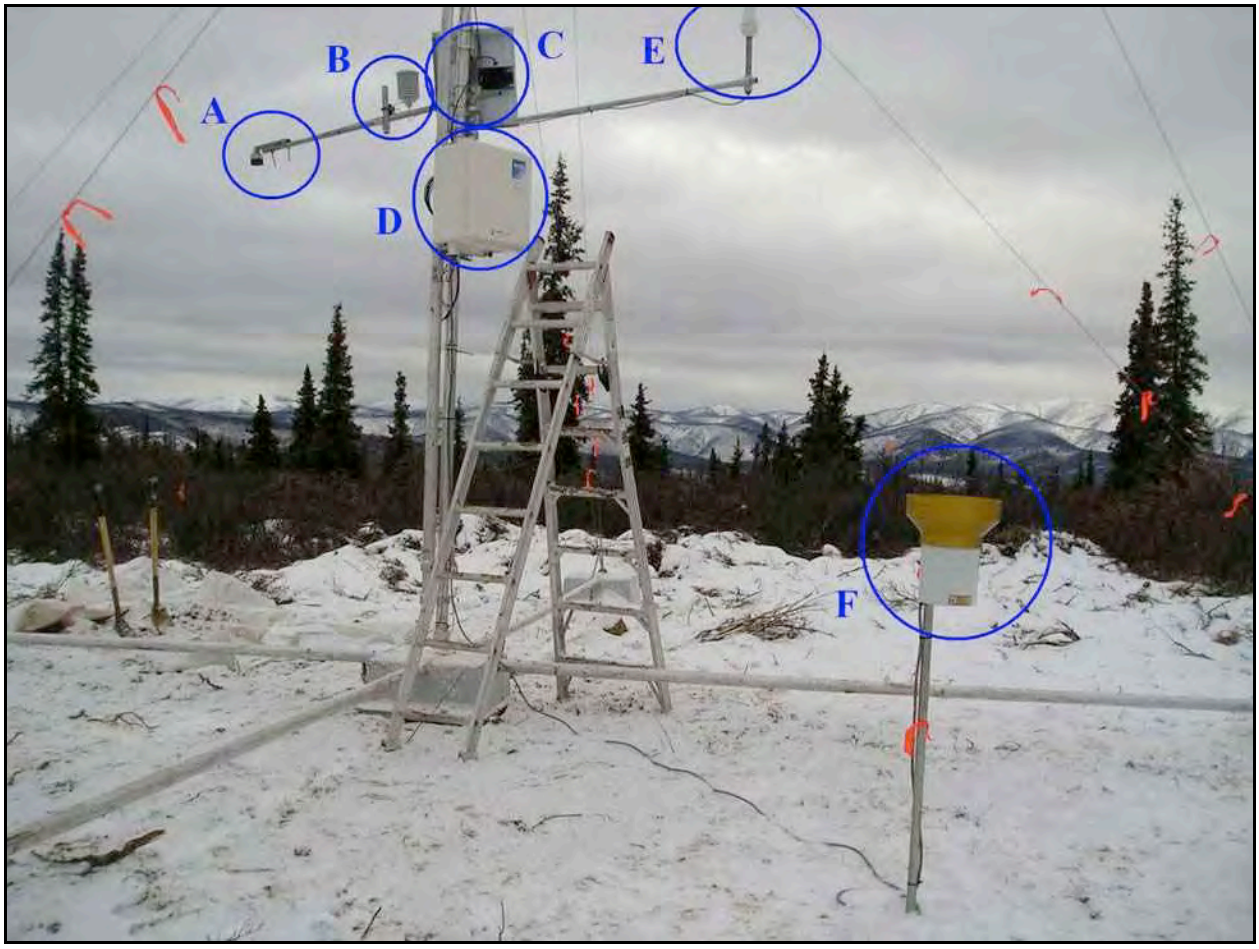

Photo 1. Casino meteorological monitoring station equipped with (A) sonic ranger, (B) relative humidity and temperature probe, (C) solar panel, (D) datalogger enclosure, (E) satellite antenna and (F) rain gauge

Three types of missing data are typically found in the datalogger of the meteorological station. The first is a missing timestamp or record for a particular averaging period. This occurs when the time series skips over a record or series of records entirely. Timestamps of missing periods are manually added to the final dataset. Values for each parameter are given a “Not a Number” (NAN) value for these periods. If missing periods persist or occur regularly, then appropriate action (e.g., send a field technician to the station) will be taken to investigate and resolve the issue.

The second type of missing data is a value for one or more parameters reported as NAN. This flag is typically given to invalid or erroneous data and is excluded in any analysis of data. If one or more parameters persistently shows NAN, then appropriate action (e.g., send a field technician to the station) will be taken to investigate and resolve the issue.

The third type of missing data is a value for one or more parameters that is reported as “0”. This may or may not be an erroneous value, depending on the parameter in question. It is not acceptable under any circumstances for barometric pressure, relative humidity and battery voltage. Values that are reported as zero for those variables will be replaced with NAN and are noted and documented in the final dataset.

Data are checked to see if they are within acceptable upper and lower limits by examining the range of values for each parameter. These limits does not reflect the instrument’s operational range, but they give the physical bounds in which the measurement makes sense. Any values outside the following limits will be considered to be erroneous and will be replaced with NAN:

- Wind speed (0 to 110 km/h);
- Wind direction (0 to 360°);
- Standard deviation of wind direction (0 to 100°);
- Air temperature (-50°C to 35°C);
- Barometric pressure (90 to 110 kPa);
- Relative humidity (0.1% to 100%);
- Rainfall (daily) (0 to 60 mm); and
- Battery voltage (10 to 15 Volts).

2.2 Aquatic Environment

2.2.1 Dates and Locations of Sampling and Surveying

2.2.1.1 General

The study design for the 2008 aquatics work was similar to the sampling design used in the 1993-1995 study by Hallam Knight Piésold. With a few exceptions, the same sampling locations were used and similar sampling techniques were employed. Five sampling trips were made from May to October (Table 1). For each trip, a fixed-wing aircraft was chartered from Alkan Air to fly from Whitehorse to the Casino property. While on the property, aquatic scientists travelled to sampling sites by helicopter (chartered from Capitol Helicopters), by all-terrain vehicles or by foot, depending on weather and trail conditions.

Table 1. Sampling Trips, Aquatic Environment, Casino Project, 2008

Date	Reconnaissance	Hydrology	Water Quality	Sediment Quality	Periphyton and Benthos	Fish and Fish Habitat
May 9	X	-	-	-	-	-
May 20-24	-	X	X	-	-	-
Jul 7-11	-	X	X	-	-	X
Sep 9-13	-	X	X	X	X	X
Oct 9-11	-	X	X	-	-	-

Dashes indicate no data were collected.

2.2.1.2 Hydrology

A total of seven hydrometric stations were installed in 2008. From May 21 to 23, dataloggers (Model 3001 Levelogger Gold, Solinst Corporation) were installed at six hydrometric stations: W1, W3, W4, W9, W11 and W14 (Table 2). This instrument uses a pressure transducer to measure water surface elevation and a thermometer to measure water temperature every hour. Pressure and temperature data were stored in the datalogger and were downloaded on subsequent trips in July, September and October. A barologger was installed at the airstrip to collect barometric air pressure (for barometric compensation for the hydrometric station loggers) and air temperature. On October 9, a seventh hydrometric station was added (H18) on Casino Creek.

Table 2. Summary of Hydrometric Stations and Datalogger Installation Dates, Casino Project, 2008

Watershed	Creek	Site	GPS Co-ordinates*			Dates	
			Easting	Northing		Installation	Winterization
Airstrip	-	-	612,244	6,957,050		May 22	-
Britannia Creek	Britannia	W1	617,439	6,971,241		May 22	Oct 10

	Casino	H18	610,860	6,951,451		Oct 9	Oct 9
	Casino	W4	609,833	6,947,575		May 22	Oct 10
Dip Creek	Dip	W9**	610,018	6,947,352		May 22	Oct 10

**UTM Zone 7N, NAD 83.*

***reference site.*

Dashes indicate no data were available.

During the May field visit, the dataloggers were surveyed using a standard survey rod and level. The water level, the streambed, and the height of the datalogger in the water were determined at each logger station in relation to benchmarks (i.e., large spikes) installed on the creek bank. This allowed for water level measurements to be calculated relative to a fixed land-based benchmark.

Three of the six hydrometric stations were located in the Britannia Creek Watershed:

- W1 on the lower reaches of Britannia Creek;
- W3 on Canadian Creek upstream of the confluence of Canadian and Britannia creeks; and
- W14 on Britannia Creek upstream of its confluence with Canadian Creek.

Two stations were located in the Casino Creek Watershed:

- W11 installed in the upper reach of Casino Creek outside of the southern edge of the proposed TIA; and
- W4 installed on Casino Creek upstream of its confluence with Dip Creek.

One station was located in the Dip Creek Watershed – W9 on Dip Creek upstream of its confluence with Casino Creek.

On October 9, a seventh hydrometric station, H18, was installed in Casino Creek downstream of its confluence with Brynelsen Creek. This station was added to quantify the contribution of flow from Brynelsen Creek.

Two of the seven stations – W3 and W9 – are reference stations, which means they will not be affected by Project activities.

From October 9 to 11, the six dataloggers were winterized by covering each instrument in a latex balloon filled with glycol to prevent damage to the sensors when the surrounding water freezes during winter. Each datalogger was then installed inside a heavy duty, 10 cm-diameters plastic pipe that was partially buried in the stream substrate. Holes were drilled in the pipe to provide hydraulic connection between the stream and the datalogger. Pipes were secured to the stream bank with steel rods anchored by 2 m-long pieces of rebar. All dataloggers were attached with direct read cables for efficient data downloading.

Instantaneous stream flows were also measured manually at additional sites (e.g., W7, W8, W12, W13, W16 and W16 in May). Those sites are summarized in Section 2.2.1.3.

2.2.1.3 Water Quality

A total of 19 sites were chosen for water quality sampling of which six were the hydrometric stations installed in May 2008 (Table 3). Five sites were in the Britannia Creek Watershed:

- hydrometric stations W1, W3 and W14;
- W2 on Britannia Creek just downstream of the confluence of Canadian and Britannia creeks; and
- W7 located on upper Canadian Creek.

Table 3. Summary of Water Quality Sampling Sites, Casino Project, 2008

Watershed	Creek/River	Site	GPS Co-ordinates	
			Easting	Northing
Britannia Creek	Britannia	W2	616,158	6,967,156
	Canadian	W7	609,913	6,959,158
Casino Creek	Casino	W12	612,163	6,958,175
	Casino	W8	613,398	6,956,258
	Meloy	W43	610,823	6,955,906
	Meloy	W13	612,275	6,953,326
	Brynelsen	W18	610,893	6,951,180
Dip Creek	Dip	W9*	610,018	6,947,352
	Dip	W5	609,219	6,947,348
	Dip	W16	600,423	6,942,454
Sunshine Creek	Sunshine	W17*	626,775	6,968,802
Yukon River	Yukon	W6a	615,375	6,973,129
	Yukon	W6b*	619,781	6,973,576
	Yukon	W15	605,721	6,975,108

Dashes indicate no data were available.

Water quality sampling was also conducted at the six hydrometric stations listed in Table 2.

**reference site.*

Five sites were in the Casino Creek Watershed:

- hydrometric stations W11 and W4;
- W12 in Proctor Gulch, the uppermost reach of Casino Creek;
- W8 in the upper reach of Casino Creek upstream of the confluence of Meloy Creek;
- W43 on the adit discharge pipe of the lower camp (which discharges into upper Meloy Creek);
- W13 on Meloy Creek upstream of its confluence with Casino Creek; and
- W18 on Brynelsen Creek upstream of its confluence with Casino Creek.

Three sites were in the Dip Creek Watershed:

- hydrometric station W9;
- W5 on Dip Creek downstream of its confluence with Casino Creek; and
- W16 on Dip Creek 11 km west of site W5 – a far-field site.

One site – W17 – was on Sunshine Creek upstream of its confluence with the Yukon River.

Three sites were located on the Yukon River:

- W6a downstream from the outflow of Britannia Creek;
- W6b upstream of the outflow of Britannia Creek; and
- W15 upstream of the outflow of Excelsior Creek.

Of these 19 sites, three – W9, W17 and W6b – are reference sites, 15 sites are potentially affected by future mine activities, and one – W43 – has already been disturbed.

2.2.1.4 Sediment Quality

A total of 12 stream sites were sampled for sediment quality between September 9 and 10:

- five sites in the Britannia Creek Watershed (W1, W2, W3, W7 and W14);
- five sites in the Casino Creek Watershed (W4, W11, W12, W8 and W13); and
- two sites in the Dip Creek Watershed (W9 and W5).

Only W9 is a reference site. The co-ordinates of the sites are shown in Tables 2 and 3.

2.2.1.5 Periphyton and Benthic Invertebrates

Periphyton and benthic invertebrates were sampled from September 10 to 13. The two communities were sampled at that date because they were expected to have reached their maximum density and diversity after a summer of growth. Four sites were sampled in the Britannia Creek Watershed (Figure 4 and Table 4):

- B1/P1 (where “B” refers to benthos and “P” to periphyton) in lower Britannia Creek upstream of its confluence with the Yukon River;

- B2/P2 in Britannia Creek downstream of the confluence of Canadian and Britannia creeks;
- B3/P3 in Canadian Creek upstream of the confluence of Canadian and Britannia creeks; and
- B8/P8 at the head of Canadian Creek in an area that is proposed to become part of the open pit of the Casino Mine.

Table 4. Summary of Benthos and Periphyton Sampling Sites and Dates, Casino Project, 2008

Watershed	Creek	Site	GPS Co-ordinates		Date
			Easting	Northing	
Britannia Creek	Britannia	B1/P1	617,661	6,973,246	Sep 11
	Britannia	B2/P2	616,163	6,967,197	Sep 10
	Canadian	B3/P3	616,043	6,966,702	Sep 10
	Canadian	B8/P8	609,807	6,958,838	Sep 12
Casino Creek	Casino	B7/P7	613,396	6,956,247	Sep 10
	Casino	B4/P4	610,115	6,947,946	Sep 10
Dip Creek	Dip	B5/P5	609.363	6,947,024	Sep 10

Two sites were sampled in the Casino Creek Watershed – site B4/P4 located upstream of the confluence of Dip and Casino creeks, and site B7/P7 located at the head of Casino Creek in an area that is proposed to be covered by the Casino TIA.

One site were sampled in the Dip Creek Watershed – B5/P5 on Dip Creek, downstream of the confluence of Casino and Dip creeks.

None of these seven sites are reference sites – all are potentially affected by future mine activities.

2.2.1.6 Fish Communities

Fish communities were sampled from July 8 to 11 and from September 10 to 13. Sampling in late May was planned but was cancelled after reconnaissance on May 9 showed that most streams were too turbid to allow visual counts of Arctic grayling spawners or to allow electrofishing.

Four sites were sampled for fish in the Britannia Creek Watershed (Figure 4 and Tables 5 and 6):

- F01 (where “F” refers to fish) on lower Britannia Creek upstream of site B1/P1;
- F03 on lower Britannia Creek below the confluence of Canadian and Britannia creeks;
- F04 on Canadian creek approximately mid-way between sites F03 and F05; and
- F05 on upper Canadian Creek.

Sites F02 and F06 were Hallam Knight Piésold sites that were not sampled in 2008.

Seven sites were sampled for fish in the Casino Creek Watershed:

- F07 on upper Casino Creek downstream of the confluence of an unnamed tributary;
- F08 on upper Casino Creek approximately 2 km downstream of site F07 at the confluence of another unnamed tributary;
- F09 on Meloy Creek, a tributary of Casino Creek;
- F10 and F11 on Brynelsen Creek, another tributary to Casino Creek;
- F12 on Austin Creek upstream of its confluence with Casino Creek; and
- F13 on lower Casino Creek upstream of its confluence with Dip Creek.

One fish sampling site was located in the Dip Creek Watershed – site F14 on Dip Creek downstream of its confluence with Casino Creek.

There were no reference sites for fish in 2008 – all sites may potentially be affected by future mine activities. In particular, sites F07, F08 and F09 are located in an area of Casino Creek that is proposed to be covered by the TIA.

Table 5. Summary of Fish and Fish Habitat Sampling Sites and Dates, Casino Project, 2008

Watershed	Creek	Site	Electrofishing	Minnow Trapping	Angling	Fish Habitat Assessment
Britannia Creek	Britannia	F01	Jul 10	Jul 11	-	-
	Canadian	F03	Jul 8	-	-	Jul 8
	Canadian	F04	Jul 8	-	-	Jul 8
	Canadian	F05	Jul 9	Jul 11	-	-

us = upstream and ds = downstream.

In addition to direct sampling of fish communities, an aerial survey of Britannia and Canadian creeks was conducted on September 11 to search for Pacific salmon spawners. The survey was followed by foot surveys of selected stream reaches to ground-truth the aerial observations.

2.2.1.7 Fish Habitat

In July, sections of stream 75 to 200 m length centred over fish sampling sites were surveyed (Table 5): two in Britannia Creek Watershed (F07 and F08) and two in Casino Creek Watershed (F03 and F04).

In September, the focus shifted to surveying representative sections of stream reaches. The reaches and reach breaks were similar to those used by Hallam Knight Piésold (1997) (Figure 4). Table 7 shows the reach numbers for each stream and the GPS co-ordinates of the centre of the representative section that was surveyed.

Table 7. Locations of Fish Habitat Surveys, September 11-12, 2008

Site	Reach	Co-ordinates		Date
		Easting	Northing	
Lower Reach of Britannia Creek	1	617,126	6,970,199	11-Sep
Upper Reach of Britannia Creek	2	616,279	6,966,540	11-Sep
Lover Reach of Canadian Creek	1	615,314	6,966,030	11-Sep

2.2.2 Sample Collection

2.2.2.1 Hydrology

In accordance with conventional stream gauging protocols for propeller-type meters, all hydrometric stations were established in straight channels, free from obstructions. Each site was selected to ensure representative hydraulic conditions.

Manual stream velocities were measured with a Marsh-McBirney Flo-mate 2000. The stream discharge (Q, m^3/s) was calculated following the United States Geological Survey mid-section method. The width of the stream was 'discretized' into 'panels', the number of which depending on the total width of the stream and the variation in stream velocity across the section. A stream velocity measurement was taken in the middle of each panel. In most instances, the number of panels was such that only between 5% and 10% of the flow passes though each panel. Stream velocity measurements were collected at 60% of the total depth at each measurement point in the cross-section. At points with depths greater than 50 cm, two velocity measurements were taken: one at 20% of the total depth; and, the other at 80% of the total depth. Flow was calculated at both points and the average of the two flows were used as the contribution of flow from that panel. Flows were summed over all the panels to obtain the total stream flow on that date.

Water stage (h, cm) was measured in two ways: measuring the height of the water at the logger installation, and measuring the depth of water at the thalweg – the deepest, fastest section of water in the cross-section.

2.2.2.2 Water Quality

All surface water samples were grab samples, collected in mid-stream approximately 20 cm under the surface with the bottle mouths facing upstream. Water quality samples were collected for general chemical parameters in pre-cleaned 500 mL plastic bottles supplied by the analytical laboratory. Samples for total metals were collected in 250 mL acid-washed plastic bottles supplied by the laboratory and preserved in the

field with laboratory-supplied nitric acid. Samples for dissolved metals were vacuum filtered in the field through 0.45-micron disposable filterware and preserved with laboratory-supplied nitric acid immediately after filtration. Samples for nutrients – ammonia, total Kjeldhal nitrogen (TKN) and dissolved orthophosphate – were collected in 250 mL bottles and preserved in the field with laboratory-supplied sulphuric acid. Total cyanide was collected in 1 L bottles containing laboratory-supplied sodium hydroxide as a preservative. Total Organic Carbon (TOC) was collected in 125 mL glass-amber bottles and preserved with laboratory-supplied hydrochloric acid. Dissolved Organic Carbon (TOC) was collected in 125 mL glass-amber bottles and preserved with laboratory-supplied hydrochloric acid immediately after filtration.

All samples were kept cold and were not allowed to freeze. They were shipped via air cargo from Whitehorse to Maxxam Analytics in Vancouver, BC. Maxxam Analytics is accredited by the Canadian Association for Environmental Analytical Laboratories. Chain of Custody forms accompanied all samples. Table 8 shows the water quality variables that were measured and their Reported Detection Limits (RDL).

Table 8. Water Quality Parameters and Detection Limits

Parameter	Units	RDL	Parameter	Units	RDL

RDL = Reported Detection Limit from Maxxam Analytics.

µS = micro-Siemens, and NTU = nephelometric units.

Field measurements of pH, temperature and specific electrical conductivity were made at each site using a YSI Pro pH/conductivity/temperature meter.

2.2.2.3 Sediment Quality

One sample of stream bottom sediment was collected in September 2008 from each of the 12 sites listed in Section 2.2.1.4. The sediment was collected using established protocols from depositional areas of the stream. Where possible, sediment samples were collected by using the jar provided by the analytical lab as a scoop. Appropriate measures were taken to reduce potential for sample contamination. For example, field staff wore disposable nitrile gloves when sampling. All samples were kept cold at all times between sample collection and delivery to the laboratory. Chain of Custody forms accompanied all samples. Table 9 shows the sediment quality variables that were measured and their detection limits.

Table 9. Sediment Quality Parameters and Detection Limits

Parameter	Units	RDL	Parameter	Units	RDL
Physical					
Percent moisture	%	0.3	Manganese	mg/kg	0.2
pH	pH units	0.01	Mercury	mg/kg	0.05
Total Metals			Molybdenum	mg/kg	0.1
Aluminum	mg/kg	100	Nickel	mg/kg	0.8
Antimony	mg/kg	0.1	Phosphorus	mg/kg	10

Lead	mg/kg	0.1	Zirconium	mg/kg	0.5
Magnesium	mg/kg	100			

RDL = Reported Detection Limit from Maxxam Analytics.

All units are mg/kg dry weight unless otherwise noted.

2.2.2.4 Periphyton

Five samples of periphyton were collected from each of the seven sampling sites from September 10 to 11, for a total of 35 samples. Each sample was collected from one rock selected from the stream bed. Each rock was scraped with a scalpel and the scrapings were washed into a sterile 500 mL plastic bottle jar with a squeeze bottle containing stream water. Each sample was preserved by adding Lugol's iodine solution.

All samples were stored in coolers and kept cool until they could be shipped to Fraser Environmental Services Ltd. (FES) of Surrey, BC, for analysis of taxonomic composition. Chain of Custody forms accompanied all samples.

Periphyton density (cells/cm^2) was calculated for each sample by dividing the total number of cells estimated for a sample by the surface area that was scraped for each sample. Sub-sampling was required to estimate numbers of cells (FES 1994). Sample surface area was estimated by tracing the outlines of each rock on a sheet of wax paper. Back in the office, the wax paper outlines were scanned to JPG file format at high resolution. The images were then rasterized and imported into AutoCAD where new vector boundaries were created based on the outside edge of the wax paper for each sample. This process ensured minimal margin of error and allowed for quick calculation once the scans were complete.

2.2.2.5 Benthic Invertebrates

Five samples of benthic invertebrates were collected from each of the seven sampling sites from September 10 to 11, for a total of 35 samples. Samples of benthic invertebrates were taken from areas of riffle habitat with similar stream depths and velocities. The Surber sampler has a surface area of 0.093 m^2 and mesh size of 250 µm. It was placed facing into the stream current with the hinged frame resting on the streambed. Substrate within the area defined by the frame was disturbed by hand for approximately 5 minutes to dislodge benthic organisms, which were swept into the net by the stream current. The organisms caught in the net were then washed into a sample bottle and preserved with 85% ethanol. This was repeated four more times at nearby areas to obtain five replicate samples at each site.

Samples of benthos were shipped to Cordillera Consulting in Summerland, BC, for taxonomic identification to the lowest practical taxonomic level, which was to the Order level for most aquatic insects, to the Class level for oligochaetes and to the Phylum level for nematodes. Chain of Custody forms accompanied all samples. All organisms in each sample were counted and identified – no sub-sampling was required.

Total density of benthic invertebrates collected by a Surber sampler was calculated by dividing the total number of organisms counted from a sample by the sampling area of the Surber sampler.

2.2.2.6 Fish Community

Three gears were used to sample fish: minnow traps, backpack electrofishers and angling. Three minnow traps were installed at each of five sites in July and two traps were installed at each of three sites in September for a total of 21 minnow trap installations. Minnow traps are made of galvanized steal wire and are conical in shape with a length of 42 cm, a width of 23 cm and a mesh size of 0.6 cm. Minnow traps were placed at each site in deep pools or among large woody debris or in slow-moving eddies. They were anchored to large woody debris or rocks and rocks were placed within the traps to weight them down. They were marked with red or yellow fluorescent flagging tape. Each trap was baited with canned salmon placed in a small perforated bag. Traps were soaked for 24 hours.

A mixture of one-pass and three-pass electrofishing was conducted. Three-pass electrofishing was conducted wherever flows were low enough that blocking nets could be installed in streams, but flows were

high enough at many sites to wash blocking nets out. For those sites, only one-pass electrofishing with no blocking nets were used.

For three-pass electrofishing, blocking nets were installed at the upstream and downstream ends of a stream section 75 m in length. Then, a two-person crew walked the stream section in an upstream direction repeatedly sweeping the stream from bank to bank with the wand of the electrofishing unit. Fish that were temporarily stunned by the electric field were scooped up with a dipnet and stored in a water-filled live bucket. After a pass was complete, the crew processed the captured fish on the stream bank. After waiting one half hour, another pass was conducted. After three passes, the blocking nets were removed and all processed fish were released live back into the stream except for those sculpin that were retained for tissue metals analysis.

Between passes, captured fish were identified to species and counted. Then, fork length was measured to the nearest 1 mm with a measuring board (total length was measured for slimy sculpin), and wet weight was measured to the nearest 0.1 g with a balance. Scales were collected from Arctic grayling for age analysis. The collection site was always on the side of the fish mid-way between the lateral line and the dorsal fin. Arctic grayling scales were sent to North Shore Environmental Services Ltd. In Thunder Bay, ON, where the scales were mounted on micro-fiches and the annuli were counted. A Chain of Custody form accompanied the samples.

Angling was conducted at two sites in July using standard angling gear. Angling effort (i.e., time spent angling) was not recorded. Fish were not processed for biological characteristics and no aging structures were collected.

2.2.2.7 Fish Tissue Metals Concentrations

A sub-set of slimy sculpin captured by electrofishing in July and September were collected for analysis of whole-body tissue metals concentrations. Each fish was placed in a labelled plastic bag and frozen immediately. The samples were sent to CANTEST analytical laboratories in Vancouver, BC. Chain of Custody forms accompanied all samples. At CANTEST, samples were digested using a nitric acid-hydrogen peroxide procedure based on U.S. EPA method 200.3. The concentrations of 32 metals were measured using Inductively Coupled Argon Plasma Spectroscopy (ICP) or ICP Mass Spectroscopy (Table 10). The concentrations of mercury were measured using Cold Vapour Atomic Absorption Spectrophotometry or Cold Vapour Atomic Fluorescence Spectrophotometry.

Table 10. Fish Tissue Metals and Detection Limits

Metal	RDL	Metal	RDL
Aluminum	0.5	Nickel	0.1
Antimony	0.1	Phosphorus	0.5
Arsenic	0.1	Potassium	1
Barium	0.1	Selenium	0.2
Beryllium	0.02	Silicon	10
Boron	2	Silver	0.01
Cadmium	0.02	Sodium	1
Calcium	1	Strontium	0.05
Chromium	0.1	Tellurium	0.1
Cobalt	0.1	Thallium	0.02
Copper	0.1	Tin	0.1
Iron	5	Titanium	0.3
Lead	0.1	Uranium	0.04
Magnesium	0.5	Vanadium	0.5
Manganese	0.1	Zinc	0.5
Mercury	0.01	Zirconium	3
Molybdenum	0.1		

All units are µg/g wet weight.

RDL = Reported Detection Limit.

2.2.2.8 Fish Habitat

Fish habitat was characterized following a modified version of the methods described in the *Fish Habitat Assessment Procedures* guide for the British Columbia government (Johnston and Slaney 1994). Stream length and stream width (i.e., wetted and bankfull width) was measured with surveyor's measuring tape. Gradient was measured with a clinometer. Stream depth was measured with a meter stick. Stream stage was assessed as low, medium or high visually by comparison between stream surface height and bankfull height. Habitat was visually assessed into the following five types:

- ***Pools*** have zero gradient, slow-moving water and a concave bottom;
- ***Runs*** (also called glides) are sections of non-turbulent, fast-flowing water;
- ***Riffles*** are areas of turbulent, fast-flowing water with gravel or cobble substrates and with obvious surface turbulence;
- ***Cascades*** are steep, stepped "riffles" of bedrock or emergent cobble or boulders in channels with gradients greater than about 4%;
- ***Other*** includes wetland complexes that lack an identifiable primary channel, sloughs, lakes, areas of sub-surface flow or areas where the channel cannot be observed (e.g., under large log jams).

Stream substrate was assessed visually into the following classes:

- fines (or silt);
- small gravel (2-16 mm particle diameter);
- large gravel (16-54 mm);
- small cobble (64-128 mm);
- large cobble (128-256 mm);

- boulder (>256 mm) or
- bedrock.

The percent of the stream surface that provided fish with cover was described using the following classes:

- deep pool;
- large woody debris (LWD);
- boulder;
- cutbank;
- instream vegetation; and
- overhanging vegetation.

The percentage of the overhead forest canopy that was closed was estimated visually.

The percentages of a stream section that belonged to each habitat type had to add to 100%, as did the percentages of the substrate of a stream section that belonged to each size class and the percent of the canopy that was closed. However, the percentages of cover provided by the various classes did not have to add up to 100%.

Stream confinement was assessed as:

- unconfined (UC) – the stream bank is not touching the valley wall;
- occasionally confined (OC) – the stream bank is occasionally confined by the valley wall or terraces;
- frequently confined (FC) – the stream bank is frequently confined by the valley wall or terraces;
- confined (CO) – the stream bank is in continuous or repeated contact at the outside of meander bends;
- entrenched (EN) – the stream bank is in continuous contact with the valley walls or terraces due to downcutting; and
- not applicable (NA) – no valley walls exist (e.g., alluvial fans).

The stream section was classified as braided or non-braided and the percent of the stream surface area made up of gravel bars was recorded.

Finally, a suite of water quality variables were measured with field instruments (e.g., YSI model 556): pH, water temperature, TDS, conductivity and dissolved oxygen concentration.

2.2.3 QA/QC

2.2.3.1 Water Quality

All field equipment were maintained in good working condition and measuring instruments were calibrated frequently. For example, the pH meter was calibrated prior to each field trip using prepared solutions with pHs of 4 and 7, and the conductivity meter was checked prior to each field trip using the standard 1,413 µS/cm conductivity solution.

Water quality samples were collected by a qualified aquatic biologist and were carried out by the same individual at each sampling site to insure consistency. All water samples were collected using industry standard sampling protocols. Appropriate measures were taken to reduce potential for sample contamination. Field staff wore disposable nitrile gloves when sampling and used bottles and preservative supplied by the analytical laboratory. All samples were collected with the mouth of the sampling bottle facing upstream. Care was taken to ensure that no upstream disturbances occurred as the result of walking within the creek bed prior to sampling.

Ten percent of the number of water quality samples were replicated, hence a total of five replicate samples were collected: two in May, two in July and one in September. Replicate sample locations were chosen randomly. Appendix B6 shows the results of analysis of replicate samples. Relative Percent Difference (RPD) was used to assess analytical variability. RPD was defined as:

$$\%RPD = \frac{2(X_1 - X_2)}{(X_1 + X_2)} * 100$$

where X_1 = the concentration of a parameter in the first sample and X_2 = the concentration of the same parameter in the second sample (i.e., the replicate). An RPD less than 25% is considered an acceptable difference, and an RPD greater than 25% warrants further examination to ensure that the result was not due to sampling error or analytical error. RPD is only relevant when both values are greater than the Practical Quantitation Limit (PQL), which was defined for this project as three times the detection limit. The PQL is considered the lowest concentration that can be accurately measured, as opposed to just detected.

As shown in Appendix B6 and Table 11, between one and seven of the 89 parameters that were measured from each sample had RPDs greater than 25% and met PQL restrictions. This was equivalent to between 1% and 8% of all parameters, which is considered to be an acceptable level of variability.

Table 11. RPD Analysis of Replicate Water Quality Samples, Casino Project, 2008

Month	Replicate	Number of Parameters with RPD>25%	Percent of Parameters with RPD>25%
May	1	7	8
May	2	3	3
July	3	1	1
July	4	3	3
September	5	2	2

A total of 89 parameters were measured from each sample.

The sites, dates and parameters for which RPD was greater than 25% were as follows:

- W1, May, turbidity, sulphate, total iron, total lead, total phosphorus, total titanium and total vanadium;
- W5, May, TSS, turbidity and dissolved thorium;

- W1, July, chloride;
- W43, July, TKN, dissolved aluminum and dissolved silver; and
- W43, September, TKN and dissolved nickel.

Sites W1, W5 and W43 should be targeted in future QA/QC monitoring to investigate further these results.

The results of the field and travel blanks are shown in Appendices B2 to B5. All values were below detection limits, indicating no contamination of samples.

Maxxam Analytics, which conducted the analyses of water and sediment samples, is a certified member of the Canadian Association of Environmental Analytical Laboratories. Maxxam split several samples into duplicates and analyzed each one separately to provide a measure of their laboratories analytical precision. Duplicates were chosen randomly by Maxxam. The results, which are not reported here, met Maxxam's standards for QA/QC.

2.2.3.2 Sediment Quality

Sediment quality samples were collected by a qualified aquatic biologist and were carried out by the same individual at each sampling site to insure consistency. All sediment samples were collected using industry standard sampling protocols. Appropriate measures were taken to reduce potential for sample contamination. Field staff wore disposable nitrile gloves when sampling and used sample bottles supplied by the analytical laboratory.

No replicate sediment quality samples were collected.

2.2.3.3 Periphyton and Benthos

Periphyton and benthic invertebrates samples were collected by a qualified aquatic biologist and were carried out by the same individual at each sampling site to insure consistency.

Fraser Environmental Services Ltd. (FES) has over ten years experience in analysis of periphyton from streams and rivers of western Canada. FES has the following standard QA/QC procedures (FES 1994):

- all microscopes are calibrated on a regular basis;
- consistent sample concentration and sub-sampling techniques are employed for identifications;
- taxonomic identifications are verified by comparison with reference collections, including an in-house reference collection;
- difficult, typical or dominant specimens are sent to external experts for confirmation. Part of this process includes compiling a list of experts for different groups of organisms. Verified specimens are incorporated into FES' reference collection; and
- all FES personnel actively participate in a taxonomists' working group.

Cordillera Consulting has over ten years experience in taxonomic analysis of benthic invertebrates from streams, rivers and lakes of western Canada. The following QA/QC procedures are followed by Cordillera Consulting (http://www.cordilleraconsulting.com):

- sorting efficiency – 10% of the whole sample number was resorted with an expectation of >90% efficiency in the sorting process.
- taxonomic efficiency – 10% of the identified sample vials were sent to another taxonomist. The two results were compared with simple statistics and the taxonomists discussed how best to correct their differences and make appropriate changes to the results.
- taxonomic precision – an externally verified reference collection is maintained by Cordillera Consulting. Any new specimens are sent away to experts of that taxon and the collection is reviewed every five years.

2.2.3.4 Fish and Fish Habitat

All fish and fish habitat field data were recorded on paper field notes and then transferred to electronic spreadsheets in the office. The spreadsheets were compared with the field notes to identify and correct transcription errors. A variety of other measures were taken to further ensure the validity of the data. For example, fish weights were plotted on fish lengths for each species separately to identify outliers that may have been due to errors in recording or transcription. Outliers were then corrected, if possible, or excluded from the analyzed dataset.

Blanks and duplicates were run by CANTEST for each of the two batches of slimy sculpin tissue that were analyzed for metals concentration. Appendix B15 shows those data. In both cases the blanks were below detection limits, indicating no contamination of equipment. RPDs were calculated for each metal from the duplicate samples. In all cases, the RPDs were below the 20% limit specified by the *British Columbia Environmental Laboratory Manual for the Analysis of Water, Wastewater, Sediment, Biological Material and Discrete Ambient Air Samples* (BC MOE 2007).

2.2.4 Data Analysis

2.2.4.1 Hydrology

In order to reconstruct a discharge hydrograph for each hydrometric station, a relationship between manual measurements of discharge and water stage (referred herein as a rating curve) was developed. A power function is used to predict discharge from water stage:

$$Q = a(h - z)^b$$

where Q is discharge (m^3/s), h is stage (m), z is gauge height at “zero flow” (m), and a and b are constants. An estimate of z was obtained by plotting log(Q) versus log (h) – z was the y-intercept when log(Q) = 0. Then, the power function was converted to a linear regression equation by taking logarithms:

$$\log(Q) = \log a + b \log(h - z)$$

and regression analysis was used to estimate values for a and b for each hydrometric site.

To reconstruct a hydrograph at each site, the continuous stage readings recorded by the datalogger were converted to hourly flows using the fitted stage-discharge relationship for each site. Daily mean discharges were calculated from the hourly discharges.

2.2.4.2 Water Quality

The minimum, median and maximum concentrations of selected water quality parameters were calculated for each site sampled in 2008. The median, rather than the arithmetic mean, was assumed to be the best estimate of the central tendency of the data because many water quality variables tend not to be normally distributed. To calculate statistics, all data for each site were pooled over the May-October sampling period and values below detection limits were replaced with one-half the detection limit.

Concentrations of water quality parameters were compared to guidelines for the protection of freshwater aquatic life issued by the Canadian Council of the Ministers of the Environment (CCME) (CCME 2008), and exceedances of the guidelines were identified.

Principal components analysis (PCA) of water quality was used to reduce the redundancy within the dataset and identify underlying trends. The first step in PCA of water quality was to remove all variables for which 90% of the records were below detection limits. For the remaining variables, all values below detection limits were replaced with one-half the detection limit. Concentrations of total and dissolved metals were transformed with natural logarithms to normalize the frequency distributions. The varimax option was used to rotate components in order to maximize the contrast between components and improve comprehension of the results.

2.2.4.3 Sediment Quality

The minimum, median and maximum concentrations of each sediment quality parameter were not calculated because only one sample was taken for each site sampled in September 2008.

The 2008 sediment quality data was compared to the CCME (2008) sediment guidelines for the protection of freshwater aquatic life. There are two classes of guidelines: the Probable Effects Level (PEL), which defines the level above which adverse effects are expected to occur frequently; and the Interim Sediment Quality Guideline (ISQG), which is lower than the PEL and which defines the concentration below which minimal effects on the aquatic environment are expected.

PCA of sediment quality was calculated in the same way as PCA of water quality. All metals for which 90% of the records were below detection limits were removed. For the remaining metals, all values below detection limits were replaced with one-half the detection limit. Metal concentrations were transformed with natural logarithms to normalize the frequency distributions, and the varimax option was used to rotate components.

2.2.4.4 Periphyton and Benthos

One-way Analysis of Variance (ANOVA) was used to compare mean densities of periphyton and of benthic invertebrates between sites. ANOVA assesses the statistical significance of differences using F-ratios. Significance was assessed as none ($P>0.05$), low ($0.01<P<0.05$), medium ($0.001<P<0.01$) and high ($P<0.001$), where P is the probability of making a Type I error (i.e., rejecting a true null hypothesis). Densities were ln-transformed to normalize the frequency distributions and to satisfy the assumption of equal variances – two prerequisites of parametric statistics.

The taxonomic composition of periphyton and benthos communities were assessed using tabular means after pooling replicates for each site.

Two indices of taxonomic diversity were calculated for each sample of periphyton and three indices were calculated for each sample of benthic invertebrates using the protocols recommended by the Canadian Aquatic Biomonitoring Network (CABIN), which is supported by the National Water Research Institute (NWRI) of Environment Canada (NWRI 2008):

- taxonomic richness (S), calculated as the total number of families in a sample, regardless of their relative abundances;
- EPT abundance (EPT), defined as the total number of mayflies (Ephemeroptera), stoneflies (Plecoptera) and caddisflies (Trichoptera) in a sample. These three orders of aquatic insects are typically most sensitive to habitat disturbance. EPT was not calculated for periphyton; and
- Shannon-Weiner diversity index (H'), calculated as $-\Sigma(p_i \ln(p_i))$, where $p_i = n_i/N$, n_i = the total number of individuals in the i^{th} species, N = the total number of organisms in the sample, and H' was calculated by summing over all species (i.e., over S).

For the purposes of calculating S and H', those taxa that could not be identified to the family or species level (e.g., unidentified flagella for periphyton and Phylum Nematoda for benthos) were treated as if they were a family or a species. The periphyton data reported by Fraser Environmental Services included less than signs (<) for some species or genus, indicating that the species or genus were present in the sample but not in sufficient numbers to allow density to be calculated. Those data were used to calculate periphyton richness, but they were not used to calculate densities and Shannon-Wiener diversity indices.

2.2.4.5 Fish and Fish Habitat

The standard error (SE) was the index of dispersion for all arithmetic means shown in this report, and n was the sample size.

Total catch-per-unit-effort (CPUE) of minnow traps was not calculated because the traps caught no fish. Electrofishing CPUE was defined as the number of fish captured per 100 seconds of electrofishing effort. Angling CPUE was not calculated because fishing effort (i.e., angling time) was not recorded.

One-way ANOVA was used to compare mean fish CPUE between seasons and sites and mean fish length and weight between watersheds.

Weight-length regressions for fish were calculated as ln(W) = a + bln(L), where W = weight (g) and L = fork length (mm), a = the intercept of the regression and b = the slope of the regression. Both weight and length were ln-transformed to normalize their frequency distributions and produce homogenous variances. The coefficient of determination (i.e., r^2) for all regressions were adjusted for the number of degrees of freedom.

The length-age relationship for Arctic grayling was estimated by fitting a von Bertalanffy growth model with non-linear regression. The model is $L = L_\infty(1 – \exp(-K(t – t_0)))$ where L = length (mm), t = age (year), L_∞ = length (mm) at infinite age (also known as asymptotic length), K = growth coefficient ($year^{-1}$) and t_0 = the age (year) at which L = 0 mm. The advantage to using a von Bertalanffy model is that it predicts non-zero lengths for 0-age fish.

Analysis of slimy sculpin tissue metal concentrations was similar to that of water quality and sediment quality: remove all metals for which 90% of the records were below detection limits, replace all values below detection limits with one-half the detection limit, and use PCA to identify underlying trends. Metal concentrations were transformed with natural logarithms to normalize the frequency distributions, and the varimax option was used to rotate components.

2.3 Terrestrial Environment

Two terrestrial reconnaissance surveys were conducted in 2008: one from July 7 to 11 and a second from September 8 to 11. Aerial surveys of the terrestrial LSA were conducted in a helicopter at low altitudes (mean height of 150 m above ground level) and low speeds (40 to 55 knots). Two observers scanned the ground with binoculars and recorded observations on vegetation communities and wildlife in field notes and on a map of the LSA. Photographs of vegetation communities were taken.

Aerial surveys were followed by ground-based surveys conducted by foot or with ATVs. A total of 33 sites – 17 in July and 16 in September – were surveyed (Figure 5). At each site, wildlife habitat was classified (e.g., aspen forest, riparian, alpine subalpine, etc.), surficial geology was classified (e.g., collivial, fluvial, bedrock, etc.), and general features of the habitat were described (e.g., slope, aspect, drainage, etc.). Soil pits were dug to a minimum 40 cm (where possible) or to the C layer. Samples of vegetation were collected and animal sighting and signs (claw marks, paw prints, antlers, scat, etc.) were photographed and their GPS co-ordinates recorded with a Garmin 76 handheld GPS with accuracy of between 5 and 10 m.

The vegetation sampling strategy was guided by the *Standards for Terrestrial Ecosystem Mapping (TEM) in British Columbia* (RIC 1998). This system provides an established and uniform means of describing vegetation, soils and terrain characteristics based on air photo interpretation and field data collection programs. Sampling of vegetation used a combination of ground inspection plots (GIF) and visual checks, using Ecosystem Field Forms adapted from methodology outlined in the *Field Manual for Describing Terrestrial Ecosystems* (BC MELP and MOF 1998). Ground inspections used FS212 (adapted) field forms to record site, soil and vegetation information. Notes describing the plot, in context and variability within the polygon, were recorded. Photographs were taken at each plot.

Visual checks involved recording brief point or area characteristics made from the air (helicopter) or ground, and were used to note the basic ecosystem unit, vegetation, and other key features. The primary function of visual plots was to aid in the delineation of polygon and to confirm the placement of polygon boundaries during the photo interpretation and mapping phases proposed for 2009.

Vegetation nomenclature followed that of the *Flora of the Yukon Territory* Second Edition (Cody 2000). A detailed rare plant survey of the Project area was not within the scope of this assessment. Instead, attempts were made to identify potentially rare, sensitive and/or endangered vegetation or vegetation communities within the study area. In general, alpine/sub-alpine and riparian communities across the LSA were expected to possess the greatest potential of harbouring rare plants or sensitive plant communities because they are sensitive to disturbance and may take above mean lengths of time to recover from disturbance. Riparian areas also provide high wildlife habitat value.

The terrestrial data collected in 2008 were reconnaissance-level only and hence were not subjected to extensive analysis. They primary purpose was to provide sufficient data to effectively plan more comprehensive surveys in the future.

3. Results and Discussion

3.1 Atmospheric Environment

There were too few meteorological data to be analyzed in this report because the Casino meteorological station has only been operating since October 3, 2008. Air temperatures recorded by the barologger at the Casino airstrip are shown in Section 3.2.1.2 below.

3.2 Aquatic Environment

3.2.1 Hydrology

3.2.1.1 Stage-Discharge Rating Curves

Appendix B1 shows the stage-discharge data for the six hydrometric stations. Table 12 summarizes the manual discharge measurements and shows the estimates of the gauge height at zero flow (z) for each of the hydrometric stations.

Table 12. Summary of Manual Discharges and 'z' for Hydrometric Stations

Creek	Site	May (m^3/s)	July (m^3/s)	September (m^3/s)	October (m^3/s)	Gauge at Zero Flow (z, m)
Britannia	W1	2.539	0.840	2.136	0.403	0.06
Canadian	W3	1.621	0.332	1.568	0.375	0.26
Casino	W4	1.499	0.495	2.118	0.809	0.18
Dip	W9	3.988	3.613	3.252	1.105	0.29
Casino	W11	0.865	0.136	0.707	0.401	0.06
Britannia	W14	0.864	0.290	0.398	0.145	0.03

Figures 7 through 12 show the stage-discharge rating curves for sites W1, W3, W4, W9, W11 and W14 respectively. The regression statistics shown in each figure – sample size (n), coefficient of determination (r^2) and the probability that the slope is equal to zero (P) – are the results of the log-linear regression analysis. In each case, the regression provided an apparently fair to strong fit to the data. However, two of the regressions – those for W9 and W11 – were not significant (P>0.05) due to the small sample size.

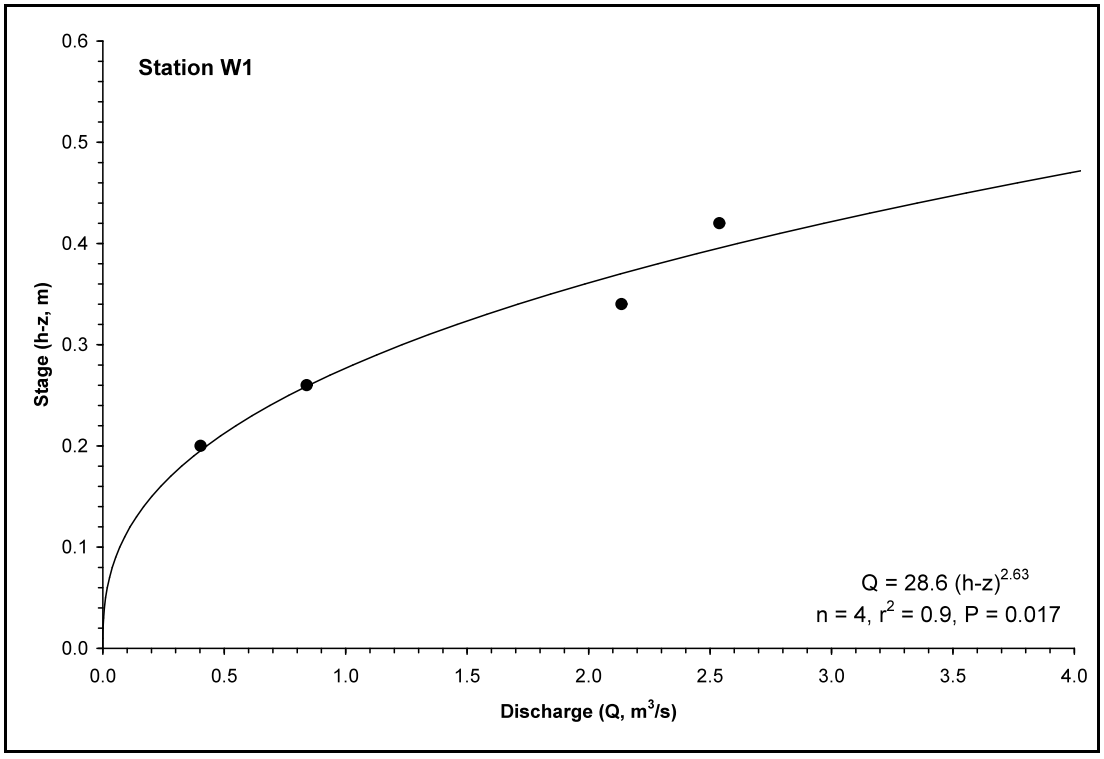

Figure 7. Stage-Discharge Rating Curve for Site W1, Britannia Creek, Casino Project, 2008

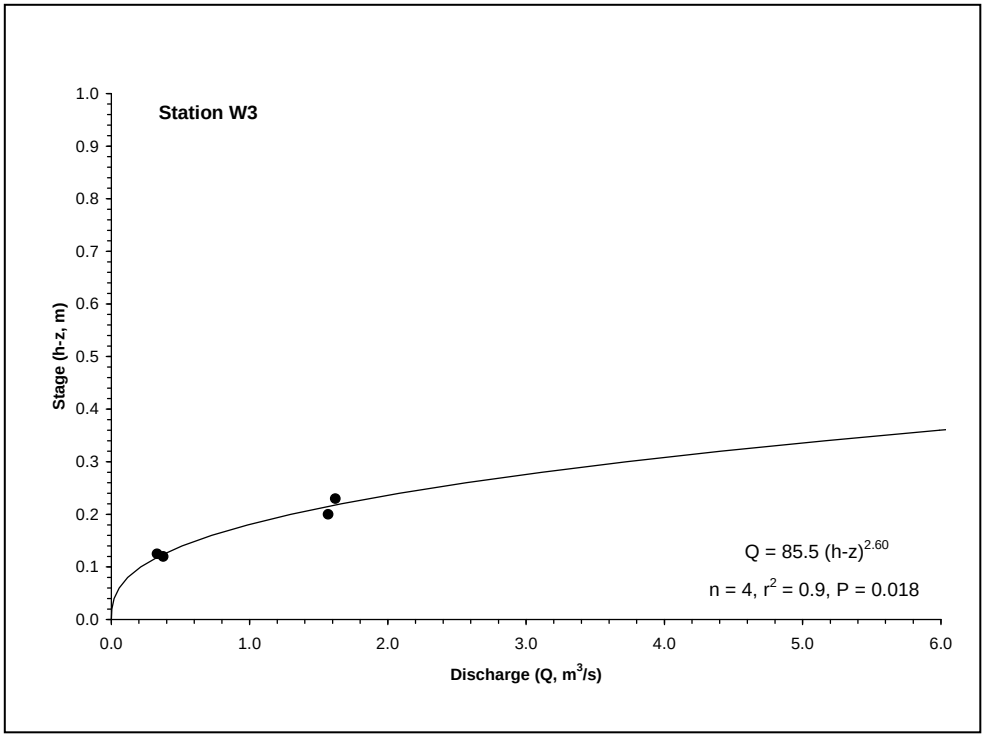

Figure 8. Stage-Discharge Rating Curve for Site W3, Canadian Creek, Casino Project, 2008

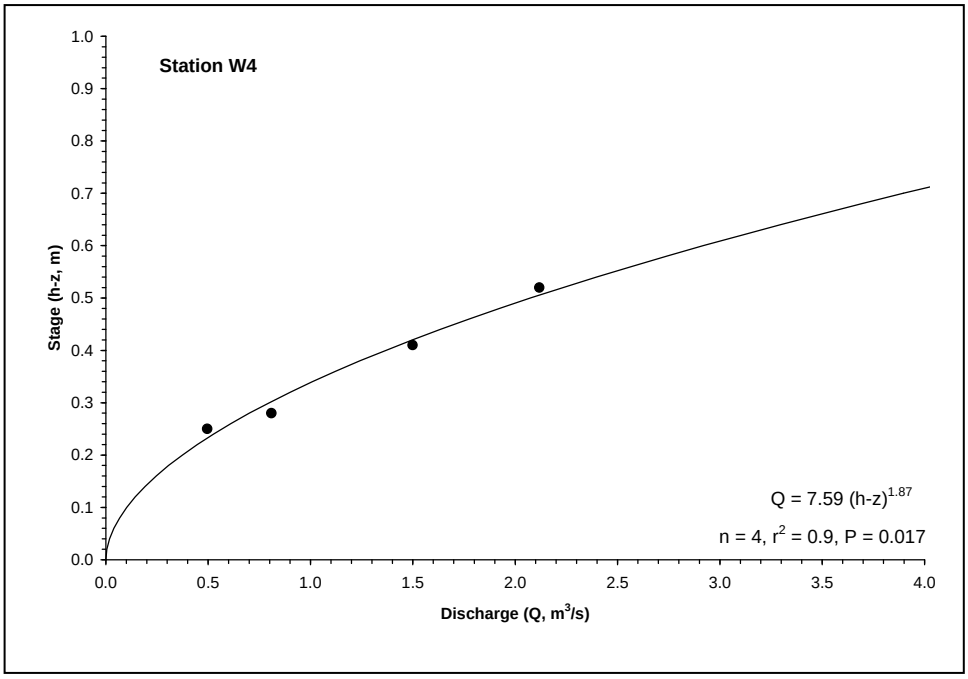

Figure 9. Stage-Discharge Rating Curve for Site W4, Casino Creek, Casino Project, 2008

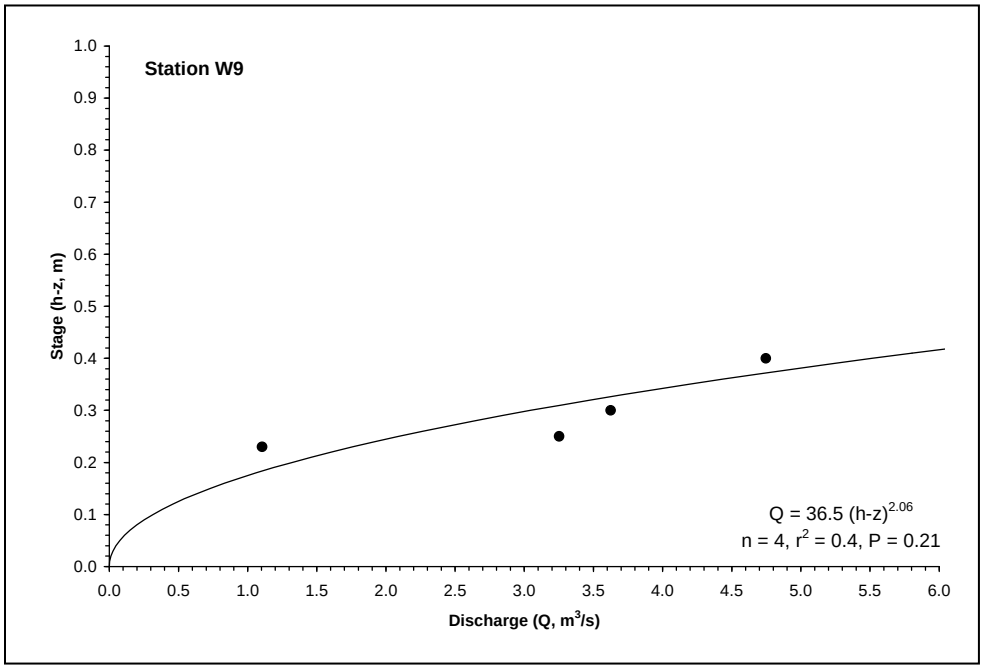

Figure 10. Stage-Discharge Rating Curve for Site W9, Dip Creek, Casino Project, 2008

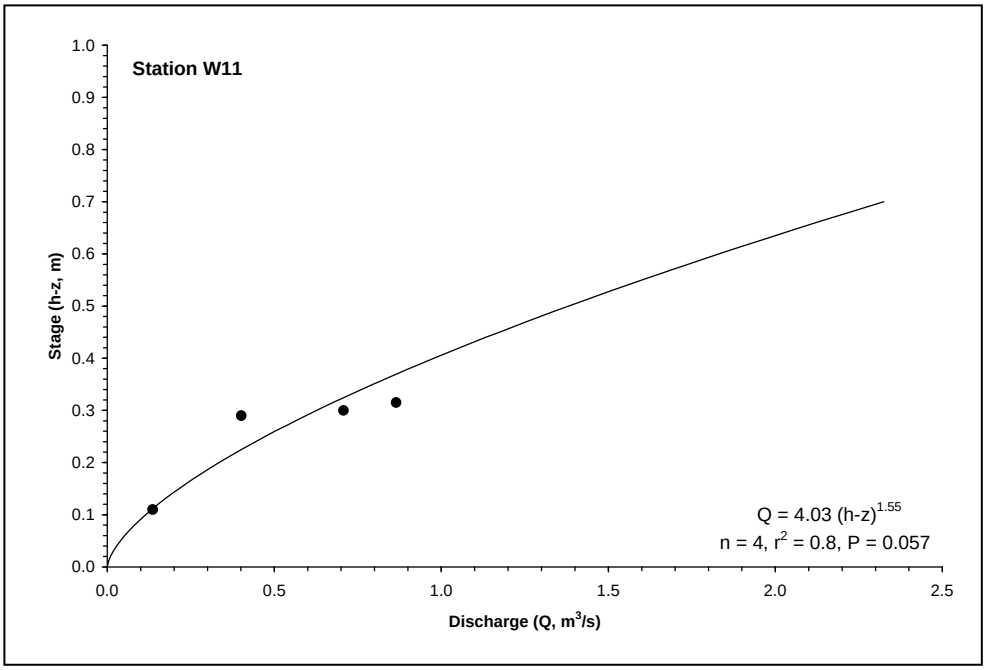

Figure 11. Stage-Discharge Rating Curve for Site W11, Casino Creek, Casino Project, 2008

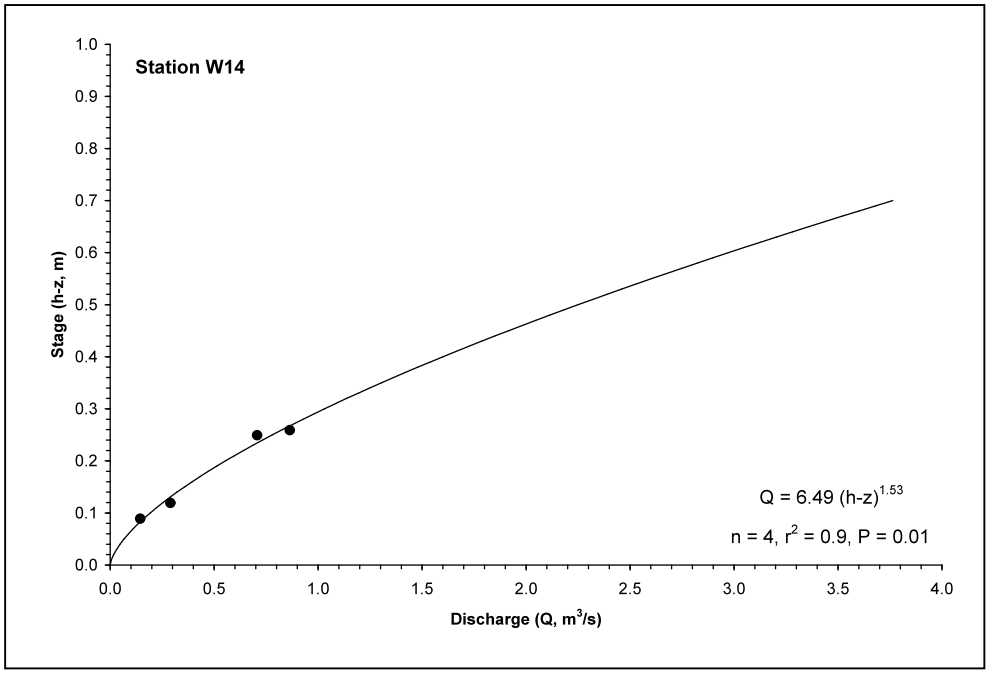

Figure 12. Stage-Discharge Rating Curve for Site W14, Britannia Creek, Casino Project, 2008

In general, the manual measurements during each field visit were conducted during medium to high flow events. Consequently, the reconstruction of discharge at lower flows is less reliable. Future field visits should attempt to capture, if possible, lower flows in efforts to produce more representative stage-discharge rating curves.

3.2.1.2 Hydrographs

Figures 13 to 18 show the hydrographs for stations W1, W3, W4, W9, W11 and W14, respectively. Discharge is shown as a solid blue line, water temperature as the dashed green line and air temperature as the dotted orange line. Due to a logger malfunction at station W4 (Figure 15), data was not collected between May 22 and July 9, 2008.

In the absence of meteorological data, it is difficult to ascertain the source (snow melt, precipitation, permafrost melting, etc.) of specific peaks in discharge for each station. However, The following observations can be made with a moderate degree of confidence, based on the temporal patterns of stream temperature and air temperature, in conjunction with the temporal pattern of specific discharge peaks:

Figure 13. Hydrograph for Station W1, Britannia Creek, Casino Project, 2008

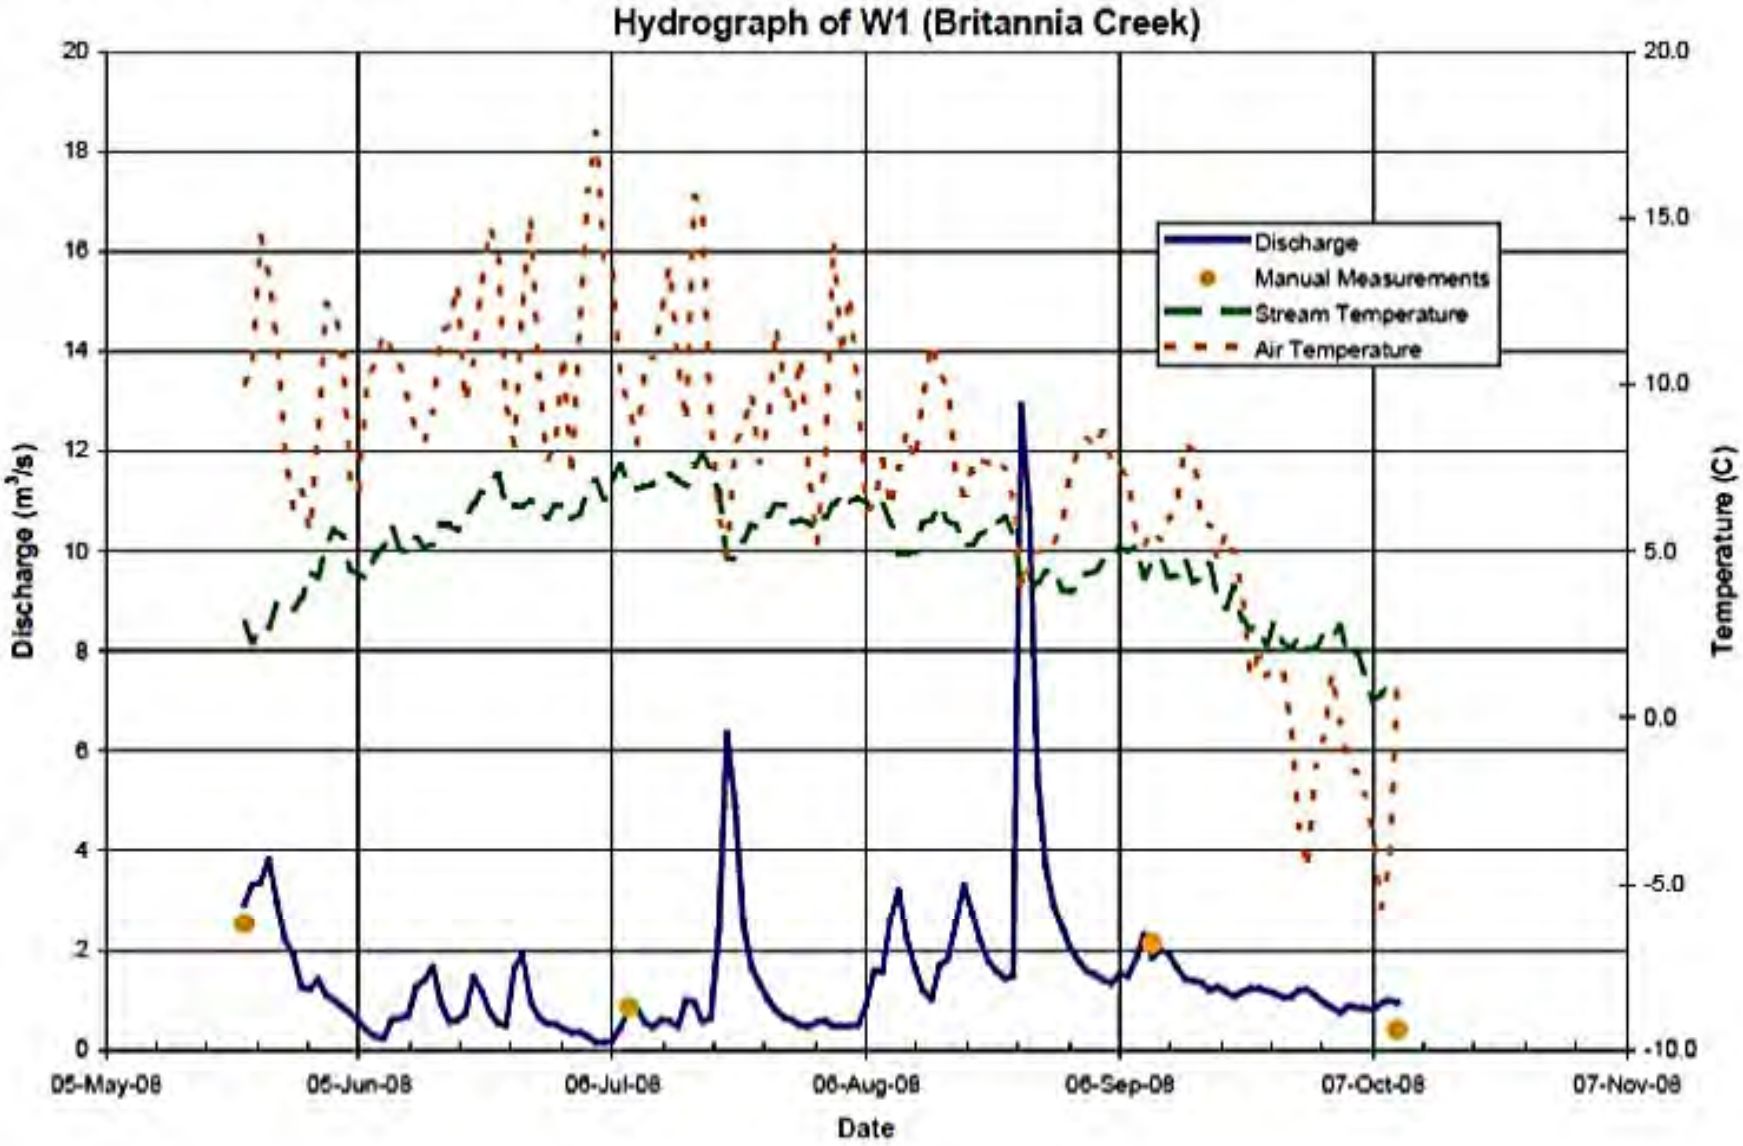

Figure 14. Hydrograph for Station W3, Canadian Creek, Casino Project, 2008

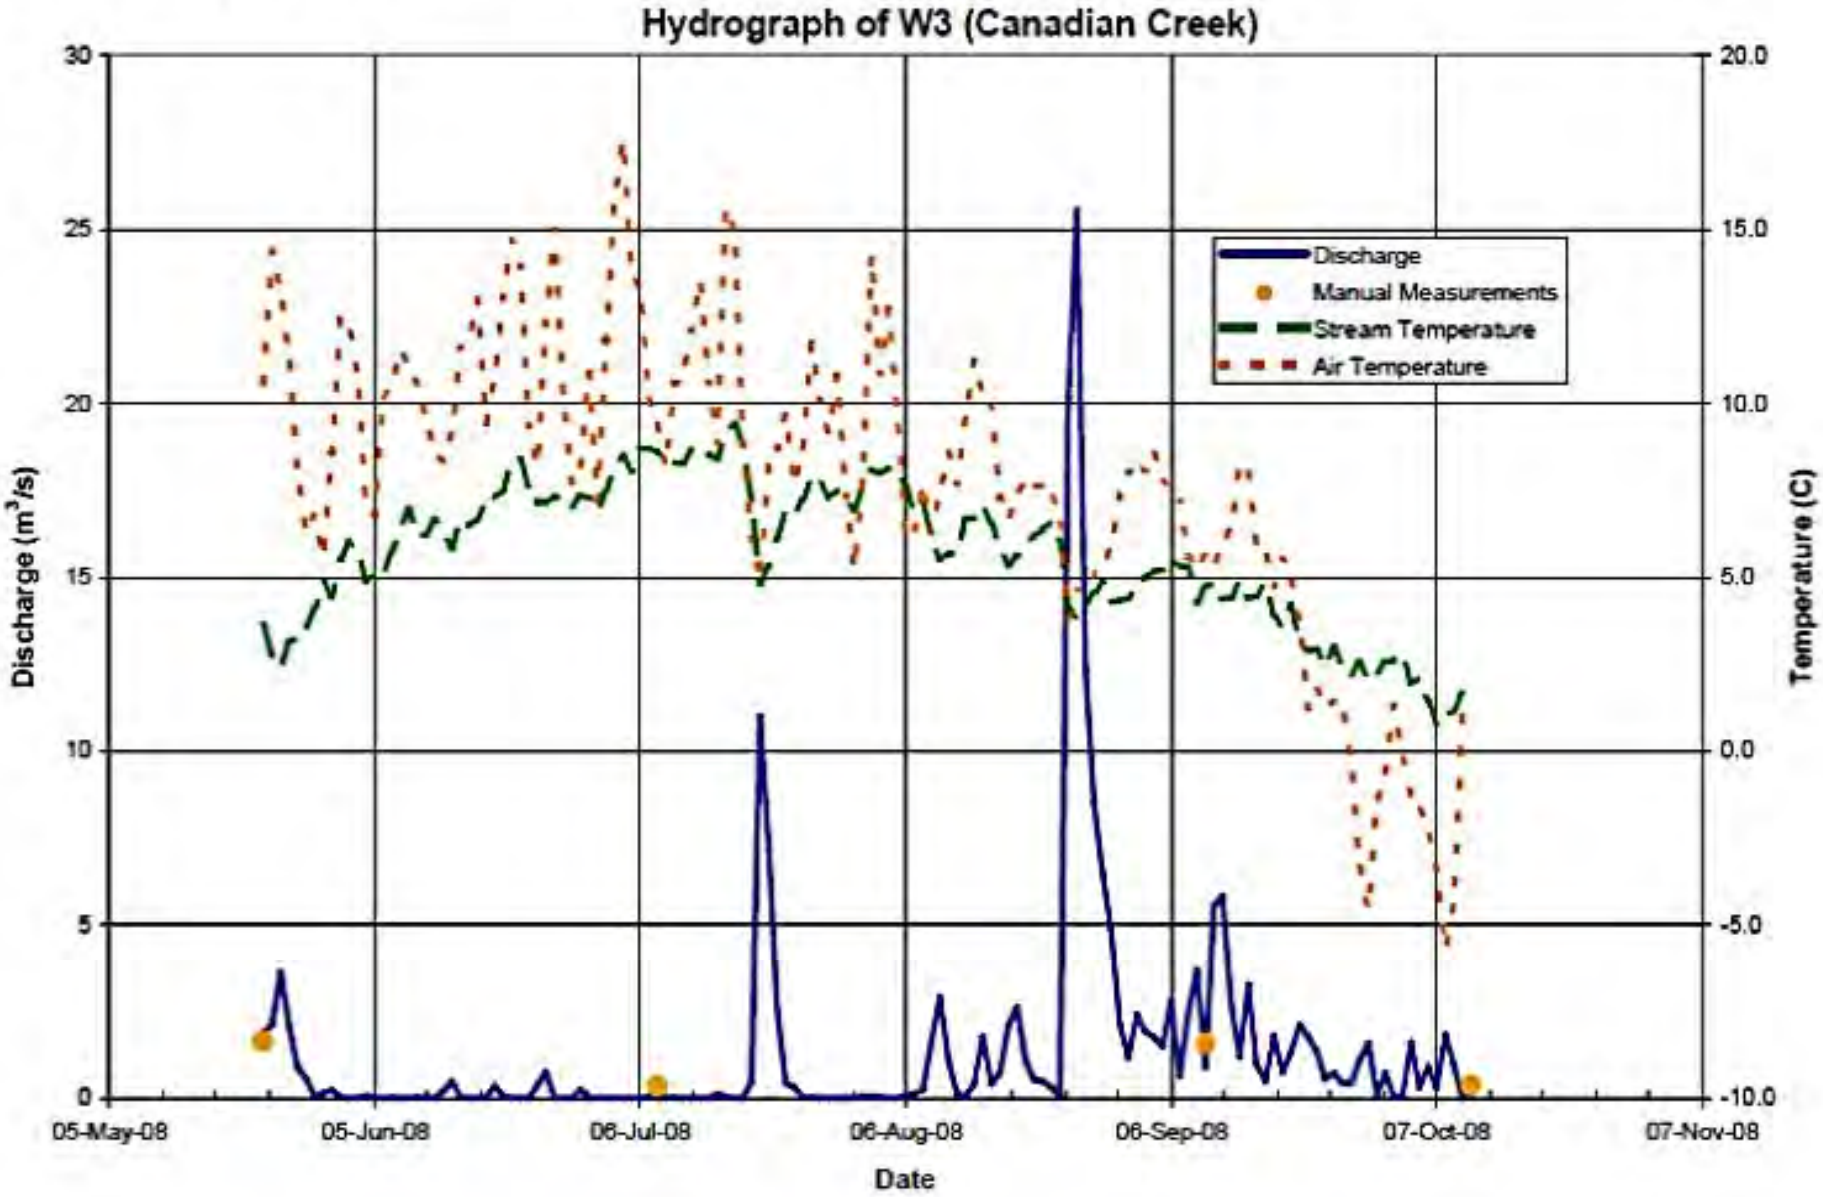

Figure 15. Hydrograph for Station W4, Britannia Creek, Casino Project, 2008

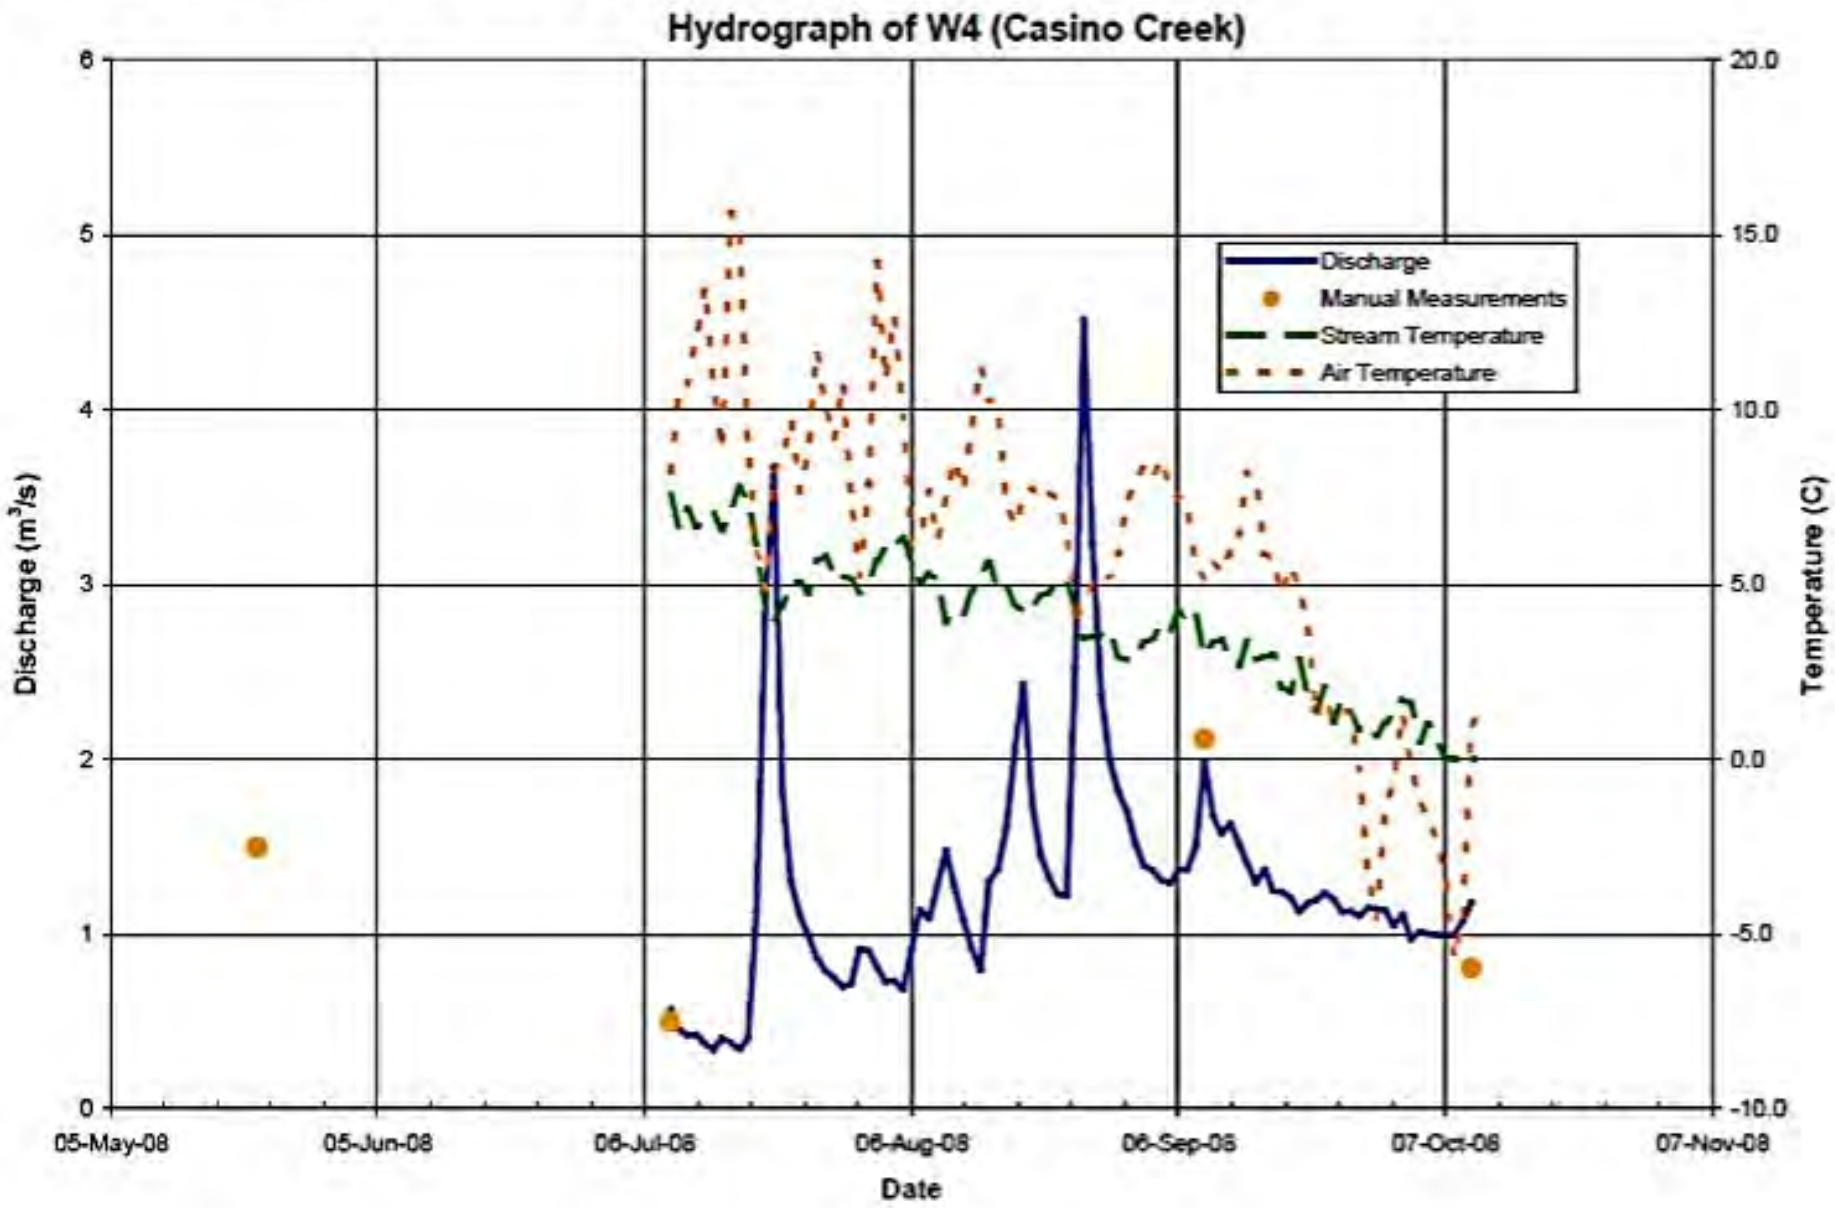

Figure 16. Hydrograph for Station W9, Deep Creek, Casino Project, 2008

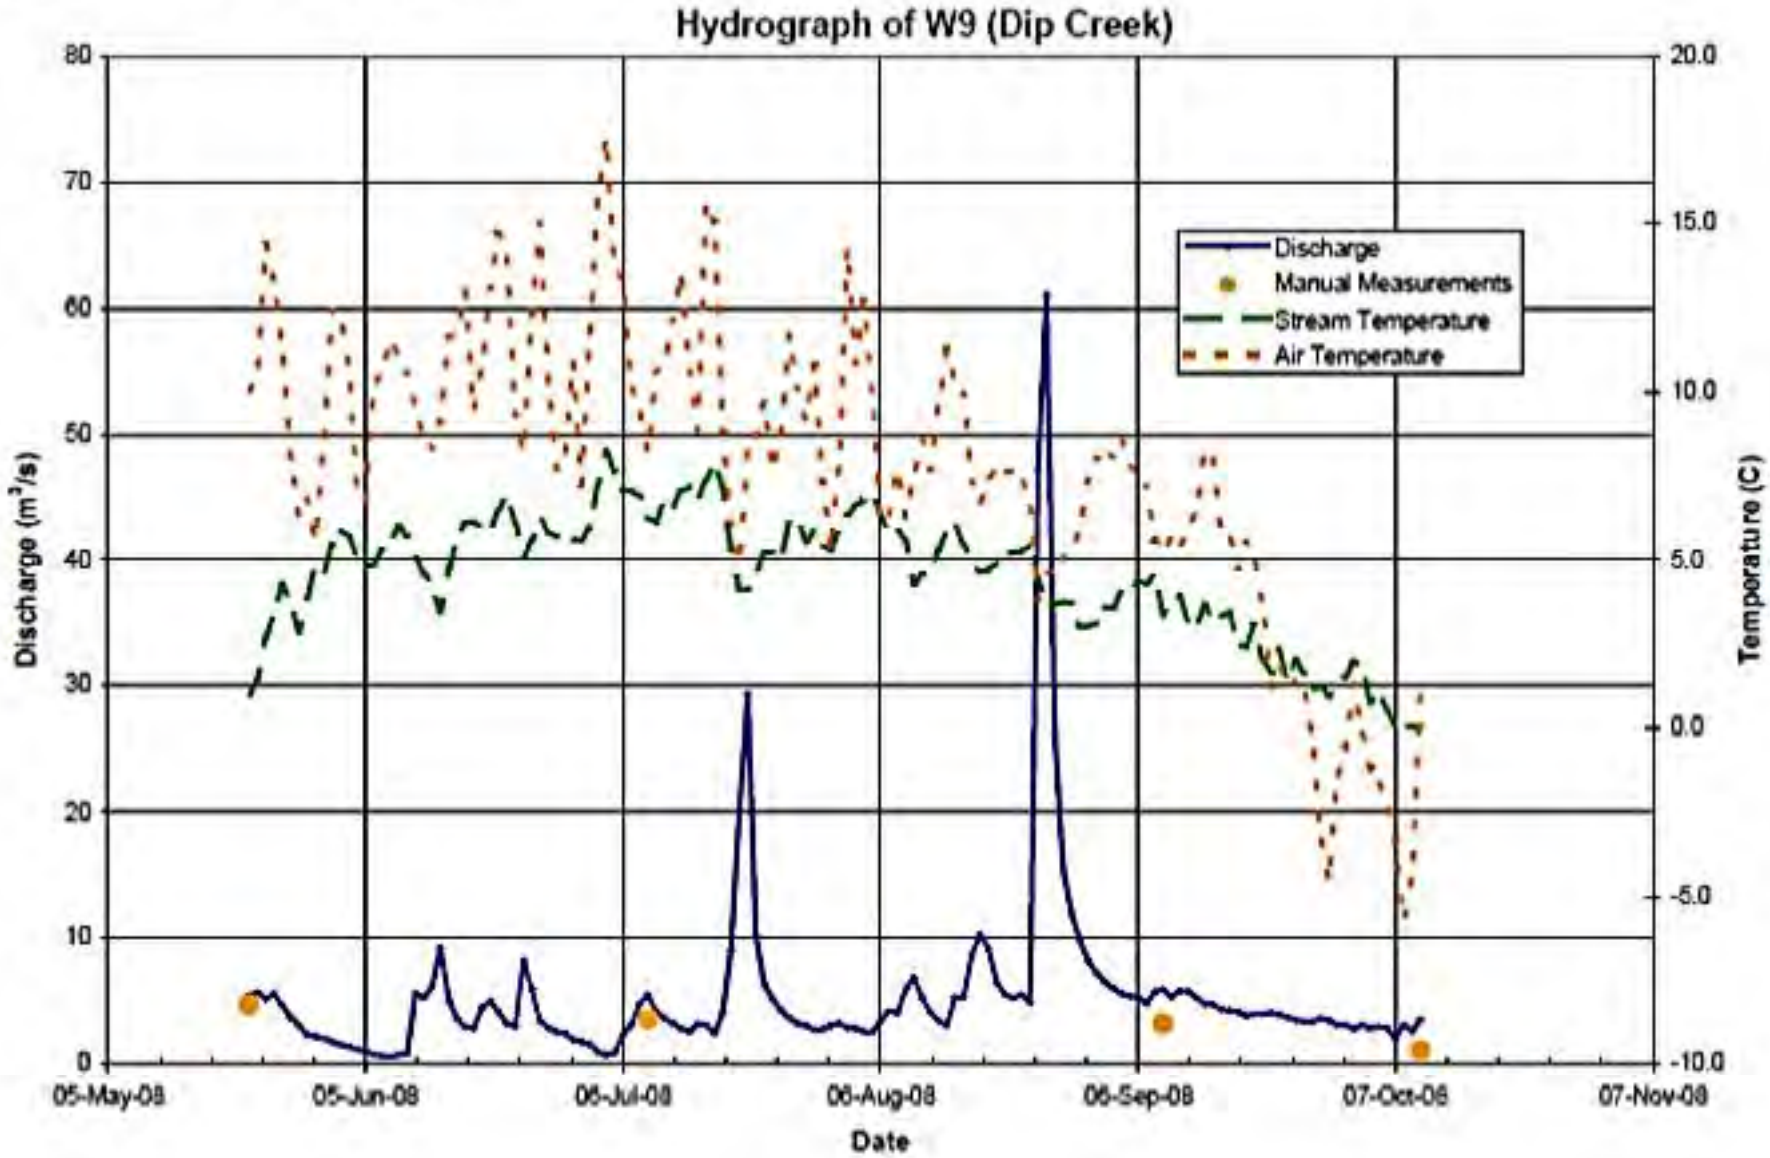

Figure 17. Hydrograph for Station W11, Casino Creek, Casino Project, 2008

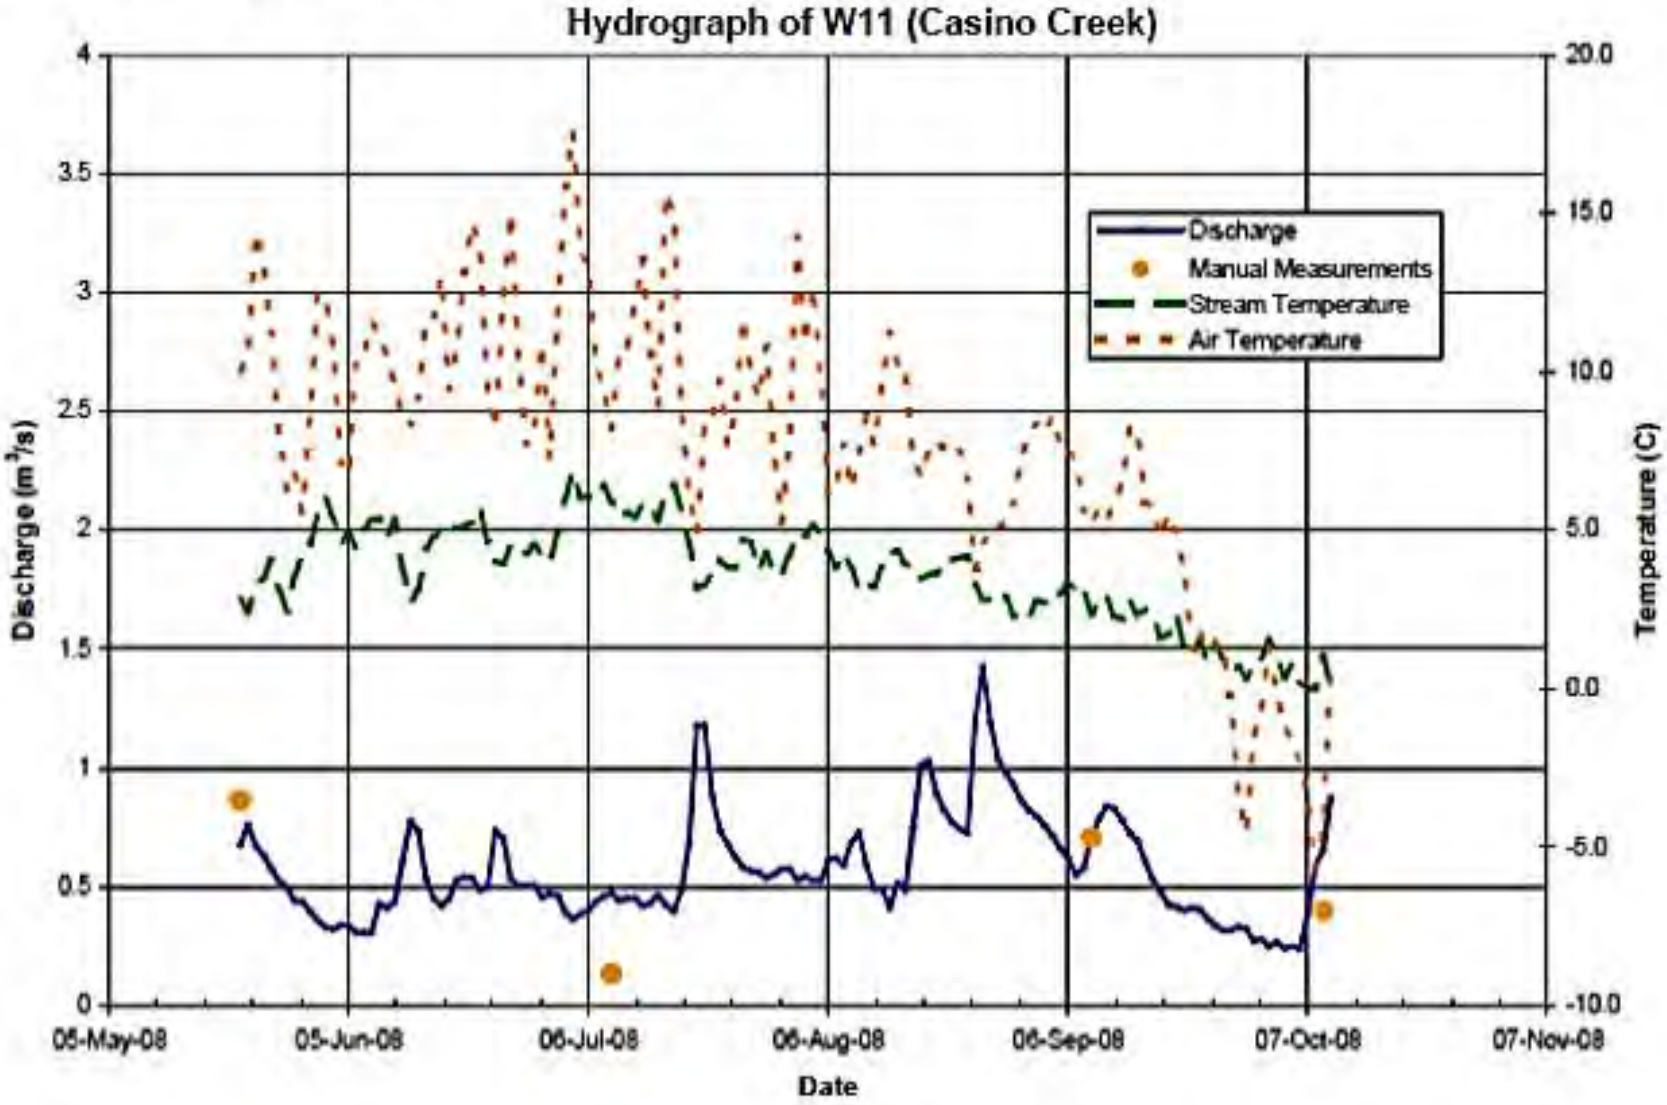

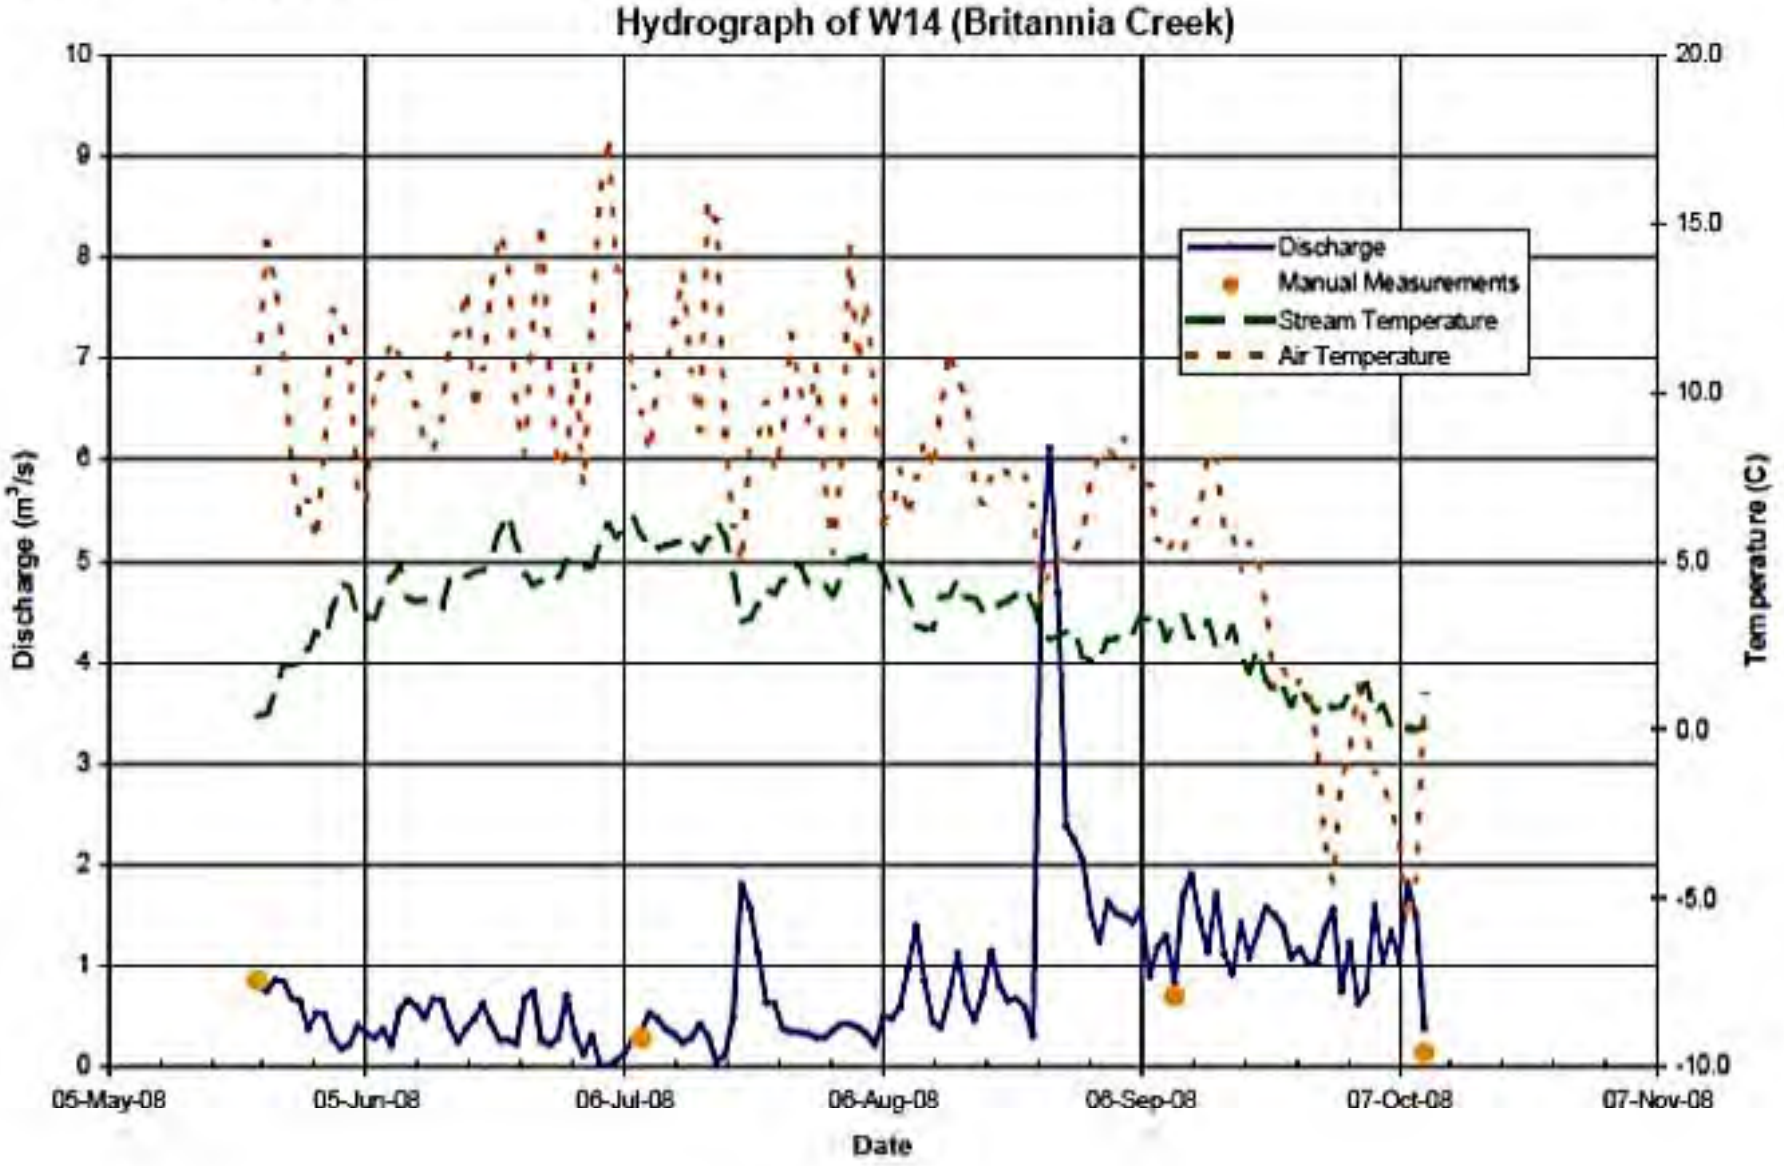

Figure 18. Hydrograph for Station W14, Britannia Creek, Casino Project, 2008

- The peak discharge of freshet, and associated 'falling limb', was only captured at sites along Britannia and Canadian creek (W1 and W3 - Figures 13 and 14).
- A large, regional precipitation event appeared to have occurred, as was evident from a decrease in stream and air temperatures, around July 20, causing a large peak in discharge on July 20 and 21 at all stations.
- A very large, regional precipitation event appeared to have occurred, as was evident from a decrease in stream and air temperatures, around August 25, causing the largest peak in discharge on August 26 for all stations. This peak discharge was large enough to overflow stream banks, as was noted by the presence of overflow channels, newly deposited silt on floodplains and newly deposited debris on floodplain during the September field visit.
- The fluctuating pattern of discharge along Casino Creek (sites W4 and W11 – Figures 15 and 17) and Dip Creek (site W9 – Figure 16) are similar, although unique when comparing these creeks to Canadian Creek (site W3 – Figure 14) and Britannia Creek (sites W1 and W14 – Figures 13 and 18).
- Britannia and Canadian creeks appear to be more "flashy" than Casino and Dip creeks. That is, they appear more responsive to assumed smaller scale precipitation events. However, meteorological data are needed to confirm this conclusion because it is possible that fluctuations in air temperature could be causing melt of permafrost, creating a similar pattern in discharge peaks.
- On several occasions it appears that there no stream flow in Canadian Creek (site W3 – Figure 14), although it is assumed that there was discharge during these times. Additional low flow manual measurements are needed to improve the rating curve at this station.

3.2.1.3 Historic Flow Data

Figures 19 to 21 show the historic flow data calculated from the HKP data that were collected in 1993 and 1994 for hydrometric sites W1, W3 and W4, respectively. When compared to the flow data that was collected in 2008, the following observations can be made:

- peak flow events at site W1 for the HKP data (Figure 19) are similar in magnitude and character (i.e., flashy response) to the peaks observed in 2008 (Figure 13);
- peak flow events at site W3 for the HKP data (Figure 20) are much lower than peak flows observed in 2008 (Figure 14). Both sets of flow data appear to have a flashy response to precipitation events; and
- peak flow events at site W4 for the HKP data (Figure 21) are similar in magnitude and characteristics to the peaks observed in 2008 (Figure 15).

It is important to note that a detailed comparative analyses between the HKP and AECOM flow data are limited due to the relatively small sample size of the manual measurements used to construct the rating curves for the 2008.

3.2.2 Water Quality

3.2.2.1 Statistical Summary

Appendices B2 to B5 show the surface water quality data for the months of May, July, September and October 2008, and Tables 13 and 14 show the minimum, median and maximum values for selected water quality parameters for sites in Casino Creek and Britannia Creek, respectively.

Figure 19. Hydrograph for Station W1, Britannia Creek, Casino Project, 1993-1994

All units mg/L unless otherwise noted
a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007
b) 0.005mg/L at pH < 6.5, [Ca2+] < 4 mg/L, DOC < 2 mg/L: 0.1 mg/L at pH ≥ 6.5, [Ca2+] ≥ 4 mg/L, DOC ≥ 2 mg/L
c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] =120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180mg/L
d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] =60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180mg/L; 0.007 mg/L at [CaCO3] > 180mg/L
e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] =60 - 120 mg/L; 0.110 mg/L at [CaCO3] =120 -180mg/L; 0.150 mg/L at [CaCO3] > 180mg/L
Italic results exceed CCME Aquatic Life Guidelines

3.2.2.2 Exceedances of Water Quality Guidelines

Table 15 shows that CCME guidelines for protection of freshwater aquatic life were exceeded for pH, total cyanide (CN) and eight total metals: aluminum (Al), cadmium (Cd), chromium (Cr), copper (Cu), iron (Fe), lead (Pb), silver (Ag) and zinc (Zn). Exceedances of at least one parameter were found at all sites except W18, but that station was only sampled in October. The number of exceedances was highest for cadmium, copper and aluminum and least for cyanide (Figure 22). Exceedances of cadmium, copper and aluminum often occurred together at the same stations. Exceedances were most numerous in May (n = 84), similar between July (n = 46) and September (n = 50), and least numerous in October (n = 24), indicating a seasonal trend related to hydrological factors such as snow melt and stream flow.

Table 15. Water Quality Parameters Exceeding CCME Guidelines, Casino Project, 2008

Site	May	July	September	October
W7	pH, Al, Cd, Cu, Fe	Cd, Cu	Al, Cd, Cu	Cd
W3	Al, Cd, Cu, Fe	-	Al, Cd, Cu	Cu
W14	Al, Cd, Cu, Fe	Al	Al, Cd, Cu, Fe	-
W2	Al, Cd, Cu, Fe	Al, Cd, Fe	Al, Cd, Cu	NS
W1	Al, Cd, Cr, Cu, Fe	-	Cu	-

W6a	Al, Cd, Cr, Cu, Fe	Al, Cd, Fe	Cd	Al, Cd
W15	Al, Cd, Cr, Cu, Fe, Pb, Zn	Al, Cd, Fe	Al, Cd	NS
W17	Al, Cd	Al, Cd	Cd	NS
W43	Cd, Cu, Pb, Zn	Cd, Cu, Pb, Zn	Cd, Cu, Pb, Ag, Zn	Cd, Cu, Pb, Ag, Zn
W12	pH, Al, Cd, Cu, Pb, Fe, Zn	pH, Al, Cd, Cu, Fe, Zn	pH, Al, Cd, Cu, Fe, Zn	pH, CN, Al, Cd, Cu, Fe, Zn
W8	Al, Cd, Cu, Fe	Al, Cd, Cu, Fe	Al, Cd, Cu, Fe	NS
W13	Al, Cd, Cu, Pb	Cd	Cd	NS
W11	Al, Cd, Cu, Fe	Cd, Cu	Al, Cd, Cu	Cd, Cu
W18	NS	NS	NS	-
W4	Al, Cd, Cu, Fe	Cu	Al, Cd, Cu	Cd, Cu
W9	Al, Cd, Cu, Fe, Pb	Al, Cu, Fe	Al	-
W5	Al, Cd, Cu, Fe, Pb	Al, Cd, Cu, Fe	Al, Cd, Cu, Fe	Cu
W16	Al, Cd, Cu, Fe	Al, Cd, Cu, Fe	Al, Cd, Cu, Fe	NS

Dashes indicate no parameters exceeded CCME guidelines. NS = Not sampled.

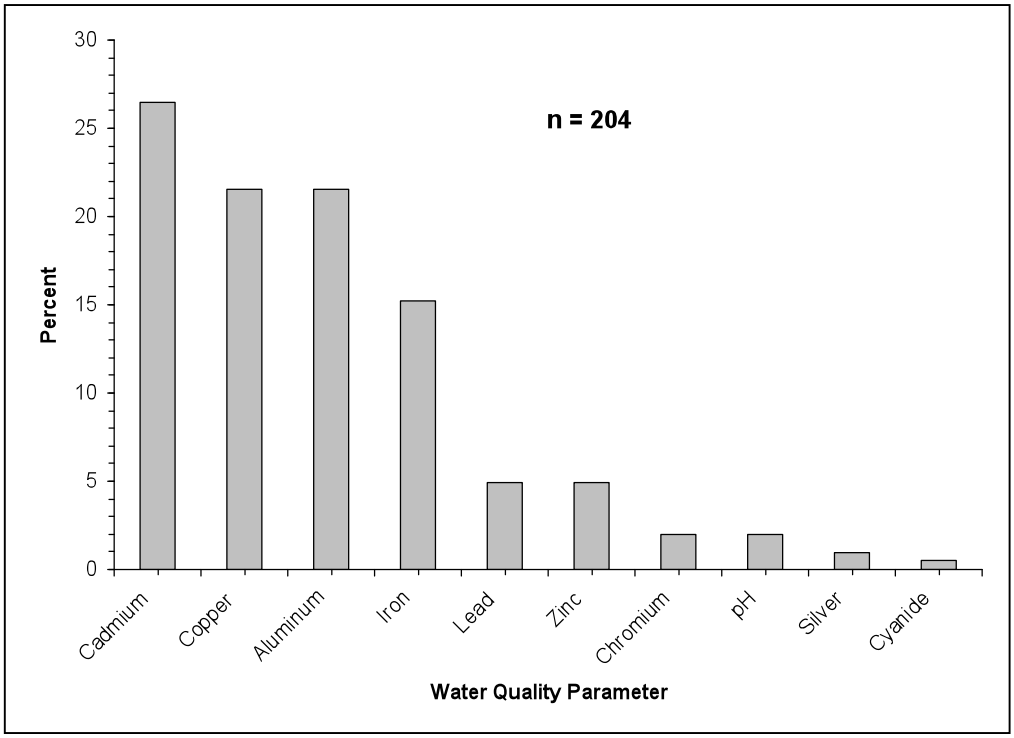

Figure 22. Water Quality Exceedances of CCME Guidelines, Casino Project, 2008

3.2.2.3 Principal Component Analysis

Data

Field measurements of pH and conductivity were excluded from the dataset because the laboratory measurements of pH and conductivity were assumed to be more accurate. Acidity and TOC were excluded because they were measured in less than 10% of the records. Six variables were excluded (total boron, total tin, dissolved bismuth, dissolved boron, dissolved mercury and dissolved tin) because 90% or more of the records were below detection limits. For the remaining 79 variables, a total of 822 records (or 14% of the dataset) were replaced: 732 records of metal concentrations below detection limits were replaced by one-half the detection limit, 60 absent records of DOC for May, July and September were replaced by the mean for October and 30 absent records of dissolved metals for station W3 on September 10 were replaced with the geometric means of dissolved metals that were calculated from records for May, July and October. All metals were ln-transformed to normalize their distributions.

Components and Their Correlations

Eleven components were extracted from the data matrix, but the first five components accounted for 70.5% of the explained variance and a scree plot (not shown here) indicated that the remaining six factors were of little significance (Table 16).

The first component, WQ1, was positively correlated with 16 dissolved and total metals, including cadmium, zinc, silver, lead, manganese, thallium, copper and antimony, and negatively correlated with total and dissolved molybdenum. This was called the “heavy metals” component because it reflects the magnitudes of the concentrations of heavy metals. The first component extracted from a water quality data set is almost always a “size” or “magnitude” component.

The second component, WQ2, was positively correlated with ten dissolved and total metals, including iron, aluminum, beryllium, cobalt, chromium and mercury, one anion – sulphate – and two nutrients – nitrite and ammonia – and negatively correlated with pH, alkalinity, barium and nitrate. This was called the “iron-pH” component because it reflects a pH- and alkalinity-related difference in metal concentrations among sites and dates.

The third component, WQ3, was positively correlated with hardness, conductivity, TDS, and 13 total and dissolved metals, including magnesium, calcium, strontium, uranium, potassium, sodium and lithium. The metals are all those associated with TDS, which typically reflects the influence of groundwater flows. Therefore, WQ3 was called the “TDS” component.

The fourth component, WQ4, was positively correlated with 12 dissolved and total metals, including vanadium, titanium chromium, phosphorus, zirconium and arsenic, TSS and TKN and negatively correlated with dissolved and total silicon. It was called the “vanadium-silicon” component.

The fifth component, WQ5, was positively correlated with dissolved and total selenium and nickel and turbidity. It was called the "selenium-nickel-turbidity" component.

Seven parameters – total cyanide, cyanide WAD, dissolved sodium, ortho-phosphorus, chloride, total bismuth and DOC – were not significantly correlated with any of the first six components.

Spatial and Temporal Variation in WQ1 Scores

The highest mean WQ1 score was observed at site W43, the discharge pipe of the adit of the lower camp, which discharges into upper Meloy Creek of the Casino Creek Watershed (Figure 23). The second highest mean WQ1 score was observed for site W12 in Proctor Gulch, the uppermost reach of Casino Creek, and the third highest mean score was at site W8 in the upper reach of Casino Creek upstream of the confluence of Meloy Creek. The lowest mean WQ1 score was for site W18 in Brynelsen Creek. Mean WQ1 scores for the other 15 sites fell within a narrow range. These findings indicate that WQ1 represents the geochemical signal of drainage from the adit of the lower camp, and that adit drainage flows downstream through all of the water quality sampling sites of Casino Creek except for Brynelsen Creek.

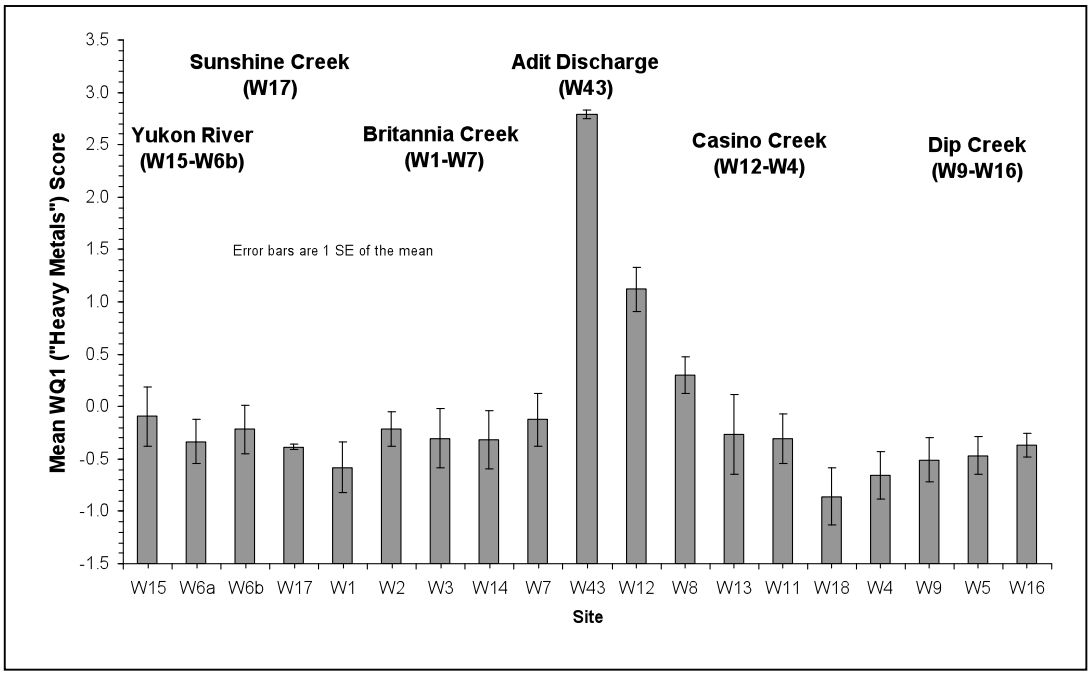

Figure 23. Plot of Mean WQ1 Scores on Sampling Site, Casino Project, 2008

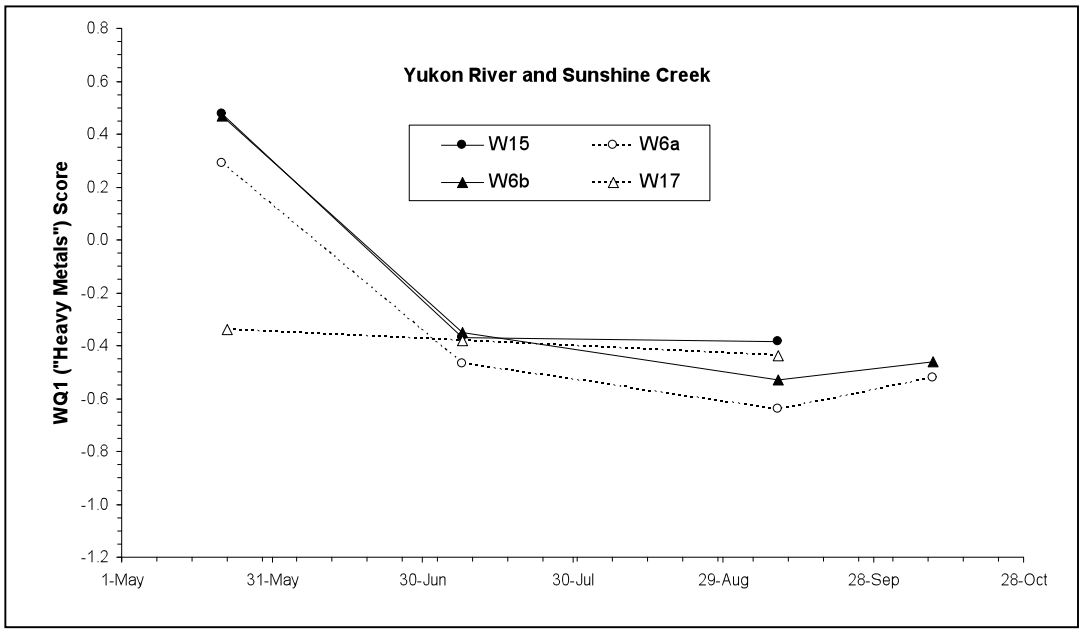
WQ1 scores were highest in May and decreased continuously over the open-water season at all three Yukon River sites (Figure 24). The WQ1 scores for site W17 in Sunshine Creek did not show a seasonal trend. WQ1 scores for the five sites in the Britannia Creek Watershed showed a strong seasonal trend with the highest scores in May and September and the lowest in July and October (Figure 25). WQ1 scores in the Casino Creek Watershed showed the downstream gradient. WQ1 scores for site W43 did not show a seasonal trend, but WQ1 scores for the other five sites showed a bimodal seasonal pattern similar to that

observed in the Britannia Creek Watershed (Figure 26). WQ1 scores for the three sites along Dip Creek showed a strong decreasing seasonal trend with less of a bimodal pattern. (Figure 27). The seasonal trends, particularly the bimodal pattern observed in Britannia and Casino creeks, indicate that WQ1 scores vary directly with stream flow.



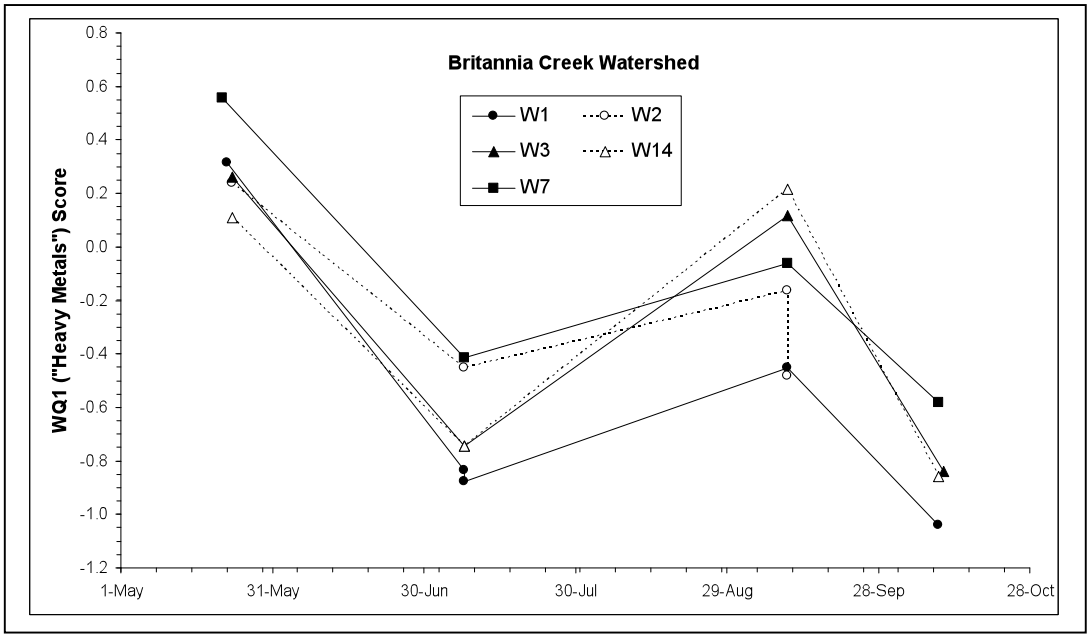


Figure 24. Plot of WQ1 Scores on Sampling Date, Yukon River and Sunshine Creek, Casino Project, 2008

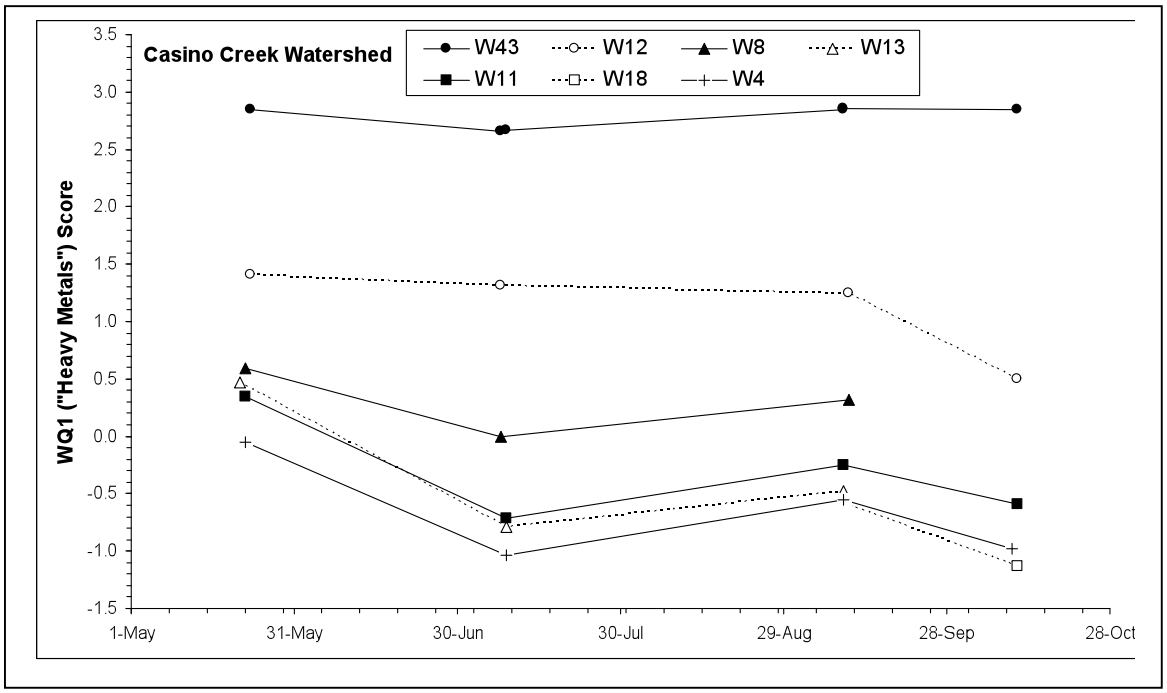

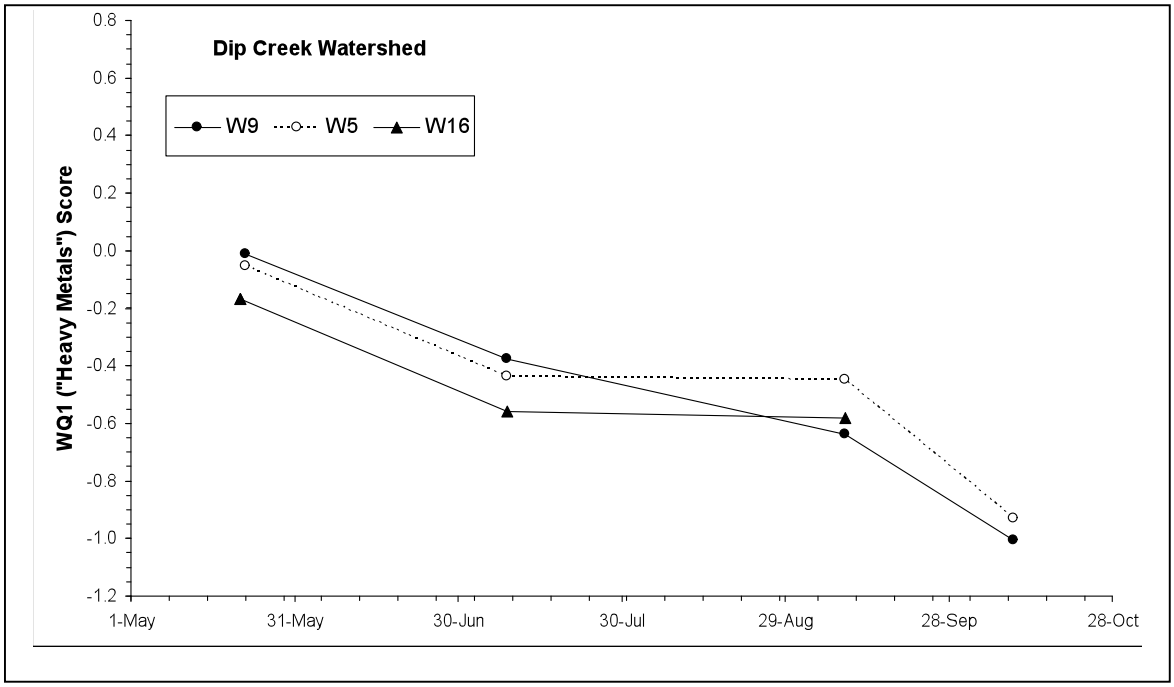

Figure 25. Plot of WQ1 Scores on Sampling Date, Britannia Creek Watershed, Casino Project, 2008

Figure 26. Plot of WQ1 Scores on Sampling Date, Casino Creek Watershed, Casino

Project, 2008

Figure 27. Plot of WQ1 Scores on Sampling Date, Dip Creek Watershed, Casino Project, 2008

In summary, these findings indicate that WQ1 represents the geochemical signal of drainage from the adit of the lower camp, and that adit drainage flows downstream through all of the water quality sampling sites of Casino Creek except for Brynelsen Creek. However, since WQ1 shows spatial and seasonal variation at sites in Dip Creek, Britannia Creek and the Yukon River, it also reflects a geochemical signature found elsewhere in the study area, albeit at lower concentrations than at the adit drainage site.

Spatial and Temporal Variation in WQ2 Scores

The highest mean WQ2 score was observed for site W12 at the head of Casino Creek and the lowest mean WQ2 score was observed at site W43, the adit discharge pipe (Figure 28). Upstream-downstream gradients in mean WQ2 score were observed for the Britannia Creek Watershed and for the upper mainstem of the Dip Creek Watershed (i.e., sites W12, W8 and W13). Mean WQ2 scores were uniformly low for the three sites in the Yukon River. The mean WQ2 score for site W17 in Sunshine Creek was between the values for the Yukon River sites and site W1 in Britannia Creek. Mean WQ2 scores for the three sites in Dip Creek were similar to those at the head of Britannia Creek (i.e., site W7). Therefore, WQ2 reflects the geochemical signature of the surficial geology of Proctor Gulch, the upper Casino Creek and Britannia Creek.

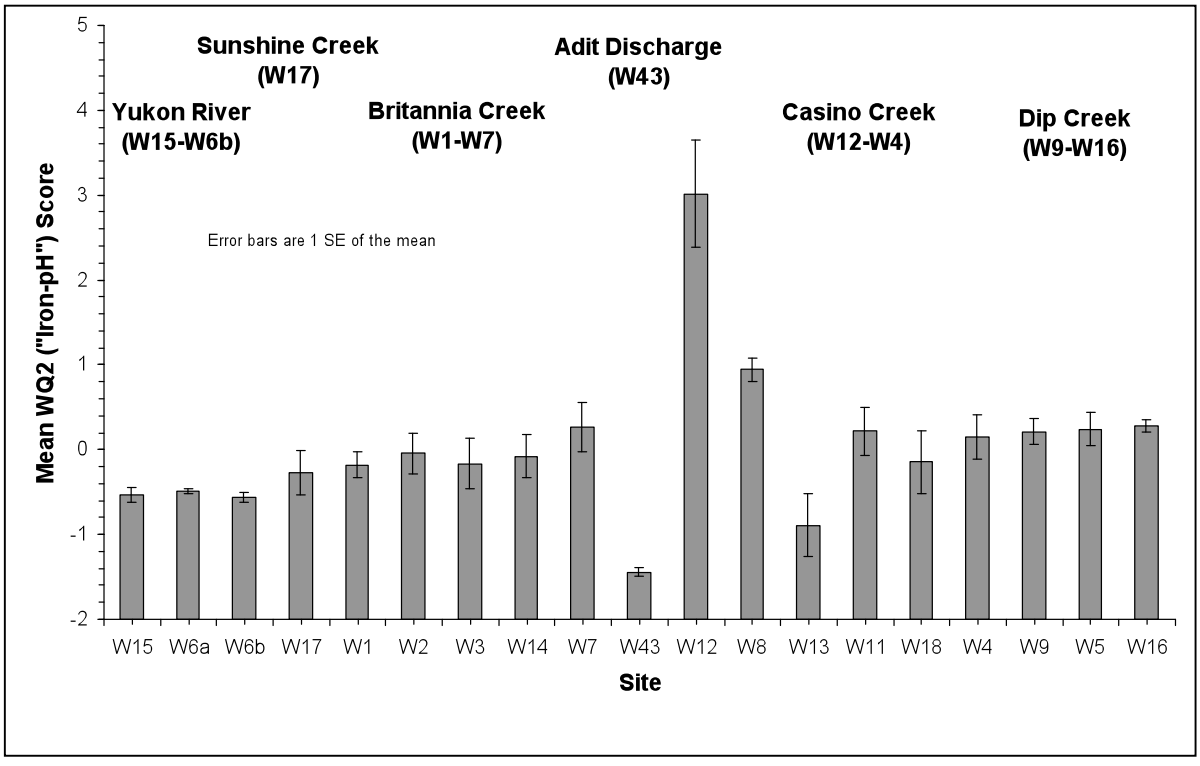

Figure 28. Plot of Mean WQ2 Scores on Sampling Site, Casino Project, 2008

With the exception of sites in the Britannia Creek Watershed, site W17 of Sunshine Creek and site W12 in upper Casino Creek, there was less seasonal variation in WQ2 scores than in WQ1 scores (Figures 29 to 32). As with WQ1, seasonal variation indicates that WQ2 scores vary directly with stream flow.

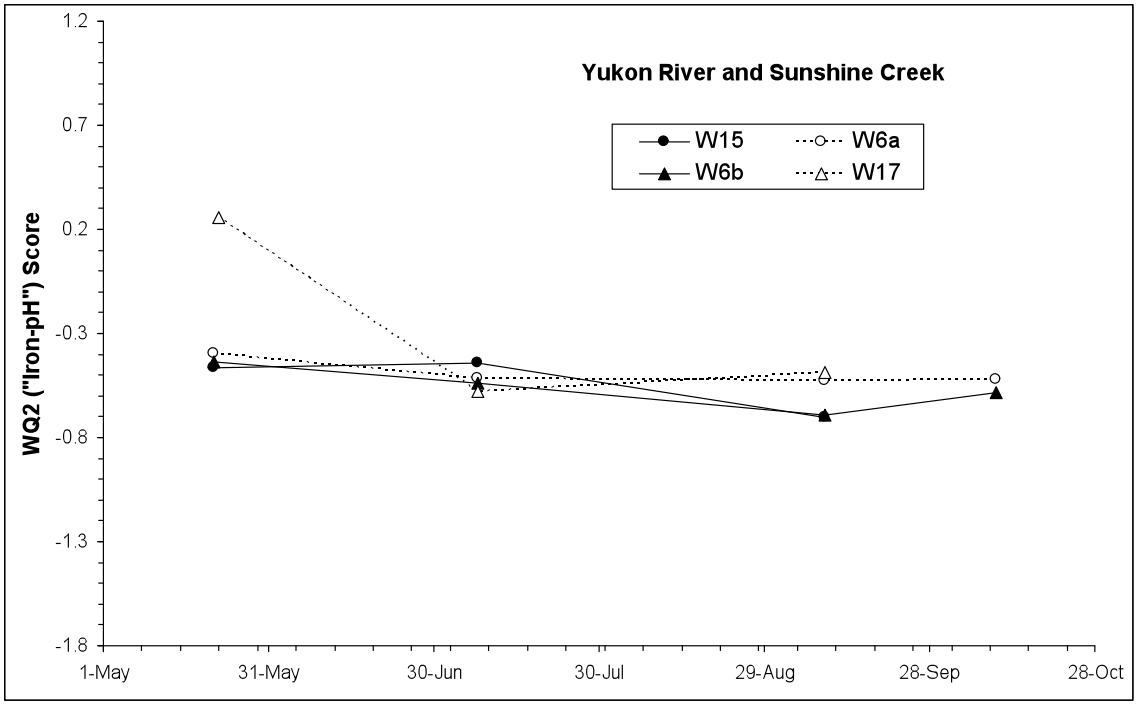

Figure 29. Plot of WQ2 Scores on Sampling Date, Yukon River and Sunshine Creek, Casino Project, 2008

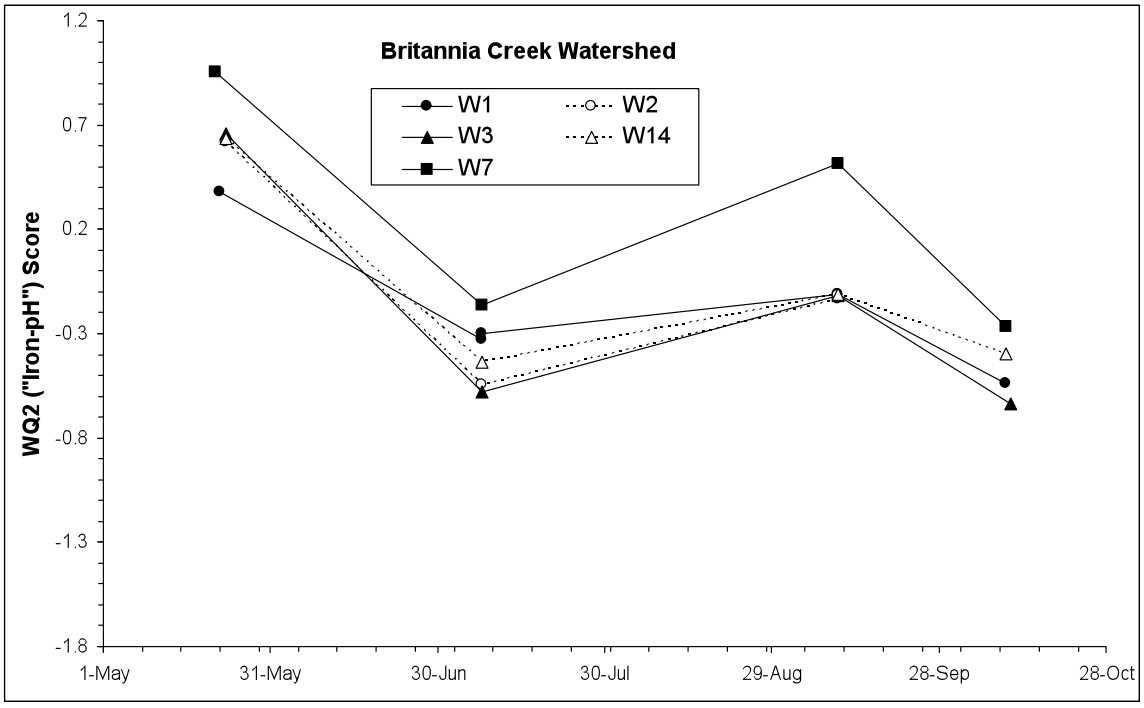

Figure 30. Plot of WQ2 Scores on Sampling Date, Britannia Creek Watershed, Casino Project, 2008

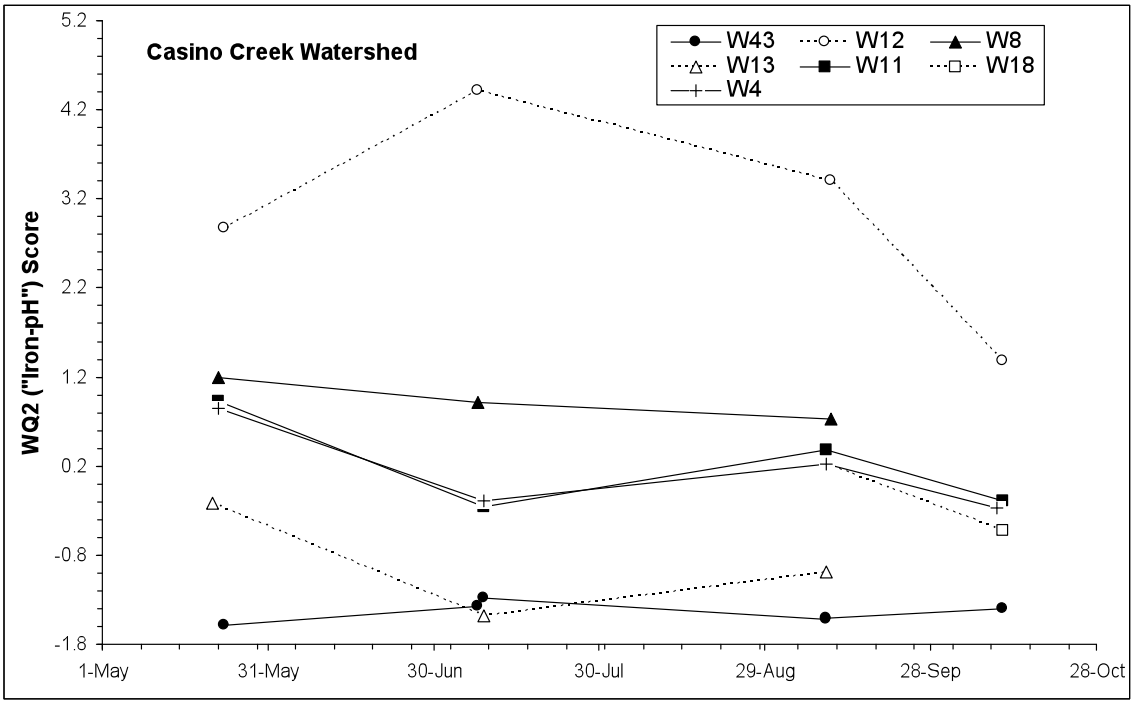

Figure 31. Plot of WQ2 Scores on Sampling Date, Casino Creek Watershed, Casino Project, 2008

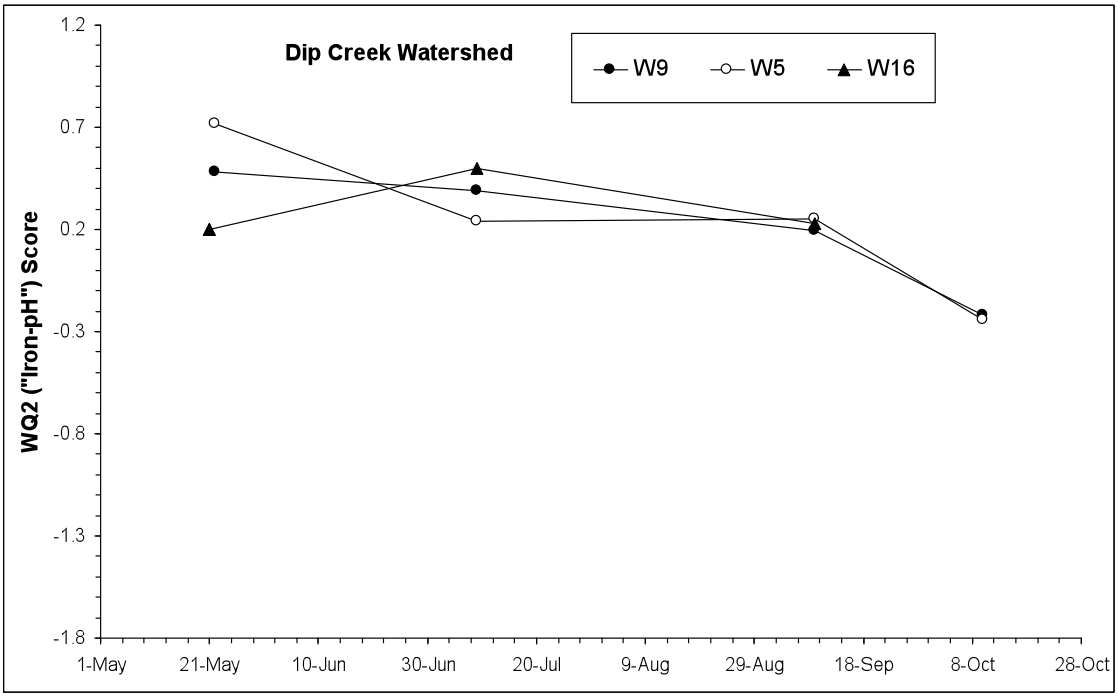

Figure 32. Plot of WQ2 Scores on Sampling Date, Dip Creek Watershed, Casino Project, 2008

In summary, these findings indicate that WQ2 reflects the geochemical signature of the surficial geology of Proctor Gulch, the upper Casino Creek and Britannia Creek. Seasonal trends in WQ2 reflect stream flows.

Spatial Variation in WQ3 Scores

Mean WQ3 scores were lowest for site W7, the uppermost site in Britannia Creek, and highest for site W12 in Proctor Gulch (Figure 33). Since WQ3 is assumed to reflects the influence of groundwater, then site W7 is much less influenced by groundwater than all other sites.

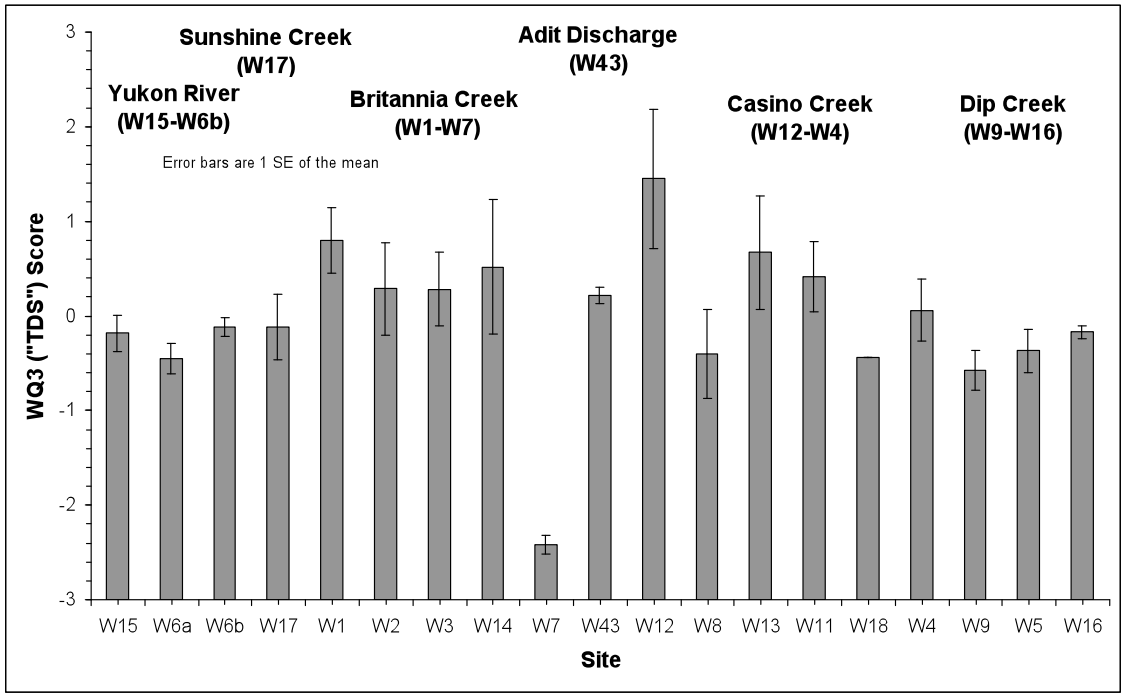

Figure 33. Plot of Mean WQ3 Scores on Sampling Site, Casino Project, 2008

Spatial Variation in WQ4 Scores

Mean WQ4 scores were lowest for sites in Casino Creek and in upper Britannia Creek, and highest for sites in Dip Creek, Britannia Creek, Sunshine Creek and the Yukon River (Figure 34). Therefore, WQ4 represents a geochemical signal found at all sites except those in Casino Creek and upper Britannia Creek.

Spatial Variation in WQ5 Scores

Mean WQ5 scores were highest for sites in the Yukon River (Figure 35). Hence, WQ5 represents a geochemical signal associated with the Yukon River.

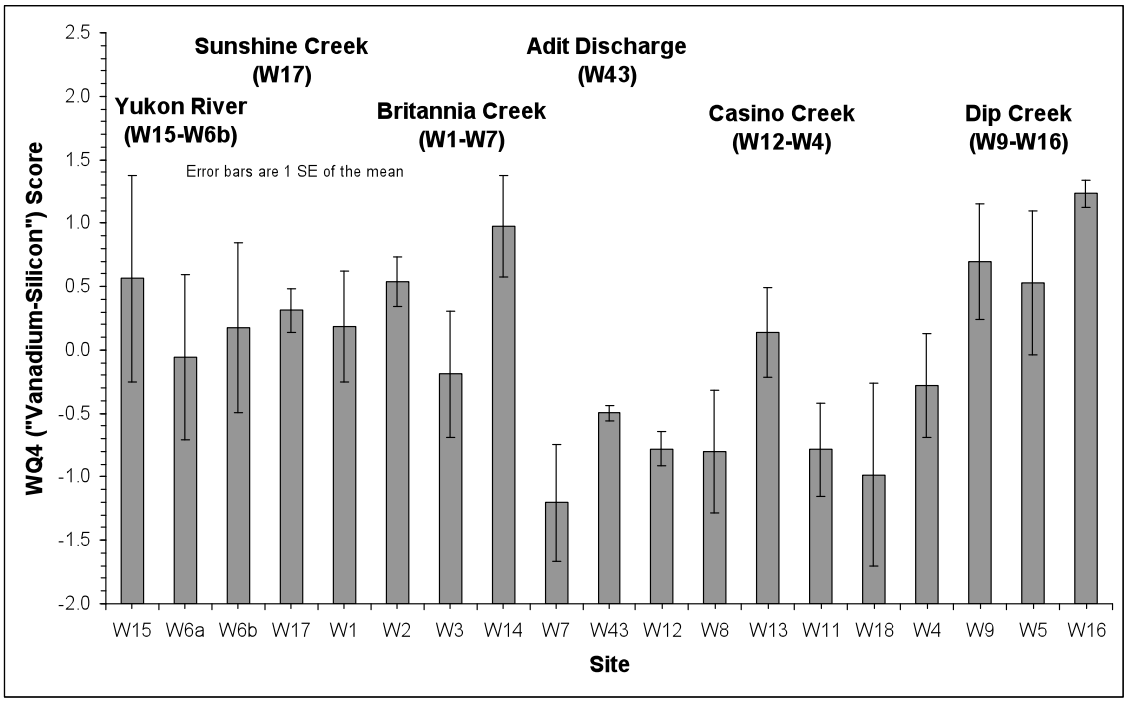

Figure 34. Plot of Mean WQ4 Scores on Sampling Site, Casino Project, 2008

3.2.3 Sediment Quality

3.2.3.1 Exceedances of Sediment Quality Guidelines

Appendix B7 shows the sediment quality data. Table 17 shows that exceedances of CCME sediment guidelines were observed for five total metals: arsenic (As), cadmium (Cd), copper (Cu), lead (Pb) and zinc (Zn). All of those metals except arsenic were also observed to exceed CCME water quality guidelines at some stations on some dates.

Table 17. Sediment Quality Parameters Exceeding CCME Guidelines, Casino Project, 2008

Site	Interim Freshwater Sediment Quality Guideline (ISQG)	ISQG and Probable Effects Level (PEL)
W7	As, Cd, Cu	-
W3	-	As
W14	As	-
W2	-	As
W1	As	-

W4	As	-
W9	As	-
W5	As	-

Dashes indicate sample did not exceed CCME Guidelines.

3.2.3.2 Principal Component Analysis

Mercury and selenium were removed from PCA because all values of those two metals were below detection limits. Of the remaining metals, a total of 10 concentrations below detection limits (or 3% of the total number of values) were replaced with one-half the detection limit. Then, pH and ln-transformed metal concentrations were entered into PCA. The first run extracted six components of which only the first three explained significant amounts of explained variance. Twelve metals (beryllium, calcium, chromium, copper, iron, magnesium, molybdenum, nickel, potassium, strontium, thallium and zirconium) were not highly correlated with those six components, hence they were removed and PCA was run a second time.

Three components were extracted that accounted for 87.7% of the explained variance: 48.1% for SQ1, 28.2% for SQ2 and 11.4% for SQ3. Table 18 shows that SQ1 was positively correlated with manganese, cadmium, cobalt, zinc, lead and antimony; SQ2 was positively correlated with vanadium, titanium, aluminum, tin, phosphorus, sodium and barium; and SQ3 was positively correlated with bismuth, silver and arsenic and negatively correlated with pH.

Table 18. Correlations of Sediment Quality Variables with Principal Components

Variable	SQ1	SQ2	SQ3
Manganese	0.941	0.279	-0.030
Cadmium	0.927	0.007	0.217
Cobalt	0.833	0.064	0.062
Zinc	0.806	0.321	0.467
Lead	0.798	0.255	0.499
Antimony	0.656	-0.079	0.629
Vanadium	0.185	0.952	0.082
Titanium	0.240	0.919	-0.110
Aluminum	0.289	0.905	0.220
Tin	0.269	0.869	0.268
Phosphorous	-0.177	0.862	0.031
Sodium	-0.369	0.796	-0.425
Barium	0.517	0.721	0.229
Bismuth	0.264	0.039	0.789
Silver	0.472	0.206	0.758
Arsenic	0.476	-0.372	0.706
pH	0.242	-0.238	-0.888

A plot of SQ1 scores on sampling site (Figure 36) showed that the highest scores were at three adjacent sites in Casino Creek (W8, W11 and W13). A plot of SQ2 scores on sampling site (Figure 37) showed a general decreasing north-south trend with the lowest scores in reach 1 of Britannia Creek and the highest scores at two sites in Dip Creek and at site W4 in lower Casino Creek. A plot of SQ3 scores on sampling site (Figure 38) showed the highest score at site W12 in the headwaters of Casino Creek.

3.2.4 Periphyton

Appendix B8 shows the densities (cells/cm^2) by taxa for each of the 35 samples of periphyton collected from the seven sampling sites in September 2008.

Figure 39 shows the mean densities of periphyton for each site. One-way ANOVA of the ln-transformed densities showed there were highly significant differences in mean density among sites ($F_{6,28}$ = 14.34, P<0.001). Post-hoc comparisons of means using the Bonferroni test showed that mean density at sites P8, P7 and P4 were significantly (P<0.05) higher than at other sites.

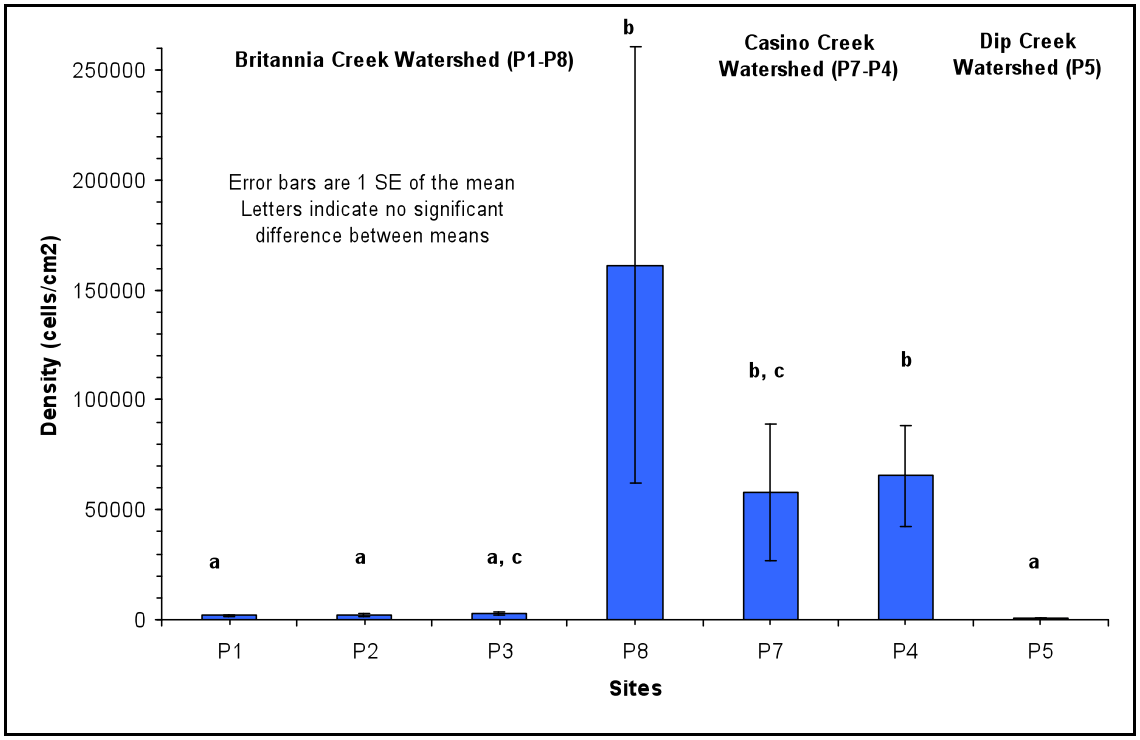

Figure 39. Mean Density of Periphyton by Site, Casino Project, 2008

Table 19 shows the percentage composition of the periphyton community at each sampling site. Britannia Creek sites P1, P2, and P3 were dominated by *Diatoma elongatum* and yellow-brown algae, *Chromulina sp.*, whereas site P8 was dominated by yellow-brown algae, *Homoeothrix varians*, and blue-green algae. Casino Creek site P4 was dominated by two blue-green algae, *Oscillatoria cf. agardhii* and *Homoeothrix varians*, whereas site P7 within the Casino Creek watershed was solely dominated by *Homoeothrix varians*. Dip Creek watershed site,P5 was dominated by blue-green algae, *Chromulina sp.*, followed by *Ceratuneis arcus*.

Figures 40 and 41 show the mean taxonomic richness and Shannon-Wiener diversity index by site. There were no significant differences among sites in diversity ($F_{6,28}$ = 1.94, P = 0.11), but there were highly significant differences among sites in richness ($F_{6,28}$ = 17.70, P < 0.001). Post-hoc tests using Bonferroni test for richness showed that the main cause for variation is the higher richness for sites P8, P7 and P4 compared to most of the other sites.

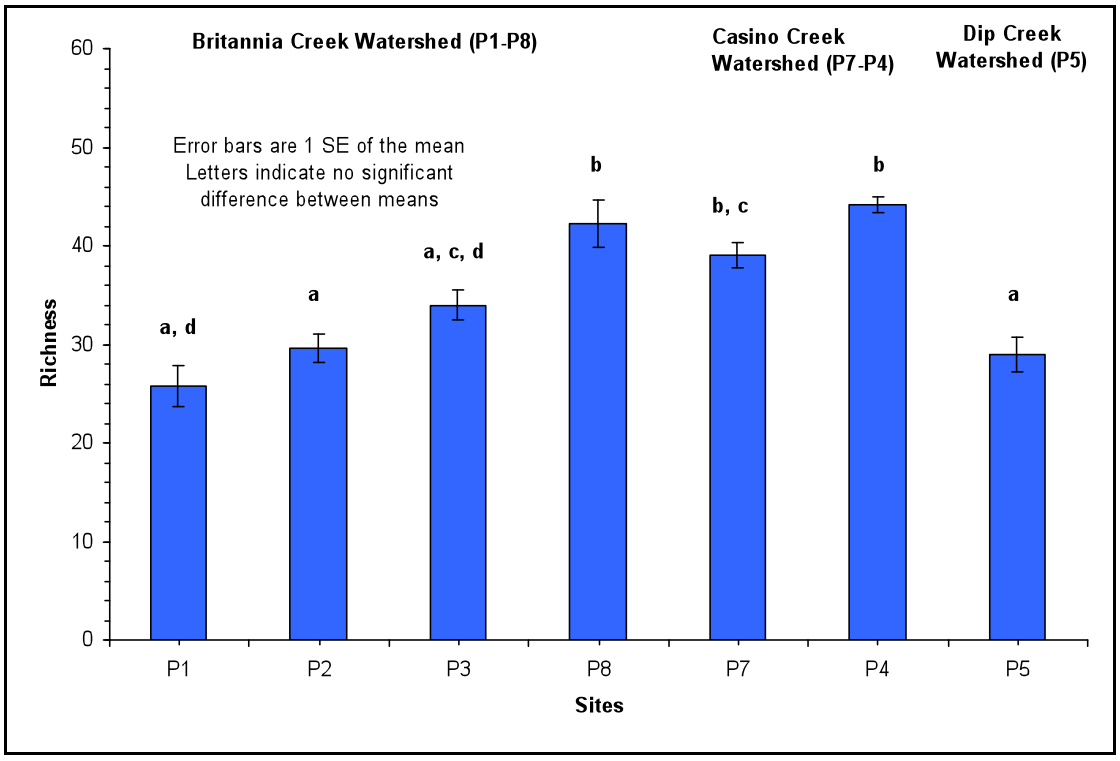

Figure 40. Mean Taxonomic Richness of Periphyton Communities, Casino Project, 2008

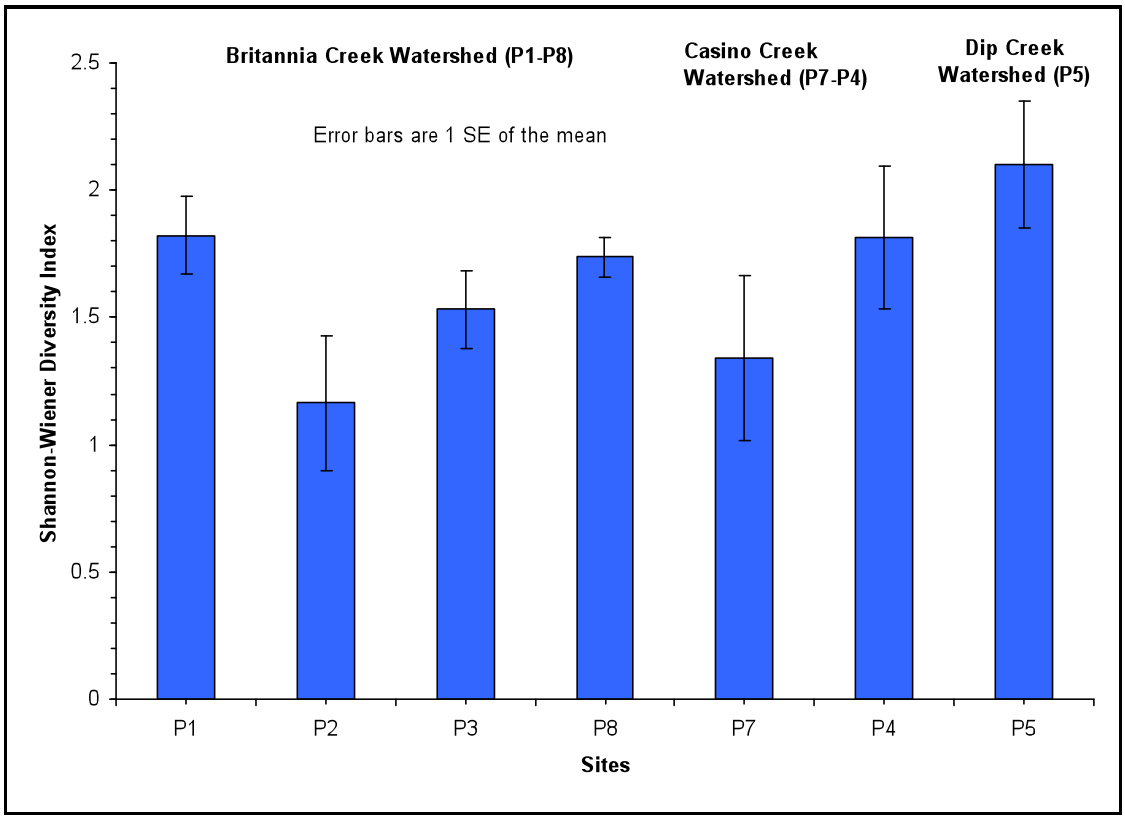

Figure 41. Mean Shannon-Wiener Diversity Index of Periphyton Communities, Casino Project, 2008

3.2.5 Benthic Invertebrates

Appendix B9 shows the number of organisms counted and identified to taxa in each of the 35 samples of benthos collected from the seven sampling sites in September 2008.

Figure 42 shows the mean densities of benthic invertebrates for each site. One-way ANOVA of the ln-transformed densities showed there were highly significant differences in mean density among sites ($F_{5,28}$ = 16.64, P<0.001). Post-hoc comparisons of means using the Bonferroni test showed that mean density at site B8 was significantly higher than the densities at all other sites except for B2 and that mean densities at sites B7 and B4 were significantly lower than mean densities at sites B2 and B3.

Table 20 shows the percentage composition of the benthic invertebrate community at each sampling site. Dipterans dominated the communities at all sites. Over 95% of the organisms at each site belonged to eight taxa: the insect Orders of Diptera, Plecoptera, Ephemeroptera, Trichoptera, Prostigmata and Collembola plus the worms of Class Oligochaeta and Phylum Nematoda.

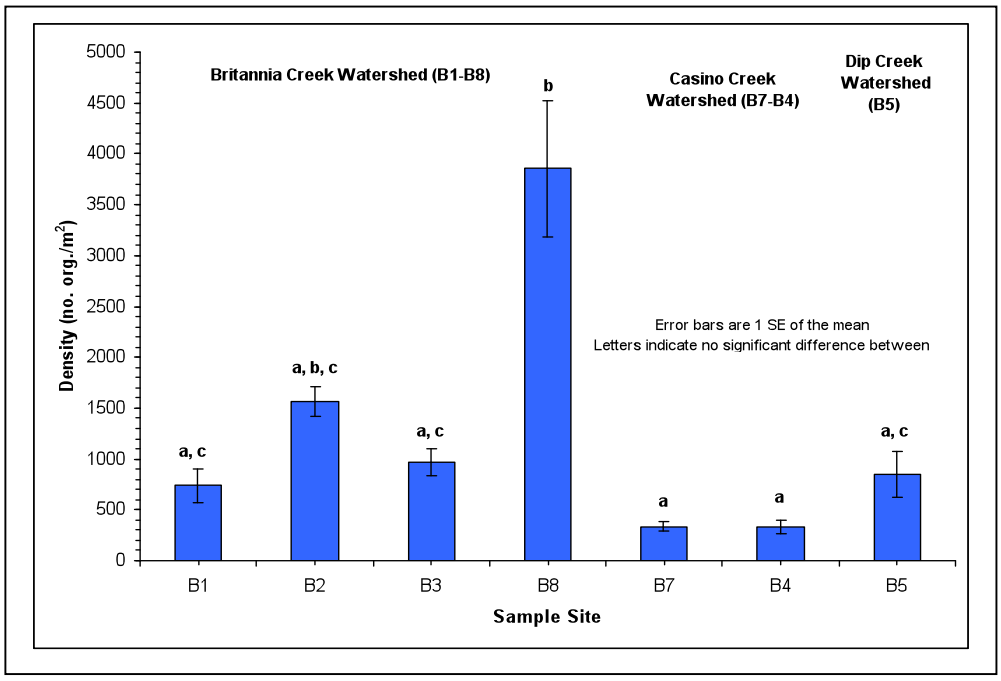

Figure 42. Mean Density of Benthic Invertebrates by Site, Casino Project, 2008

Order Gastropoda	0.0	0.1	0.0	0.0	0.0	0.0	0.0

Figures 43 to 45 show the mean taxonomic richness, total EPT abundance and Shannon's index of diversity, respectively, by site. There were highly significant differences among sites in richness ($F_{6,28}$ = 4.79, P<0.001), total EPT ($F_{6,28}$ = 17.07, P<0.001) and in Shannon-Wiener diversity index ($F_{6,28}$ = 7.18, P<0.001). Post-hoc tests using the Bonferroni test showed that the main cause for variation in richness was low richness at site B7 compared to high richness at sites B2 and B5. Post-hoc tests using the Bonferroni test showed that the main cause for variation in total EPT was high total EPT at site B8 compared to low total EPT at all the other sites. Also, site B2 had

significantly higher total EPT than sites B7 and B4. Post-hoc tests using the Bonferroni test showed that the main cause for variation in Shannon-Wiener diversity index was higher diversity for sites B4, B5 and B1 than for sites B2, B3, B8, and B7. Also, diversity was significantly higher for site B4 compared to sites B8 and B7.

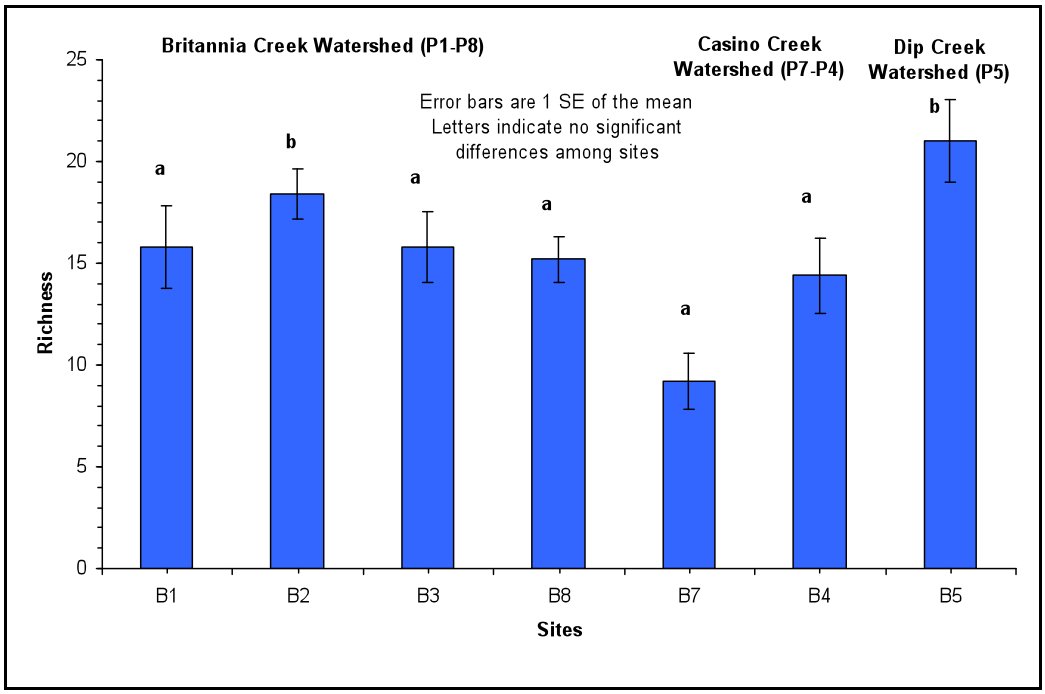

Figure 43. Mean Taxonomic Richness of Benthic Invertebrate Communities, Casino Project, 2008

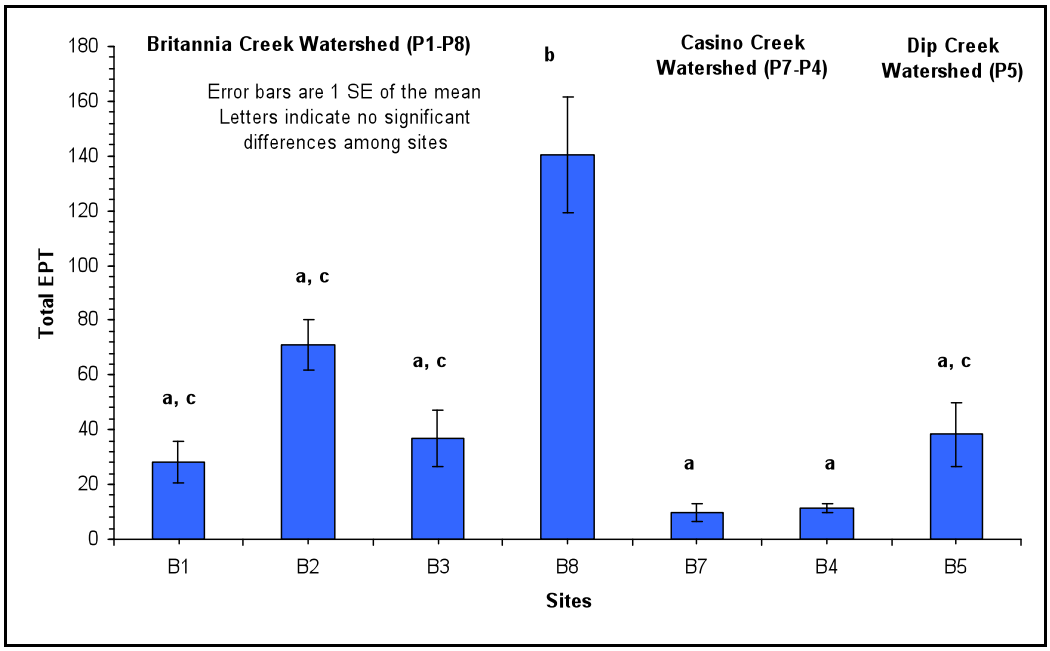

Figure 44. Mean Total EPT of Benthic Invertebrate Communities, Casino Project, 2008

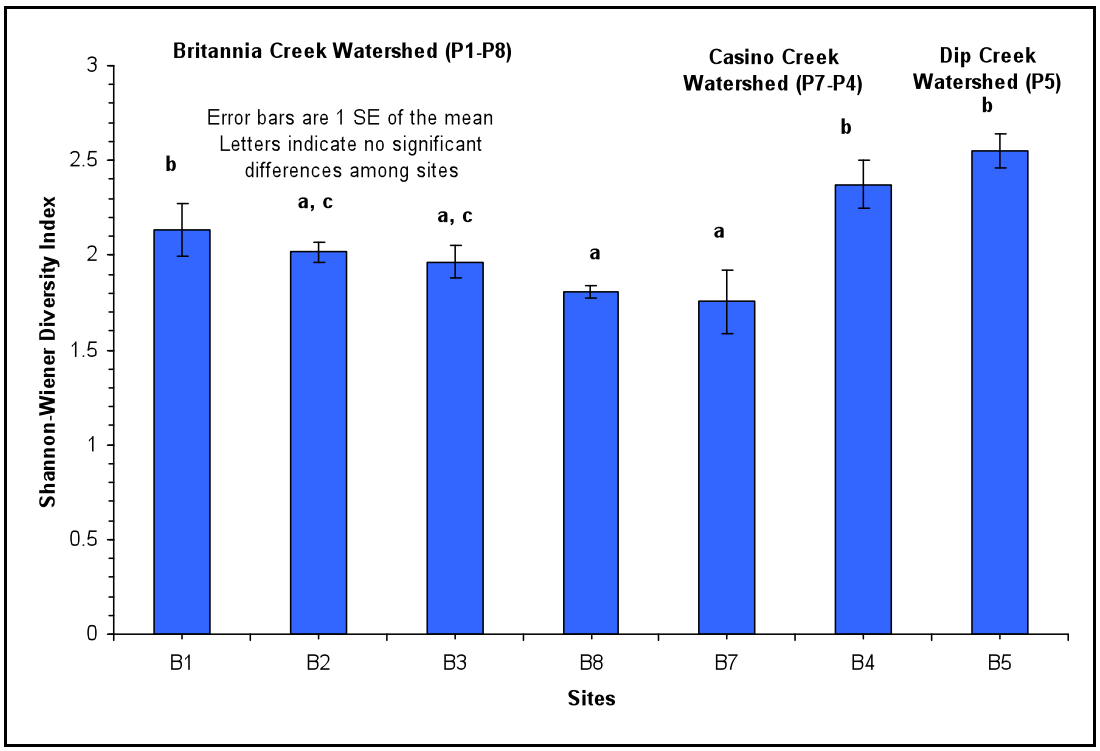

Figure 45. Mean Shannon-Weiner Index of Diversity of Benthic Invertebrate Communities, Casino Project, 2008

3.2.6 Fish Community

3.2.6.1 Catch, Effort and CPUE

Appendices B11, B12 and B13 show the fish catch, effort and CPUE for minnow traps, electrofishing and angling, respectively. A total of 40 fish from two species – Arctic grayling (*Thymallus arcticus*) and slimy sculpin – were captured from the Casino Project LSA in July and September 2008 (Table 21). Apart from one Arctic grayling caught by angling, all were captured by electrofishing.

Only Arctic grayling were found in the Britannia Creek Watershed, but both Arctic grayling and slimy sculpin were found in Casino Creek and Dip Creek watersheds. Slimy sculpin made up the majority of the catch (81 to 86%) in those two watersheds, respectively.

A total of 15 sites were electrofished – 12 in July and three in September. Three sites were electrofished twice. Of those 15 surveys, four were three-pass and 11 were single pass, for a total of 23 separate passes.

Stream sections ranged in length from 75 to 220 m with a mean of 140 m (n = 12, SE = 18). Voltage for each of the passes ranged from 300 to 750 V with a mean of 556 V (n = 23, SE = 23) and effort ranged from 340 to 1,591 sec with a mean of 669 sec (n = 23, SE = 70).

Table 21. Fish Catch, Casino Project, 2008

Gear	Arctic grayling	Slimy sculpin	Total
Britannia Creek Watershed			
Minnow Trap	0	0	0
Electrofishing	7	0	7
Angling	0	0	0
subtotal	7	0	7
Casino Creek Watershed			
Minnow Trap	0	0	0
Electrofishing	6	20	26
Angling	0	0	0
subtotal	5	21	26
Dip Creek Watershed			
Minnow Trap	0	0	0
Electrofishing	0	6	6
Angling	1	0	1
subtotal	1	6	7
Combined			
Minnow Trap	0	0	0
Electrofishing	12	27	39
Angling	1	0	1
Total	13	27	40

Of the four three-pass surveys, one caught no fish (F07 on July 9) and two (F03 on July 8 and F08 on July 9) did not show decreases in catch of Arctic grayling with successive passes. The fourth survey (F13 on July 10) did not show a decrease in catch of Arctic grayling with successive passes, but it did show clear decreases for slimy sculpin. Such decreases are required to estimate total fish number using the three-pass method (e.g., Peterson *et al*. 2004). The low number of three-pass surveys and the general lack of decreasing catch per pass meant that total fish number was not estimated using the three-pass algorithm. Instead, the CPUE of each survey was used as an index of population abundance.

A plot of CPUE on fish sampling site along a north-south trend line (Figure 46) shows that mean CPUE of Arctic grayling in the streams of the LSA was higher in July (mean = 0.10, SE = 0.04, n = 13) than in September (mean = 0.00 fish/100 sec, SE = 0.00, n = 3). This was due to outmigration of Arctic grayling in late summer in search of overwintering habitat. Arctic grayling from the Britannia Creek Watershed migrated to the Yukon River and those from Casino Creek Watershed moved downstream into Dip Creek.

Figure 47 shows that slimy sculpin were absent from the Britannia Creek Watershed in July and September 2008. Unlike Arctic grayling, the mean CPUE of slimy sculpin for Casino and Dip Creeks in September (mean = 0.24, SE = 0.21, n = 3) was not significantly different ($F_{1,8}$ = 0.091, P = 0.08) than the mean for July (mean = 0.16, SE = 0.16, n = 7), indicating that slimy sculpin did not outmigrate from Casino Creek until later in the year.

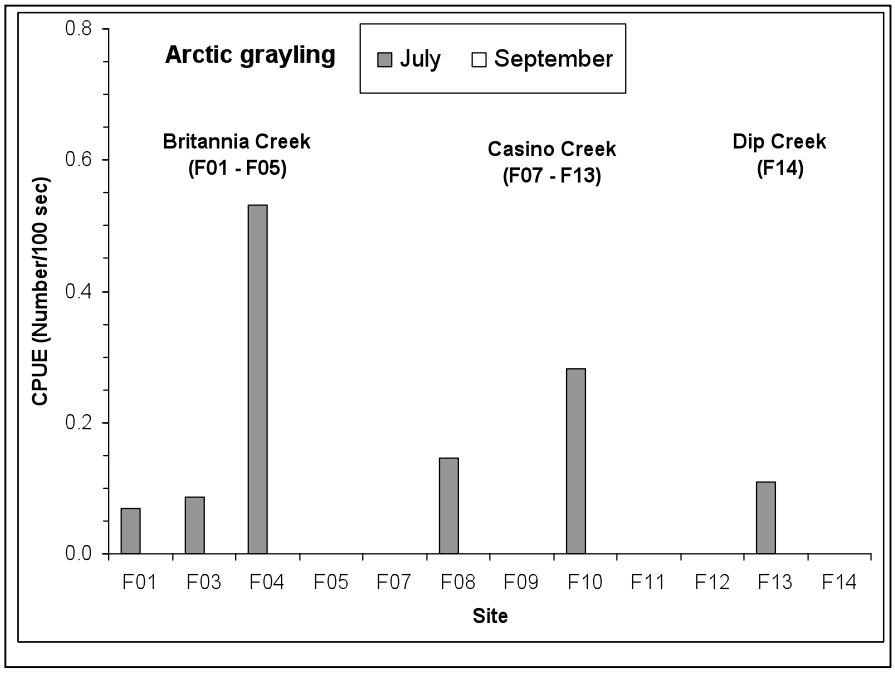

Figure 46. Electrofishing CPUE, Arctic Grayling, Casino Project, 2008

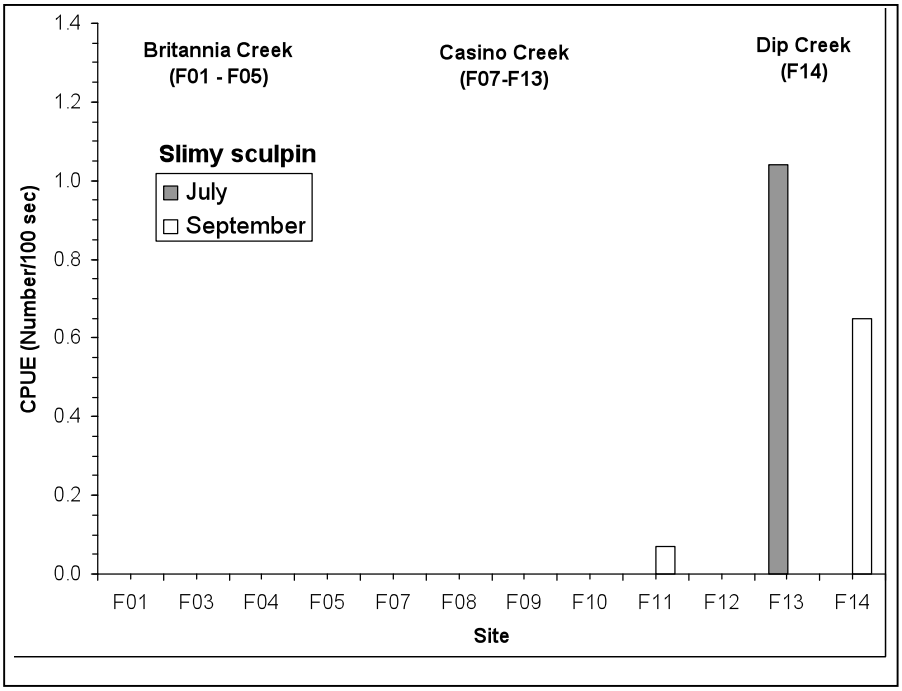

Figure 47. Electrofishing CPUE, Slimy Sculpin, Casino Project, 2008

Although the maximum CPUE of sculpin in Casino and Dip creeks for the combined July and September surveys was higher than the maximum for Arctic grayling in the LSA, the variance of both sets of CPUE was sufficiently high that the mean CPUE of slimy sculpin of Casino and Dip Creeks for the combined July and

September surveys (mean = 0.18, SE = 0.12, n = 10) was not significantly different ($F_{1,20}$ = 0.042, P = 0.52) from the mean CPUE of Arctic grayling in July.

These results were similar to those reported for 1993 and 1994 by Hallam Knight Piésold (1997), but with some important differences. As in 2008, Arctic grayling were observed throughout the Britannia Creek Watershed (Table 22). However, Arctic grayling fry were only observed in lower Britannia Creek near the confluence with the Yukon River in August 1993, indicating that this area provides spawning and rearing habitat for Arctic grayling, but not on a consistent basis.

Table 22. Fish Species in the Aquatics Local Study Area, Casino Project, 1993 to 2008

Species	Life Stage	Britannia Creek Watershed				Casino Creek Watershed		
		1993	1994	2008		1993	1994	2008
Arctic grayling	juveniles/adults fry	Jun, Aug. Sep Aug	Jun, Aug -	Jul -		Jun, Aug, Sep -	Jun, Aug, Sep Aug	Jul
Slimy sculpin	Juveniles/adults	Aug	Aug	-		Jun, Auig, Sep	Jun, Aug, Sep	Jul, Sep
Chinook salmon	juveniles fry	Aug June	- -	- -		- -	- -	- -
Round whitefish	juveniles	Aug	-	-		-	-	-
Burbot	juvenile	Sep	-	-		-	-	-

Unlike 2008, slimy sculpin were observed in the lower reach of Britannia Creek in 1993 and 1994, as were several round whitefish (*Prosopium cylindraceum*), one juvenile burbot (*Lota lota*) and several juvenile chinook salmon (*Oncorhynchus tshawytscha*). Therefore, lower Britannia Creek appears to provide temporary rearing habitat for juvenile fish from the Yukon River fish community. It is not clear why slimy sculpin do not move further upstream in the Britannia Creek Watershed, as they do in the Casino Creek Watershed. The presence of chinook salmon fry in lower Britannia Creek in June 1993 suggests the presence of some chinook salmon rearing habitat in lower Britannia Creek, but the absence of spawners in 1993, 1994 and 2008 indicates little spawning potential.

As in 2008, only slimy sculpin and Arctic grayling were observed in Casino Creek Watershed in 1993 and 1994, but Arctic grayling were found in September 1993 – later than in 2008 – indicating that the time of outmigration varies among years. No Arctic grayling fry were observed in the Casino Creek Watershed in any year, indicating that it offers poor rearing habitat for that species.

3.2.6.2 Size, Age and Growth

Appendix B14 shows lengths, weights and ages for fish captured in the Casino LSA in 2008. There were no significant differences in mean length ($F_{1,10}$ = 1.59, P = 0.24), weight ($F_{1,8}$ = 3.74, P = 0.09) or age ($F_{1,8}$ = 3.6, P = 0.09) of Arctic grayling between Britannia Creek and Casino Creek watersheds, which would be expected based on their geographic proximity. Hence, those data were pooled to calculate mean length, weight and age (Table 23). Since all slimy sculpin were captured from Casino and Dip creeks, which are directly connected, all those data were also pooled to calculate mean length and weight.

Table 23. Mean Size and Age of Fish, Casino Project, 2008

	Arctic Grayling				Slimy Sculpin	
Statistic	Length (mm)	Weight (g)	Age (year)		Length (mm)	Weight (g)
Mean	257	194.2	5		72	4.8
SE	14	25.0	1		9	8.8
n	13	11	11		26	26
minimum	173	44.5	2		29	0.5
maximum	300	260.0	6		129	19.3

SE = standard error and n = sample number.

The length frequency distribution for Arctic grayling shows two modes: one at a length range of 150-199 mm that are assumed to represent juveniles and a second mode at 250-299 mm that are assumed to represent adults (Figure 49). The length frequency distribution for slimy sculpin showed only one mode one at a length range of 50-99 mm that is assumed to represent a mixture of juveniles and adults.

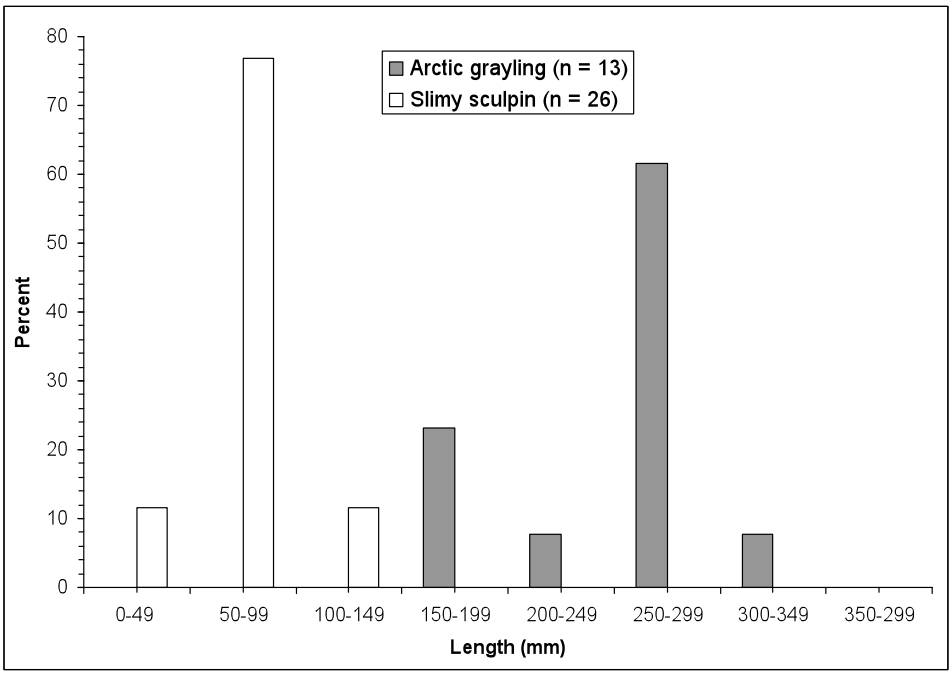

Figure 48. Length Frequencies of Arctic Grayling and Slimy Sculpin, Casino Project, 2008

Linear regressions of weight on length were highly significant for both species and explained between 96 and 97% of the variance in ln(weight) (Figure 50). The slopes of the regressions were both close to the value of 3.0 that is commonly assumed for fish.

The age frequency distribution for Arctic grayling shows two modes: one for fish aged two to three years (juveniles) and a second for fish aged five to six years (adults) (Figure 51). A plot of mean length on age showed that growth rate slows over age and hence mean length begins to approach an asymptote by age five or six years (Figure 52).

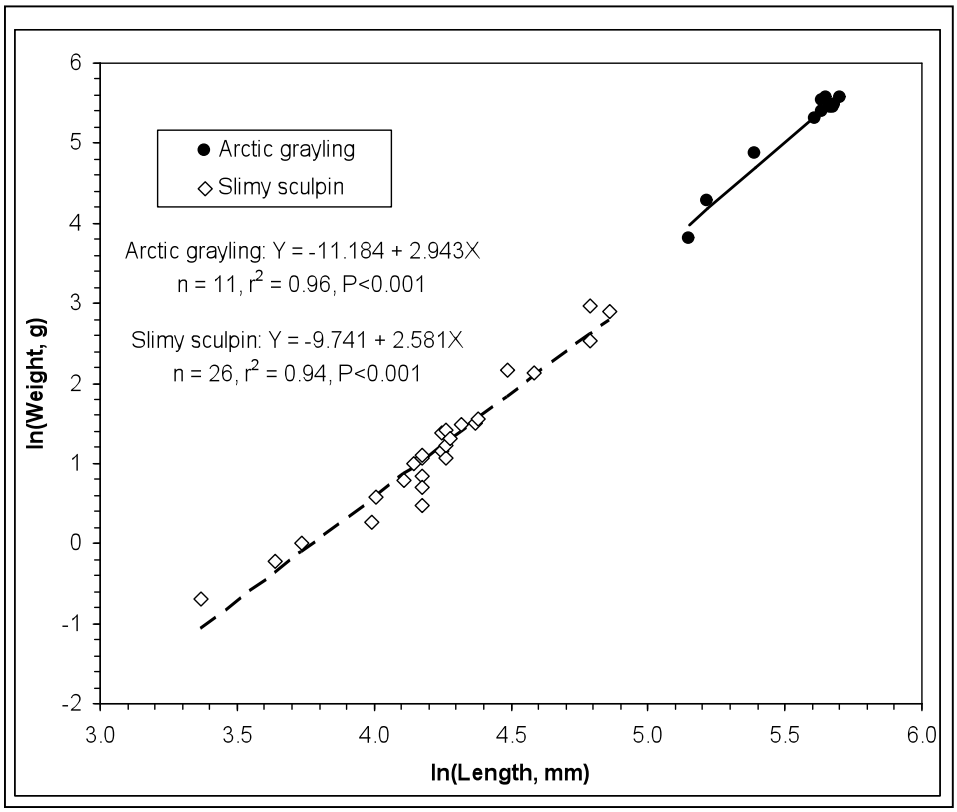

Figure 49. Weight-length Regressions for Arctic Grayling and Slimy Sculpin, Casino Project, 2008

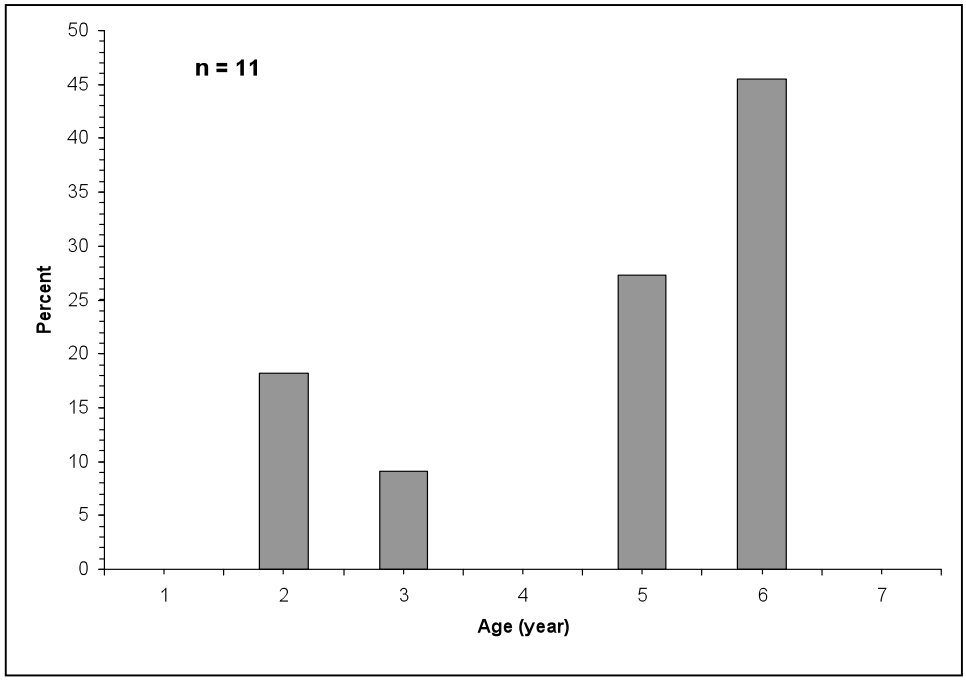

Figure 50. Age Frequency Distribution, Arctic Grayling, Casino Project, 2008

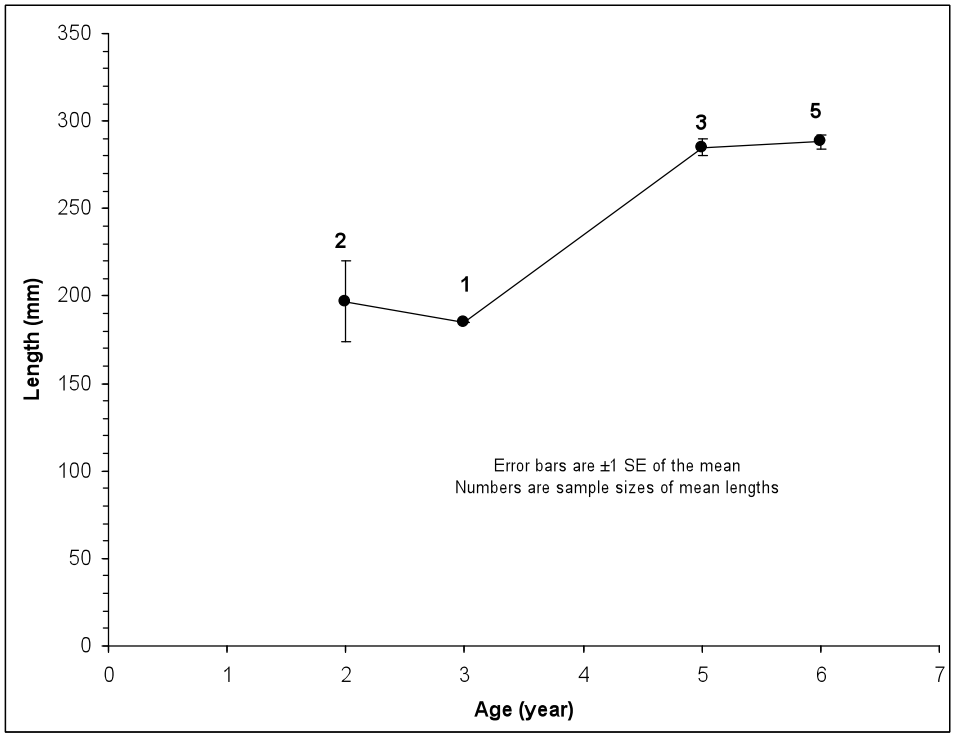

Figure 51. Length-Age Plot, Arctic Grayling, Casino Project, 2008

Too few Arctic grayling were captured in 2008 to permit growth modelling even if data were pooled from both Britannia and Casino watersheds. Therefore, length and age data reported by Hallam Knight Piésold (1997) for 1993 and 1994 were pooled with the 2008 data and von Bertalanffy growth curves were fit to data for Britannia and Casino watersheds separately (Figures 53 and 54). Both models explained 98% or more of the variance in length. There were sufficient data for the Britannia Watershed, particularly length-age data for the critical ages of zero and one years, to provide a good fit to length-at-age data. There were insufficient data for Casino Watershed as is shown by the predicted length at age zero years of 111 mm – twice the value predicted for Britannia Watershed and biologically unrealistic.

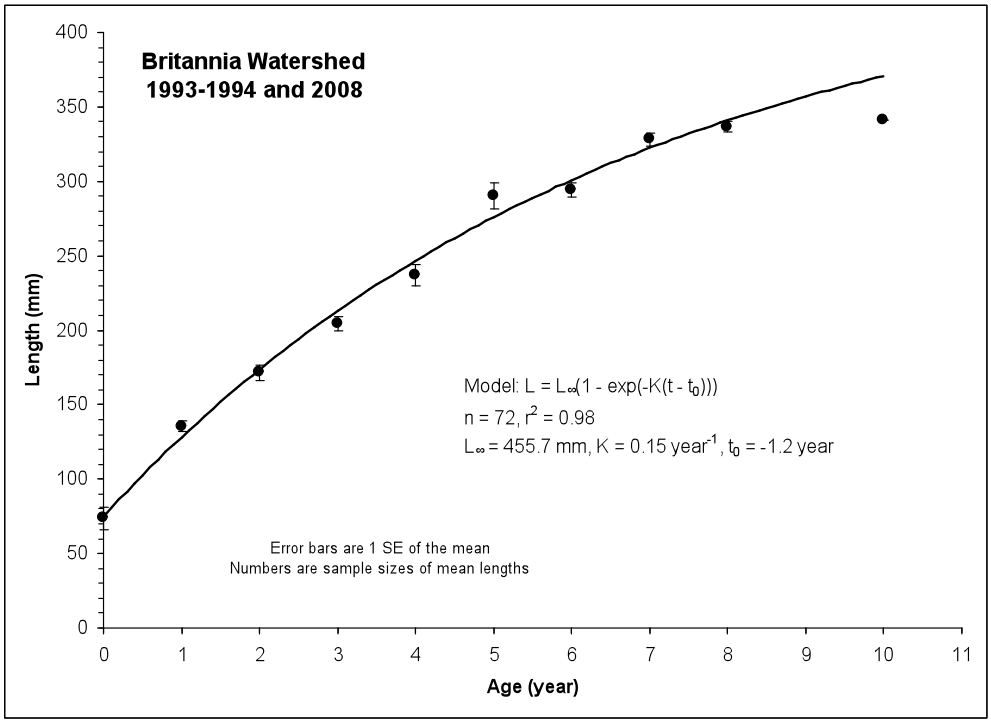

Figure 52. Length-Age Relationship, Arctic Grayling, Britannia Watershed, 1993-1994 and 2008

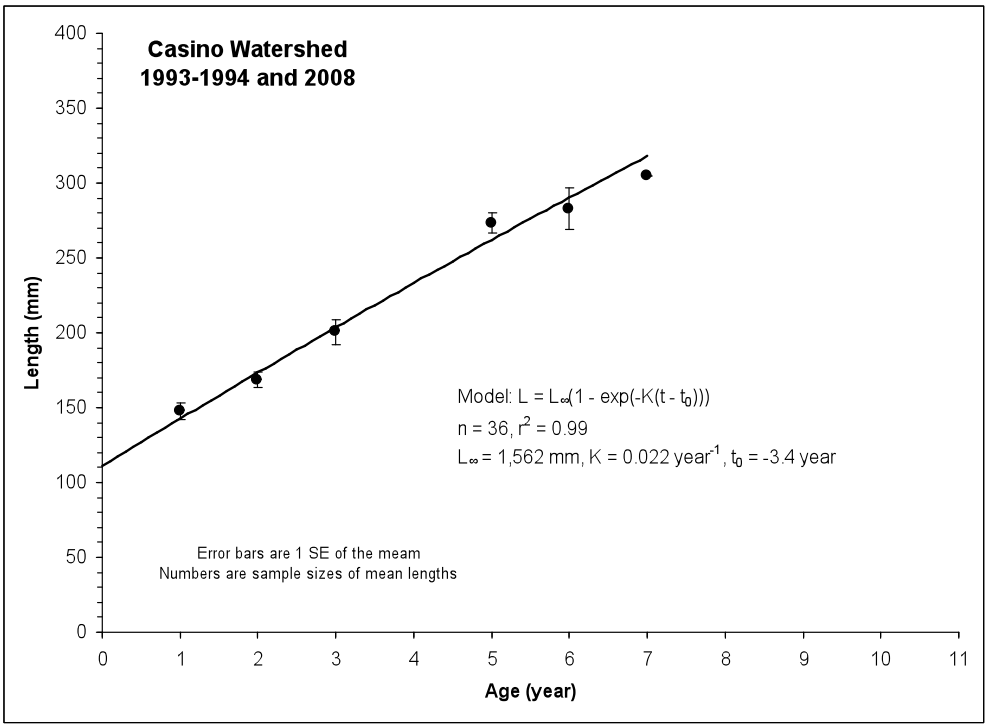

Figure 53. Length-Age Relationship, Arctic Grayling, Casino Watershed, 1993-1994 and 2008

3.2.6.3 Tissue Metals Concentrations

Appendix B15 shows the concentrations of metals measured in nine whole-body samples of slimy sculpin collected from Casino and Dip creeks in July and September 2008. Of the 33 metals, eight (antimony, beryllium, boron, molybdenum, tellurium, thallium, tin and zirconium) were excluded from analysis because all nine values were below detection limits. For the remaining 25 metals, all values below detection limits were replaced by one-half the detection limit to allow statistical analysis. This resulted in replacing 20% of the concentrations (i.e., 44 of 225). Table 24 shows the mean concentrations of metals, sorted in ascending order of mean concentration.

Table 24. Mean Whole-Body Metal Concentrations, Slimy Sculpin, Casino Project, 2008

Metal	Concentration (µg/g wet weight)			
	mean	SE	min	max
Silver	0.006	0.001	0.005	0.010
Mercury	0.040	0.008	0.020	0.090
Cadmium	0.07	0.02	0.00	0.24
Lead	0.08	0.03	0.05	0.30
Nickel	0.08	0.03	0.05	0.30
Chromium	0.09	0.03	0.05	0.30
Cobalt	0.09	0.03	0.05	0.30
Uranium	0.10	0.03	0.02	0.29
Arsenic	0.1	0.02	0.1	0.3
Vanadium	0.48	0.14	0.25	1.50
Selenium	0.7	0.1	0.4	1.1
Copper	1.2	0.1	0.9	2.1
Barium	4.3	0.9	1.2	9.8
Titanium	7.9	2.3	3.7	24.6
Manganese	10.6	2.3	3.1	25.4
Strontium	20.91	4.33	4.89	52.40
Zinc	27.5	3.9	19.2	57.4
Silicon	43	5	22	66
Aluminum	56.8	29.9	9.8	294.0
Iron	143	70	49	693
Magnesium	459	58	295	900
Sodium	1,526	232	1,090	3,360
Potassium	3,447	325	2,510	5,860
Phosphorus	9540	1758	4590	22900
Calcium	13,222	3,196	3,760	37,400

SE = standard error, min = minimum and max = maximum.

N = 9 for all metals.

None of the sculpin had mercury concentrations that exceeded the 0.5 µg/g guideline established by Health Canada (http://www.hc-sc.gc.ca/ahc-asc/media/advisories-avis/_2002/2002_41-eng.php).

PCA extracted two components from the dataset of ln-transformed metals. Four metals – mercury, cadmium, silicon and selenium – were not correlated with either component. Therefore, PCA was run a second time after removing those four metals. The first component, PC1, accounted for 60.8% of the explained variance and the second component, PC2, accounted for another 27.4% for a total of 88.2% of the explained

variance. Table 25 shows the correlations of the metals with each component. PC1 was highly correlated with ten metals including those often associated with metal deposits such as iron, lead and nickel. PC2 was highly correlated with 11 metals many of which are essential biological structural elements such as phosphorus, sodium and calcium and which are present in relatively high concentrations in whole-body tissue samples.

Table 25. Correlations of Principal Components with Slimy Sculpin Tissue Metal Concentrations

Metal	PC1	PC2
iron	0.99	0.13
lead	0.98	0.12
nickel	0.98	0.12
arsenic	0.94	0.30
aluminum	0.94	-0.03
chromium	0.94	-0.07
cobalt	0.93	0.10
titanium	0.91	0.39
vanadium	0.90	0.34
manganese	0.74	0.48
phosphorus	0.09	0.98
sodium	0.11	0.96
calcium	0.10	0.96
magnesium	0.34	0.93
zinc	0.32	0.91
silver	0.14	0.88
strontium	0.08	0.88
potassium	-0.13	0.83
copper	0.13	0.81
barium	0.57	0.74
uranium	0.50	0.68

A plot of PC2 scores on PC1 scores for the nine sculpin showed that seven of the nine fish clustered together in a region with relatively low scores, and that fish from all three sampling sites were present in that cluster (Figure 55). Two fish were outliers; one from site F13 had a relatively high PC2 score and one from site F14 had relatively a high PC1 score.

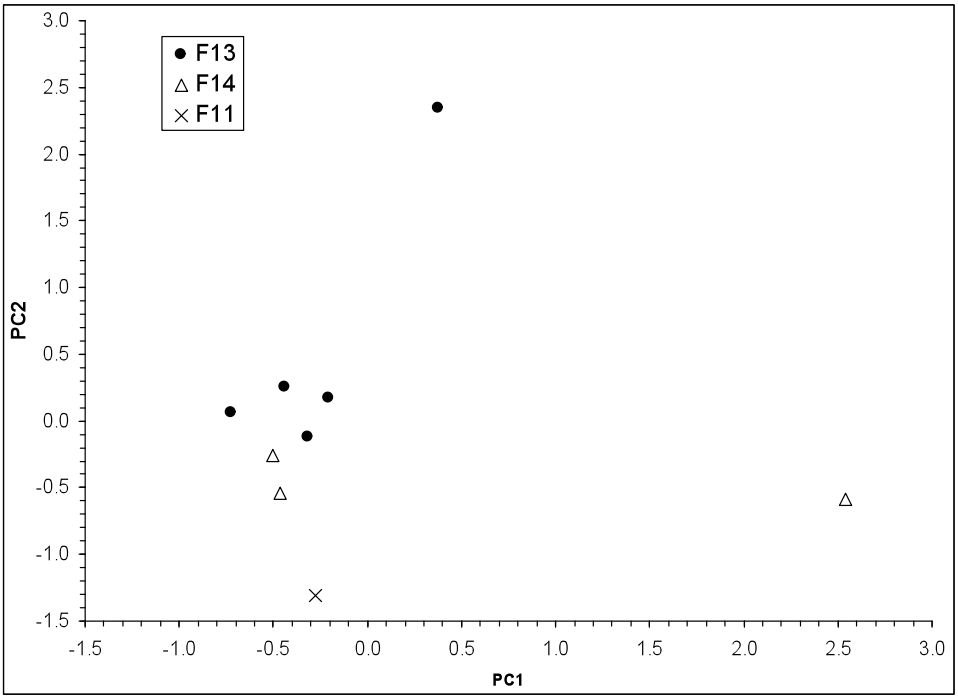

Figure 54. Plot of PC2 Scores on PC1 Scores for Slimy Sculpin Tissue Metal Samples

3.2.6.4 Salmon Spawning Survey

No Pacific salmon spawners were observed during the aerial survey of September 11, but good spawning habitat was observed in 50% of reach 2 of Britannia Creek and approximately 40 m^2 of spawning habitat was observed in Canadian Creek upstream from the confluence with Britannia Creek.

3.2.7 Fish Habitat

3.2.7.1 General

Appendices B16 and B17 show the stream habitat records for the July and September surveys, respectively.

3.2.7.2 Britannia Creek Watershed

The lower reach of Britannia Creek was surveyed on September 11 (Photo 2). At that time the stream stage was classified as high. Habitat consisted of 50% riffles, 30% runs and 20% pools. Gradient was close to 0%. Wetted depth ranged from 0.20 to 0.35 m with a mean of 0.28 m. The substrate was composed of 20% fines, 20% small gravel, 50% small cobble and 10% large cobble. Only 10% of the stream area provided cover and 80% of that area was provided by LWD and 20% by deep pools. Approximately 20% of the stream area consisted of gravel bars. The stream was classified as occasionally confined. This reach was classified as salmonid rearing habitat class II by DFO under the Yukon Placer Authorization (Government of Canada 2000).

Photo 2. Lower Reach of Britannia Creek Looking Upstream, September 11, 2008

The upper reach of Britannia Creek (i.e., reach 2) was also surveyed on September 11 (Photo 3). Habitat consisted of 70% riffle, 20% run and 10% pools. At that time its stage was high, hence its mean wetted width (4.1 m) was the same as its bankfull width. Wetted depth ranged from 0.16 m to 0.42 m with a mean of 0.29 m. Gradient was 1%. The substrate consisted of 30% small gravel, 30% large gravel, 20% large cobble and 10% boulder. Only 10% of the stream area provided cover of which 70% was provided by LWD, 20% by cutbank and 10% by overstream vegetation. The stream was unconfined and contained 10% gravel bars. The crown closure was 20%.

The lower reach of Canadian Creek, upstream of the confluence with Britannia Creek, was surveyed on July 8 (at fish site F03) and on September 11. In early July, the stream stage was low, hence mean wetted width (5.0 m) was lower than mean bankfull width (8.3 m) (Photo 4). Habitat consisted of 90% riffles and 10% pools. Gradient was 3%. The substrate consisted of 10% fines, 15% small gravel, 35% small cobble, 30% large cobble and 10% boulder. Forty five percent of the stream area provided cover of which 40% was provided by LWD, 40% by overhanging vegetation, 15% by cutbanks and 5% by boulders. The stream was unconfined and contained no gravel bars or braids. The crown closure was 7%.

Photo 3. Upper Reach of Britannia Creek Looking Upstream, September 11, 2008

Photo 4. Canadian Creek Above the Confluence with Britannia Creek (Site F03) Looking Upstream, July 8, 2008

In September, habitat consisted of 40% riffle, 40% run and 20% pools. Although the stream stage of the lower reach of Canadian Creek was high, the mean wetted width (4.8 m) was only 61% of the bankfull width (7.9 m) (Photo 5). Wetted depth ranged from 0.26 to 1.00 m with a mean of 0.63 m. Gradient was close to 0%. The substrate consisted of 10% fines, 10% small gravel, 10% large gravel, 20% small cobble and 50% large cobble. Only 10% of the stream area provided cover of which 80% was provided by LWD and 20% by deep pools. The stream was unconfined and contained no gravel bars. The crown closure was 10%.

Photo 5. Lower Reach of Canadian Creek Looking Upstream, September 11, 2008

Reach 2 of Canadian Creek (the cascade pools) was surveyed on July 8 and September 11. In July, the stream stage was low, hence the mean wetted width (5.2 m) was lower than the mean bankfull width (6.5 m) (Photo 6). Habitat consisted of 100% cascade pools. Gradient was 4%. The substrate consisted of 5% fines, 20% large gravel, 15% small cobble, 10% large cobble and 50% boulders. Fifty percent of the stream area provided cover of which 80% was provided by boulders, 10% by LWD and 10% by overhanging vegetation. The stream was unconfined and contained no gravel bars, but it was braided. The crown closure was 17%.

In September, habitat consisted of 100% cascade pools and gradient was 15%. The stream stage of the lower reach of Canadian Creek was high, hence its mean wetted width (8.0 m) was the same as its bankfull width (Photo 7). Wetted depth was 0.43 m. The substrate consisted of 90% boulder, 5% small gravel and 5% fines. Fifty percent of the stream area provided cover of which 100% was provided by boulders. The stream was frequently confined and contained no gravel bars. The crown closure was 0%.

Photo 6. Lower Reach of Canadian Creek (F04) Looking Downstream, July 8, 2008

Photo 7. Reach 2 of Canadian Creek (Cascade Pools) Looking Upstream, September 11, 2008

The upper reach (reach 3) of Canadian Creek was surveyed on September 11 (Photo 8). Habitat consisted of 80% riffles, 10% runs and 10% pools. The stream stage was high, hence its mean wetted width (3.0 m) was the same as its bankfull width. Wetted depth ranged from 0.16 to 0.36 m with a mean of 0.26 m. Gradient was 3%. The substrate consisted of 60% large cobble, 20% boulder, 15% small cobble and 5% fines. Twenty percent of the stream area provided cover of which 100% was provided by boulders. The stream was unconfined and contained no gravel bars. The crown closure was 0%.

Photo 8. Upper Reach (number 3) of Canadian Creek Looking Upstream, September 11, 2008

3.2.7.3 Casino Creek Watershed

The upper reach (reach 2) of Casino Creek was surveyed on September 12 (Photo 9). Habitat consisted of 50% pools, 40% riffles and 10% runs. The stream stage was high, hence its mean wetted width (5.4 m) was the same as its bankfull width. Wetted depth ranged from 0.08 to 0.40 m with a mean of 0.27 m. Gradient was 3%. The substrate consisted of 40% boulders, 20% large cobble, 20% small cobble, 10% large gravel and 10% fines. Thirty percent of the stream area provided cover of which 80% was provided by boulders and 20% by overstream vegetation. The stream was unconfined and contained no gravel bars. The crown closure was 0%.

The lower reach (reach 1) of Casino Creek was surveyed on September 12 (Photo 10). Habitat consisted of 40% runs, 30% riffles and 30% pools. The stream stage was high, hence its mean wetted width (5.7 m) was the same as its bankfull width. Wetted depth ranged from 0.27 to 1.50 m with a mean of 0.71 m. Gradient was 2%. The substrate consisted of 40% large cobble, 30% fines, 20% small cobble, 5% large gravel and 5% small gravel. Thirty percent of the stream area provided cover of which 70% was provided by deep pools and 30% by LWD. The stream was unconfined and contained no gravel bars. The crown closure was 20%.

Photo 9. Upper Reach (number 2) of Casino Creek Looking Upstream, September 12, 2008

Photo 10. Lower Reach (number 1) of Casino Creek Looking Downstream, September 12, 2008

Reach 1 of Meloy Creek, the most upstream named tributary of Casino Creek, was surveyed on September 12 (Photo 11). Habitat consisted of 50% runs, 30% riffles and 20% pools. The stream stage was high, hence its mean wetted width (1.1 m) was the same as its bankfull width. Wetted depth ranged from 0.21 to 0.40 m with a mean of 0.30 m. Gradient was 2.5%. The substrate consisted of 80% fines, 10% boulders, 5% small cobble and 5% small gravel. Seventy percent of the stream area provided cover of which 80% was provided by overstream vegetation and 20% by deep pools. The stream was unconfined and contained no gravel bars. The crown closure was 10%.

Photo 11. Reach 1 of Meloy Creek Looking Upstream, September 12, 2008

The upper reach (Reach 2) of Brynelsen Creek was surveyed on September 12 (Photo 12). Habitat consisted of 70% riffles and 30% pools. The stream stage was high, hence its mean wetted width (4.1 m) was the same as its bankfull width. Wetted depth ranged from 0.35 to 0.40 m with a mean of 0.38 m. Gradient was 2.5%. The substrate consisted of 70% boulders, 20% large cobble and 10% small cobble. Twenty percent of the stream area provided cover of which 80% was provided by boulders and 20% by LWD. The stream was unconfined and contained no gravel bars. The crown closure was 10%.

The lower reach (Reach 1) of Brynelsen Creek was surveyed on September 12 (Photo 13). Habitat consisted of 60% riffles, 20% runs and 20% pools. The stream stage was high, hence its mean wetted width (5.4 m) was the same as its bankfull width. Wetted depth ranged from 0.12 to 0.49 m with a mean of 0.29 m. Gradient was 2%. The substrate consisted of 30% fines, 20% large gravel, 20% small cobble, 20% large cobble and 10% boulders. Ten percent of the stream area provided cover of which 90% was provided by boulders and 10% by overstream vegetation. The stream was unconfined and braided and contained no gravel bars. The crown closure was 10%.

Photo 12. Upper Reach of Brynelsen Creek Looking Upstream, September 12, 2008

Photo 13. Lower Reach of Brynelsen Creek Looking Upstream, September 12, 2008

The upper reach (Reach 2) of Austin Creek was surveyed on September 12 (Photo 14). Habitat consisted of 70% pools, 20% runs and 10% riffles. The stream stage was high, mean wetted width was 1.1 m and mean bankfull width was 0.9 m. Wetted depth ranged from 0.29 to 0.56 m with a mean of 0.43 m. Gradient was not measured. The substrate consisted of 90% fines and 10% boulders. Ninety percent of the stream area provided cover of which 90% was provided by overstream vegetation and 10% by deep pools. The stream was unconfined and braided contained no gravel bars. Crown closure was 0%.

Photo 14. Upper Reach of Austin Creek Looking Upstream, September 12, 2008

The lower reach (Reach 1) of Austin Creek was surveyed on September 12 (Photo 15). Habitat consisted of 70% pools and 30% runs. The stream stage was high, hence the mean wetted width (1.8 m) was the same as mean bankfull width. Wetted depth ranged from 0.39 to 0.54 m with a mean of 0.47 m. Gradient was close to 0%. The substrate consisted of 100% fines. One hundred percent of the stream area provided cover of which all was provided by overstream vegetation. The stream was unconfined and braided contained no gravel bars. Crown closure was 0%.

3.2.7.4 Dip Creek

The reach of Dip Creek that encloses site F14 was surveyed on September 12 (Photo 16). Habitat consisted of 40% riffles, 30% runs and 30% pools. The stream stage was high, hence its mean wetted width (10.5 m) was the same as its bankfull width. Wetted depth was 1.25 m. Gradient was close to 0%. The substrate consisted of 50% fines, 30% small cobble, 10% large cobble and 10% small gravel. Twenty five percent of the stream area provided cover of which 50% was provided by LWD and 50% was provided by deep pools. The stream was unconfined and braided contained no gravel bars. The crown closure was 10%.

3.3 Terrestrial Environment

3.3.1 Soils and Vegetation

Surveys of the Casino LSA in July and September showed that it is characterized by smooth, rolling topography with moderate to deeply incised valleys.

Wildlife habitat consists of a variety of plant communities ranging from sparsely vegetated bare rock, large expanses of heath tundra, wet sedge meadows with tall riparian shrubland and treed slopes dominated by spruce, aspen, birch and willows. Open stands of black spruce and white spruce occur in valleys and lower slopes, with black spruce on wetter sites and white spruce on better drained sites. Willow, shrub birch, Labrador tea, mosses and lichens are principal understory species.

During the July and September surveys, a total of 33 soil pits were dug and plants were sampled and described for the various cover types: spruce, spruce/aspen, spruce/birch, shrub birch/willow, heath tundra, wet sedge meadow, and burns. Appendices C1 and C2 show the data for each of the sampling sites, and Photos 17 to 22 show representative examples of wildlife habitat.

3.3.2 Wildlife Observations

3.3.2.1 General

Appendix C3 shows the observations of wildlife made in July and September of 2008, as well as observations made by other field crews in May and August. Table 26 lists the common names and scientific names of observed wildlife.

Table 26. Common and Scientific Names of Wildlife Observed at the Casino Project Area, 2008

Common Name	Scientific Name	Common Name	Scientific Name
Mammals		**Birds**	
Moose	*Alces alces*	American robin	*Turdus migratorius*

Least chipmunk	*Eutamias minimus*		

3.3.2.2 July 7 to 11 Survey

Moose were observed along the Yukon River and along Casino and Dip creeks. The area being considered for the proposed Casino Project appears to be a preferred moose wintering area. No caribou were seen in the LSA, however caribou sign (e.g., pellets, shed antlers, trails, etc.) were found on ridge tops. Several small groups of caribou were observed south of the LSA during the flight from Whitehorse. Terrestrial lichens occur primarily on north-facing slopes and provide an abundant food source for caribou.

Numerous wolf tracks and scats were observed along Dip Creek, suggesting the presence of a den site close by, but it could not be located. Three individual grizzly bears (two blonde and one chocolate brown) and one black bear were observed during the July survey. Bear scats were also observed in the major creek drainages (Canadian, Britannia, Austin, Dip), and on the trails between the airstrip and the lower camp, and the airstrip and tank farm. Bear use appeared to be concentrated at this time of year in areas with buffaloberries, bearberries, and *Hedysarum*.

Small mammals observed in the LSA included snowshoe hare, red squirrel and voles. Well-developed small mammal trails were observed in some spruce habitat.

The rock outcrops on Patton Hill, and various treed habitat types were surveyed by helicopter and on foot for raptors but none were observed or heard. However, waterfowl, upland birds (e.g., ptarmigan) and various songbirds were seen or heard.

3.3.2.3 September 8 to 11 Survey

Wolves were heard howling along Dip Creek, and observed by Casino camp construction personnel on Britannia Creek. Lynx were also seen at the lower camp and on Britannia Creek.

Black and grizzly bears were observed by Casino camp construction personnel on six separate occasions in August and September. Grizzly bear observations included a sow with two, 2-year-old cubs, and a lone, chocolate-brown grizzly bear. Black bear observations included three lone bears, and one sow with two yearling cubs. Bear scats were also observed in the major drainages (Canadian, Britannia, Austin and Dip creeks), and on the trails between the airstrip and the lower camp, and the airstrip and tank farm. Bear use appeared to be concentrated at this time of year in areas with buffaloberries, cranberries, and blueberries.

Moose were observed along the Yukon River, Britannia, Casino and Dip creeks. Caribou were seen in the LSA by Casino camp construction personnel on five separate occasions, and caribou sign (e.g., pellets, shed antlers, trails) were found on ridge tops. One small group of caribou were observed along the proposed road route east of the Casino mine site.

Potential summer and winter range, lambing areas and escape terrain for sheep are limited within the survey area. No thinhorn sheep were observed along the Yukon River bank directly across from Britannia Creek during a survey conducted on September 9.

Small mammals observed in the LSA included snowshoe hare, red squirrel, bog lemmings, Arctic ground squirrel and voles.

The rock outcrops on Patton Hill, and various treed habitat types were surveyed by helicopter and on foot for raptors. Raptors observed or heard included great horned owl, northern harrier, northern hawk owl, and golden eagle. Other birds including tundra swans, ptarmigan, grouse and various songbirds were seen or heard.

Attention: **Rick Palmer**

Subject: **Casino Mine – Methodology Report for Installation of Meteorological Station**

RWDI AIR Inc. (RWDI) was retained by Gartner Lee Limited to install a meteorological monitoring station at the Casino Mine. This report provides a discussion on the status of this project and a description of the station.

On September 30, 2008, Geoff Doerksen and Jackson Mak from RWDI arrived at Casino Mine to install the meteorological station. Installation of the meteorological tower was started that afternoon and the tower was erected by the following morning. By the evening of October 1, 2008, all the instruments were mounted on the tower. While configuring the equipment the morning of October 2, 2008, a connection with the data logger could not be established remotely by either the RWDI Vancouver office or by the equipment supplier. It was suspected that the Iridium modem or the antenna was not functioning properly. The satellite modem system was therefore returned to Vancouver for further testing. The removal of the satellite modem system from the station did not affect the meteorological observations as they continued to be collected and stored on the data logger. Data recorded at the station are valid from October 3, 2008 at midnight to present.

Mr. Doerksen and Mr. Mak were scheduled to leave Casino Mine on Thursday afternoon. However, due to poor visibility, the Alkan Air plane was unable to land at the mine site and Mr. Doerksen and Mr. Mak were forced to spend an extra night at camp. The following day they were picked up by a helicopter late in the morning and spent the remainder of the day travelling back to Vancouver.

Upon returning to Vancouver, the satellite modem system was further tested with support provided by the equipment supplier. While there were no apparent problems with the system it was thought that a lose connection with the antenna cable may have been the cause of the problem. The antenna cable was properly secured and a remote connection was established while testing the equipment in Vancouver. The equipment was subsequently shipped back to Casino Mine on October 22, 2008. The satellite modem system was re-installed at the site by Scott Casselmen, the camp manager of Casino Mine. After installation a remote connection with the station was attempted; however it was unsuccessful.

In discussions with the equipment supplier it was determined that the only way to resolve the problem with the satellite modem system was for a technician to travel to the site and replace the non-working equipment. On November 7, 2008 Mark Milner from RWDI travelled to Casino Mine and replaced several components of the satellite modem system including the modem, antenna and data kit. Subsequent tests on the system were successful and a remote connection with the station was established. The station including the satellite modem system is now currently functioning properly and a remote connection with the station is now possible. Data was successfully downloaded remotely on November 7, 14, and 21, 2008.

STATION DESCRIPTION

The meteorological station consists of a 10-m free-standing tower equipped with instrumentation, data logger, and logger enclosure. As shown in Figure 1, the tower is secured by two sets of guy wires attached to the base of the tower. One set of guy wires is attached at the top of the mast while the other set is attached midway up the mast. The guy wires may be a potential hazard; therefore they are flagged with orange flagging tape. The tower base is constructed from five fibreglass pods arranged in a square formation with one pod located at the centre. The four outer pods are connected to the centre pod by aluminum pipes for support. The fibreglass pods are filled with soil to give the base of the tower weight and ensure that the tower is properly secured. The design of the tower has been approved by an engineer.

Figure 1: Meteorological Tower at Casino Mine

The meteorological station is located approximately 300 km northwest of Whitehorse. The station is sited in a transition zone between tree line and alpine with an unobstructed fetch of at least 100 m in all directions. The site is sparsely covered in low brush and trees that are approximately 10 m tall. Figure 2 shows the location of the monitoring station. The map coordinates of the station are summarized in Table 1.

Figure 2: Location of Casino Meteorological Station South of the Yukon River

Table 1: Location of Casino Meteorological Station

Latitude	62º 43’ 27.837” North
Longitude	138º 49’ 0.562” East
Easting (m)	611,609
Northing (m)	6,956,775
UTM Grid Reference	Zone 7
Datum	NAD83
Elevation (m)	1,203

The meteorological station has instrumentation capable of measuring wind speed and direction, rainfall, air temperature, barometric pressure, relative humidity and snow depth. These measurements will provide the necessary observations to calculate atmospheric stability class needed as input for air quality modelling. Observations are recorded and stored by a data logger, which is powered by a battery charged with a solar panel at the station. The data logger is equipped with a satellite modem for remotely accessing the data. The specific model numbers of the equipment are summarized in Table 2.

Table 2: Casino Station Equipment

Equipment	**Model Number**
Datalogger with 4M RAM Memory	CR800-XT
Solar Panel 20 Watt 12 Volt	MSX20R
Iridium Satellite Remote Modem	A3LA-MPT
Iridium Modem Accessory Antenna 1616-1626 MHz	SAF5350A
Iridium Modem Accessory Remote Power & Data Kit	SYN-DC-936R
Relay Kit Crydom 7 Amp c/w Wires	C1701
Enclosure Fiberglass 16” x 18”	ENC 16/18
Sonic Ranger 50 KHz Module	SR50A
Relative Humidity & Air Temperature Probe	HC-S3-XT
RM Young Wind Monitor	05103-10-L
RM Young Barometric Pressure Sensor	61205V
Texas Electronics Tipping Bucket Metric Rain Gauge	TE525M

As shown in Figure 3, the snow depth instrument (Sonic Ranger) is mounted on a cross arm three metres above ground from the main mast. The relative humidity and air temperature probe is housed in a radiation shield mounted on the same cross arm as the Sonic Ranger. The anemometer is mounted at the top of the 10 m tower. The rain gauge has been installed approximately two metres from the tower on a separate post that is approximately one metre above ground.

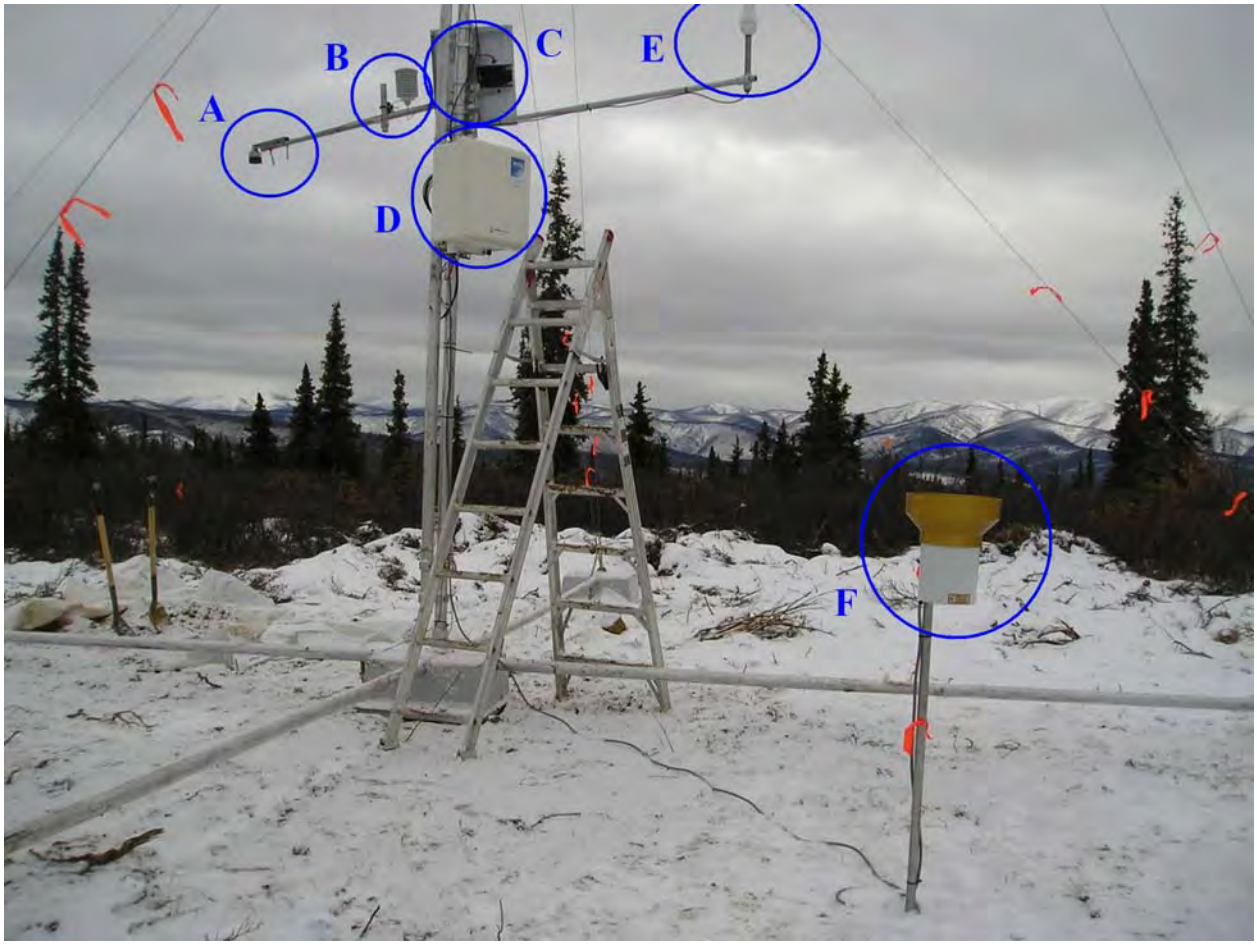

Figure 3: Casino Meteorological Monitoring Station Equipped with A) Sonic Ranger, B) Relative Humidity and Temperature Probe, C) Solar Panel, D) Data Logger Enclosure, E) Satellite Antenna and F) Rain Gauge

The barometric pressure sensor is housed in the data logger enclosure at a height of 2.8 m above ground. The pressure sensor is vented to the outside of the logger enclosure by way of a poly tube attached to a small port on the enclosure. By convention, barometric pressure observations are corrected to report sea-level pressure. The following equation is used to determine the pressure correction factor:

P = 1013.25 [1 – (1 – Elevation/44307.69231) ^5.253283]

where P is the correction factor (in hPa) and elevation is given in metres above sea level.

The solar panel is mounted about three metres above ground facing due south on the main mast. The solar panel is tilted at an angle of 78º relative to ground to receive maximum insolation and prevent the collection of snow. This angle is calculated based on manufacturer's specifications. The data logger enclosure, which houses the data logger, Iridium modem and pressure sensor, has been mounted at a height of 2.8 m above ground. The satellite modem antenna is mounted on a second cross arm extending from the main mast located approximately three metres above ground. A summary of instrumentation measurement heights is provided in Table 3.

Table 3: Measurement Height

Measurement	Height Above Ground (m)
Snow Depth	3
Relative Humidity and Air Temperature	3
Barometric Pressure	2.8
Rainfall	1
Wind Speed and Direction	10

We trust that this report meets your information requirements. If you have any questions or require further information, please contact the undersigned at (604) 730-5688 ext. 3227.

Sincerely,
RWDI AIR Inc.

Notes:

All units mg/l unless otherwise noted.

a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007.

b) 0.005 mg/L at pH <6.5, [Ca2+] <4 mg/L, DOC <2 mg/L: 0.1 mg/L at pH ≥6.5, [Ca2+] ≥4 mg/L, DOC ≥2 mg/L.

c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] = 120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180 mg/L.

d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] = 60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180 mg/L; 0.007 mg/L at [CaCO3] >180 mg/L.

e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] = 60 - 120 mg/L; 0.110 mg/L at [CaCO3] =120 - 180 mg/L; 0.150 mg/L at [CaCO3] >180 mg/L.

Notes:

All units mg/l unless otherwise noted.

a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007.

b) 0.005 mg/L at pH <6.5, [Ca2+] <4 mg/L, DOC <2 mg/L: 0.1 mg/L at pH ≥6.5, [Ca2+] ≥4 mg/L, DOC ≥2 mg/L.

c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] = 120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180 mg/L.

d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] = 60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180 mg/L; 0.007 mg/L at [CaCO3] >180 mg/L.

e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] = 60 - 120 mg/L, 0.110 mg/L at [CaCO3] =120 - 180 mg/L; 0.150 mg/L at [CaCO3] >180 mg/L.

Notes:

All units mg/l unless otherwise noted.

a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007.

b) 0.005 mg/L at pH <6.5, [Ca2+] <4 mg/L, DOC <2 mg/L: 0.1 mg/L at pH ≥6.5, [Ca2+] ≥4 mg/L, DOC ≥2 mg/L.

c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] = 120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180 mg/L.

d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] = 60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180 mg/L; 0.007 mg/L at [CaCO3] >180 mg/L.

e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] = 60 - 120 mg/L; 0.110 mg/L at [CaCO3] =120 - 180 mg/L; 0.150 mg/L at [CaCO3] >180 mg/L.

Italic *Results exceed CCME Aquatic Life guidelines.*

Notes:

All units mg/l unless otherwise noted.

a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007.

b) 0.005 mg/L at pH <6.5, [Ca2+] <4 mg/L, DOC <2 mg/L: 0.1 mg/L at pH ≥6.5, [Ca2+] ≥4 mg/L, DOC ≥2 mg/L.

c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] = 120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180 mg/L.

d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] = 60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180 mg/L; 0.007 mg/L at [CaCO3] >180 mg/L.

e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] = 60 - 120 mg 0.110 mg/L at [CaCO3] =120 - 180 mg/L; 0.150 mg/L at [CaCO3] >180 mg/L.

Notes:

All units mg/l unless otherwise noted.

a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007.

b) 0.005 mg/L at pH <6.5, [Ca2+] <4 mg/L, DOC <2 mg/L: 0.1 mg/L at pH ≥6.5, [Ca2+] ≥4 mg/L, DOC ≥2 mg/L.

c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] = 120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180 mg/L.

d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] = 60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180 mg/L; 0.007 mg/L at [CaCO3] >180 mg/L.

e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] = 60 - 120 mg/L; 0.110 mg/L at [CaCO3] =120 - 180 mg/L; 0.150 mg/L at [CaCO3] >180 mg/L.

Notes:

All units mg/l unless otherwise noted.

a) Canadian water quality guidelines for the protection of aquatic life, Council of Ministers of the Environment, 2007.

b) 0.005 mg/L at pH <6.5, [Ca2+] <4 mg/L, DOC <2 mg/L: 0.1 mg/L at pH ≥6.5, [Ca2+] ≥4 mg/L, DOC ≥2 mg/L.

c) 0.002 mg/L at [CaCO3] = 0 - 120 mg/L; 0.003 mg/L at [CaCO3] = 120 - 180 mg/L; 0.004 mg/L at [CaCO3] >180 mg/L.

d) 0.001 mg/L at [CaCO3] = 0 - 60 mg/L; 0.002 mg/L at [CaCO3] = 60 - 120 mg/L; 0.004 mg/L at [CaCO3] =120 -180 mg/L; 0.007 mg/L at [CaCO3] >180 mg/L.

e) 0.025 mg/L at [CaCO3] = 0 - 60 mg/L; 0.065 mg/L at [CaCO3] = 60 - 120 mg/L; 0.110 mg/L at [CaCO3] =120 - 180 mg/L; 0.150 mg/L at [CaCO3] >180 mg/L.

Notes:

EF = electrofishing, AN = angling, ARGR = Arctic grayling and SLSC = slimy sculpin.

B15. Fish Tissue Metal Concentrations, Casino Project, 2008

Analysis Report

REPORT ON: Amended Report - Analysis of Tissue Samples

REPORTED TO: Gartner Lee Limited
490-6400 Roberts St
Burnaby, BC
V5G 4C9

Att'n: Genevieve Martin

CHAIN OF CUSTODY: 188716
PROJECT NAME: Casino
PROJECT NUMBER: 80049

NUMBER OF SAMPLES: 5

REPORT DATE: December 11, 2008

DATE SUBMITTED: July 15, 2008

GROUP NUMBER: 90716049

SAMPLE TYPE: Tissue

NOTE: Results contained in this report refer only to the testing of samples as submitted. Other information is available on request.

TEST METHODS:

Mercury in Tissue - samples were digested using a nitric acid-hydrogen peroxide digestion procedure based on EPA Method 200.3. Analysis was performed using Cold Vapour Atomic Absorption Spectrophotometry or Cold Vapour Atomic Fluorescence Spectrophotometry.

Metals in Tissue - samples were digested using a nitric acid-hydrogen peroxide digestion procedure based on EPA Method 200.3. Analysis was performed using Inductively Coupled Argon Plasma Spectroscopy (ICP), or ICP Mass Spectrometry (ICP/MS).

COMMENTS:

Amended Report - This report supercedes final hard copy sent on August 6, 2008 via mail. The tissue results are based on a wet weight basis - not dry weight as indicated in the footnotes of the report. cjw December 11, 2008

TEST RESULTS:

ug/g = micrograms per gram, dry basis
R.P.D. = Relative Percent Difference
PASS = Duplicate sample results were in the range of one to five times the detection limit. R.P.D. calculation is not applicable in this range. Acceptance criteria is a maximum difference between the duplicates equivalent to the value of the detection limit.
NC = Not Calculated. Duplicate sample results were less than the detection limit. Relative Percent Difference calculation is not defined for analyte levels of less than detection limit.

ug/g = micrograms per gram, dry basis
R.P.D. = Relative Percent Difference
PASS = Duplicate sample results were in the range of one to five times the detection limit. R.P.D. calculation is not applicable in this range. Acceptance criteria is a maximum difference between the duplicates equivalent to the value of the detection limit.
NC = Not Calculated. Duplicate sample results were less than the detection limit. Relative Percent Difference calculation is not defined for analyte levels of less than detection limit.

Soil Classification								
Comments								
	Immature Trembling aspen stand with ~ 3 m height. Scattered standing aspen remnants throughout stand. Aspen trees have silver coloring from unknown insect infestation. Soils shallow with coarse frags and bare soil prevelant across site.	Buried organic horizons to 10 cm with mottles present. Alder, willow and birch dominate understory shurb layer.	Plot located at crest of long slope near area of exposed bedrock with willow, dwarf birch and mossess dominating site.	Plot located on steep graminoid/forb dominated sideslope immediately above Dip Creek.	Plot located on north facing, poorly drained, wet tundra slope.	Plot within shrubby slope transitiong into open alpine located at upper slope position.	Plot located at saddle of alpine area with large amounts of exposed bedrock.	Plot located on open tundra slope with scattered dwarf birch and willow with the site dominated by ericarious shrubs and feathermoss.

Soil Classification									
Comments									
	Dry south facing, immature aspen stand dominated by short shrubs.	Plot characteristic of similar topographic positions throughout local study area.	Numerous dead standing snags, remnants of previous burn with large amounts of blowdown across hillside.	Plot located near top of Black spruce/ dwarf birch/lab tea scrub slope. Open tundra slope to west. Coluvium or fractured bedrock immediately below moss layer with very little soil present.	Immature aspen stand on Southwest facing slope. Some birch and spruce scattered throughout.	Characteristic aspen stand on south or southwest facing well drained slope.	Open, dry south facing slope with vegetation primarily ground shrubs (bearberry).	Black spruce stand on North facing slope, characterized as a Sb treed bog on a slope. Surfacewater moving downslope over surface of permafrost.	Open shrubby bog with cottongrass and sphagnum hummocks throughtout caused by surface water held up from permafrost.

Comments					
	Vegetation hardened of and done for the season. Crest and upper slope position easily typed the same.	Rocky Scree slope grades into birch shrub.	Surface and subsurface drainage channels into shallow gully with a high water table.	Aspen stand on dry, south facing slope, charactistic of these types observed thoughout study area.	South of site #108 where slope decrease and drainage is poor. Black spruce treed bog.

Comments						
	Shrub layer generally <1 m. Extremely Hummocky ground with tussock sedge.	Site in proximity to historic placer mining activity, east of lod air strip. Area appears to be in historicly burned in early 90's.	Thick mor humus form with evidence of historic burn as seen thru charcoal within profile. Very gravelly Bm horizon.	C horizon contains high % gravel with mica flakes and limited soil present. High % of lichen cover observed on site. Site was a black spruce dominated stand on a northwest facing slope	Poorly developed soil horizons as a result of depostional characteristics and periodic flooding events. Island in middle of Yukon river, site is unlike any other within LSA, Poplar stand with rich shrub layer.	Large healthy stand of high quality white birch. Buried log at 36 cm with former Ah horizon below within the soil profile.

Comments					
	East of pure Bw stand wich grades into mixedwood type. Very large white spruce stems (~30 m height and Diam 57.8 cm). Ground Vegetation and soils similar to that of site 115.	Very shallow soils. High % coarse fragments.	Scrubby black spruce treed bog with large patches of birch.	Rocky/Bouldery scree slope grades into birch and willow shrub slope on south facing site. Shallow soils with poor drainage. Seepage present within soil profile.	Shrubby scree slope.

Appendix B Water Quality

1.0 SUMMARY

Proctor Gulch is a small alpine stream in the vicinity of the Casino Property in the southwest Yukon Territory. This creek intermittently flows underground and consequently passes through a fault zone. The gougy material within the fault zone contains iron sulphides which are oxidized by the water to form sulphuric acid. The water which re-emerges to the surface is highly acidic and loaded with metals.

Proctor Gulch confluences with Casino Creek, a larger alpine stream. Above the confluence of these two streams, Casino Creek has a near neutral pH and relatively low metal content. This study is designed to investigate the aerial extent and the nature of effects Proctor Gulch has on the aquatic and riparian environs of Casino Creek.

Six sampling sites were located along the Casino Creek watershed. The upper Casino Creek site above the outfall of Proctor Gulch site served as a control on the downstream portion of Casino Creek. The composition of the natural pollutant was established by a sample station on Proctor Gulch. Four sample sites between Proctor Gulch and the outfall of Casino Creek were used to delineate the aerial extent of the effects of Proctor Gulch.

Samples of water, stream sediment, algae and benthos were collected at all sites during 1993 and 1994. In 1992, soil samples were collected at regular intervals along the upper reaches of Casino Creek and Proctor Gulch. Species lists were compiled from vegetation plots on Upper Casino Creek, Proctor Gulch and three sites below Proctor Gulch. One of these plots were done in 1993 and the others in 1994.

Water quality appears heavily influenced by Proctor Gulch. Casino Creek shows loadings of copper and iron up to 7 km downstream of the Proctor Gulch confluence. The creek is strongly acidic 500 m below the outfall of Proctor Gulch. Algae and benthic invertebrates in Casino Creek may be influenced by Proctor Gulch. The variation in diversity and abundance between sampling sites may be the result of the natural acid rock drainage flowing into Casino Creek. Differences in habitat are likely to influence algae and benthos. Species composition in Proctor Gulch is much different than all sampling sites on Casino Creek. Both algae and benthos are dominated by one species. This is likely due to the constant and specific nature of the habitat.

Soil samples seem to indicate leaching of metals. Some soil metals appear less concentrated in Proctor Gulch than in Casino Creek. Due to a rapid rise in pH, metals may be deposited at the outfall of Proctor Gulch. Soil chemistry, as influenced by natural acid rock drainage, is likely to affect vegetation. Species composition is visibly different between Upper Casino Creek and Proctor Gulch. This may be due to the influence of Proctor Gulch. Factors such as gradient, elevation and aspect probably play an important role in determining species composition along Casino Creek.

2.0 INTRODUCTION

Casino Creek, which is located about 300 km north north-west of Whitehorse, Yukon Territory, originates on the south flanks of Patton Hill at elevation 1200 m and flows in a south westerly direction over a total length of 13 km where it eventually discharges to Dip Creek at elevation 700 m for a total fall of approximately 500 m. Dip Creek discharges to the Yukon River drainage via the White River and ultimately flows to the Bering Sea.

Casino Creek has a drainage area of approximately 83 km^2. Peak flows occur during summer when annual precipitation is at a maximum. Flows measured during the summer of 1993 were found to be 0.537 m^3/s. Low flows are expected to occur in mid-winter. A low flow of 0.397 m^3/s was measured in the late fall of 1993 before the onset of cold weather.

In the upper reach of Casino Creek, very near its origin, is a small tributary called Proctor Gulch which originates as groundwater recharge in the alpine areas of Patton Hill. It has an overall length of about 1.5 km and total drop of 300 m before discharging to Casino Creek.

Flows in Proctor Gulch, which are estimated to contribute about 0.006 m^3/s to the flows in Casino Creek, intermittently disappears underground. During one such occurrence, the water flowed through a geologic formation called the Casino Fault. The water re-emerging at the surface, some 25 m beyond its entry to the ground, underwent marked chemical changes. Somewhere in this 25 m interval, the pH of Proctor Gulch drops from around 6.4 to 3.5 and increases in metal content.

It is postulated that the drop in pH and increase in metal content is likely a result of its contact with oxidizable iron sulphides (pyrites) within the gougy material comprising the fault zone (Tom Becker, per. comm.). These sulphides, when in contact with water and oxygen or oxygenated water, oxidize to form sulphuric acid, which in turn solubilizes trace metals in the surrounding rocks and soils. As a result, the water in Proctor Gulch, re-emerges from the fault zone carrying the products of pyrite oxidation and is acidic and laden with metals.

As it travels the remaining 670 m to Casino Creek, the pH continues to decline. pH values as low as 3.02 have been measured near the mouth of Proctor Gulch immediately upstream of its confluence with Casino Creek.

There are three possible causes for this declining gradient in pH:

- exposure to atmospheric oxygen
- residual biological activity
- evaporation

As Proctor Gulch re-emerges from the fault zone, it is exposed to turbulence and mixed with atmospheric oxygen, in which case dissolved oxygen levels in the water would be expected to increase. This creates an increase in the oxidation of ferrous iron which then reacts with water to form ferric hydroxide and hydrogen ions. The result would be a decrease in pH.

The presence of *Thiobacillus ferrooxidans* a bacteria associated with pyrite oxidation may also cause a decrease in pH. The rate at which this bacteria can oxidize ferrous ions is dependent on temperature (Knapp, 1987). A profile of Proctor Gulch does show temperature increase with distance downstream as it approaches Casino Creek. If the pH is dependant on these bacteria, the increasing temperature may lead to the observed pH decrease.

The third possibility is evaporation of creek water leading to the concentration of H^+ ions.

Whatever the causes for the state of Proctor Gulch, the end result is a naturally occurring point source of metal and acid pollution for Casino Creek. Due to its location (near the origin of the creek) this point source has the potential to affect nearly the entire length of the Casino Creek and the waterways beyond.

The purpose of this investigation is two fold:

- delineate the downstream aerial extent of effects of Proctor Gulch on Casino Creek, and
- characterize the nature of the effects on aquatic and riparian environs including water quality, stream sediments, periphytic algae, benthos, soils and vegetation,.

3.0 WATER QUALITY

3.1 Methods

In order to determine the effects of acid rock drainage on Casino Creek, water quality samples were collected from the six sampling locations by J. Himmelright (CC1, CC2, CC3, CC4) and Casino Property personnel (W4, W8). Site CC3 represents Upper Casino Creek, just above the outfall of Proctor Gulch. Data collected from this site were used as a control or an indication of the water quality before being influenced by the acidic stream. Water quality samples from Proctor Gulch were also analyzed (CC4). This allowed interpretation as to which parameters within Casino Creek were being strongly influenced by the gulch. Four separate sampling sites, spread over the remaining length of Casino Creek (W8, CC2, CC1, W4), indicated the influence of Proctor Gulch with distance downstream.

Each sample set consists of five bottles: general analysis (1000 ml), cyanide (1000 ml), mercury (500 ml), dissolved metals (250 ml) and total metals (250 ml). The dissolved metals samples are filtered at the time of collection using disposable 60 cc syringes and 45 μ (micron) millipore filters. Samples are sent to Analytical Services Laboratories Ltd. of Vancouver for analyses. An complete list of the test parameters and their detection limits are presented in Table 1. Water quality samples were collected during July and August of 1994.

3.2 Results

The results of water quality sampling are presented in Table 9. Table 10 contains guidelines set by both CCME and MMLER. These guidelines provide standards for drinking water, liquid mine effluent and safety of aquatic life. Those water quality parameters exceeding CCME (Canadian Council of Ministers of the Environment) guidelines for aquatic life included pH, total cyanide, total aluminium, total cadmium, total copper, total iron, and total zinc. Drinking water guidelines for total dissolved solids, pH, sulphate, total copper, total iron and total manganese were exceeded. At a few locations, pH and total copper parameters exceeded MMLER (Metal Mining Liquid Effluent Regulations) guidelines for mine effluent.

At all sampling sites, at least one parameter exceeded the guidelines for aquatic life. With a pH of 3.5 - 3.02, Proctor Gulch exceeds CCME guidelines for aquatic life. Water is still too acidic at W8 (pH = 4.25) to be considered safe for aquatic organisms. The amounts of total cyanide found at CC2 (0.007 mg/l), CC1 (0.009 mg/l) and W4 (0.006 mg/l) were in exceedence of the CCME limit (0.005 mg/l). CCME recommends a maximum of 0.1 mg/l aluminium. CC3 (0.305 mg/l), CC4 (12.7 mg/l), W8 (4.31 mg/l), CC2 (0.618 mg/l) and CC1 (0.748 mg/l) are all above this concentration. Cadmium values exceed guideline limits (0.0002 mg/l) only in Proctor Gulch where total cadmium was sampled at 0.0033 mg/l. Although it may appear that CC3 and W8 also exceeded this value, high water hardness at these sites will mitigate the toxicity of

cadmium. Copper is one of the most abundant metals found in this watershed. Concentrations of copper in Casino Creek are shown in Table 9. All values are above the CCME guideline of 0.002 mg/l. Iron concentrations is also above these guidelines in all cases except W4 (refer to Table 9 and Table 10). With a zinc concentration of 0.034 mg/l, Upper Casino Creek is above the CCME guideline of 0.03 mg/l. The same is true of CC4 (0.293 mg/l) and W8 (0.115 mg/l).

Upper Casino Creek Gulch exceeds drinking water guidelines for total manganese (0.187 mg/l) and total iron (0.827 mg/l). Water from Proctor Gulch is not fit for human consumption. A comparison of values presented in Table 9 and Table 10 shows many examples of guideline exceedence.

Water quality at W8 is somewhat better than at Proctor Gulch. The only concentrations of concern are total iron (7.58 mg/l) and total manganese (0.571 mg/l). The pH at this site was 4.25, which is below CCME guidelines. Farther down Casino Creek, at CC2, the iron content (0.692 mg/l) is still above the guideline. At CC1, total manganese (.054 mg/l) is above suggested concentration. With a value of 0.718 mg/l , iron is considered a problem at this point in the creek. At W4, near the Casino/Dip Creek confluence, all measured water quality parameters are safe for drinking.

Water quality at two sample sites exceeded even the MMLER regulations for mine effluent. Proctor Gulch pH and copper values (3.02, 1.39 mg/l) are beyond those acceptable for mine effluent (6.0 and 0.3 mg/l respectively). Site W8, just downstream of the Proctor Gulch outfall, has the same problem. Copper is measured as 0.465 mg/l and the pH is 4.25.

3.3 Discussion

Water quality in Casino Creek above the outfall of Proctor Gulch is less than good. Copper, iron, aluminium, zinc and manganese are all found in relatively high concentrations. Although pH values are neutral (7.22 in collected sample), this creek is high in metals. This may be a function of the creek's underlying lithology. The acid rock drainage flowing from Proctor Gulch is toxic; high levels of metals and hydrogen ions make it unsafe for drinking or most aquatic life.

As Proctor Gulch empties into Casino Creek, it increases metals concentrations already present in the creek and decreases pH. The result is water that is too poor to drink or support most aquatic life. In the area immediately downstream of the outfall water quality exceeds guidelines for mine effluent.

At least 500 m of Casino Creek are heavily influenced by Proctor Gulch. The water this far downstream shows large increases in those metals found in the gulch. The influence of Proctor Gulch at CC2, 5 km below the confluence, seems to be diluted. Metals concentrations

approximate values found in Upper Casino Creek. If the metals in Upper Casino Creek are the result of its underlying lithology, a dilution ratio of 1:16 between Upper Casino and Casino Creek at CC2 should have reduced those concentrations. Poor water quality at this point in the creek may be due to Proctor Gulch. Cyanide concentrations at CC2 (and all other sample sites downstream) exceed those recommended for aquatic life.

Farther downstream, at CC1, metals concentrations are not much different than CC2. Since the dilution ratio between CC2 and CC1 is 1:1.5 there is less chance for dilution between these two points which may explain the stabilized values. At the outfall of Casino Creek, water quality seems good. Due to the influx of Bryanelsen Creek, dilution between here and Proctor Gulch is 89:1; concentrations resulting from the gulch would likely not be detected.

Although Casino Creek at W4 is "clean" , this does not mean that the problem of metals contamination has been solved. It is unlikely that concentrations originating in Proctor Gulch have simply been diluted to safe levels. A gradual decrease in the dissolved metals concentration (see graphs in Appendix B) seems to indicate partitioning processes within the Casino Creek. Increases in sediment metal levels at more downstream sites (Table 11) also indicate transitions in the phase of Casino Creek metals. Since partitioning may affect bioavailability and hence the toxicity of these metals, it may be important to realize both proportions and total amounts of partitioned states. Chapman *et al.* (1983) have shown concretion to be an important process for metal removal in streams polluted by acid mine drainage. Precipitation may also help to remove metals from solution (Boult *et al.* 1994). Those portions adsorbed to suspended material and remaining in solution will also play a role in the overall toxicity of the aquatic environment.

Also contributing to overall toxicity is temporal variation in concentrations. Daily "pulses" of copper at near lethal concentrations have been shown to affect survival of rainbow trout and *Daphnia pulex*, even though average concentrations were below the "no effect" limit (U.S. EPA, 1985). The water quality presented in this report represents summer low flows. Higher discharges may resuspend sediments (Boult *et al.* 1994) which would carry metals farther downstream.

4.0 ALGAE & BENTHOS

4.1 Methods

Periphyton samples were collected in concurrence with the benthic sampling at all sampling stations. Samples were normalized by sampling areas with similar depth and velocity. Algae samples were removed from representative natural substrate (cobbles) at each site using a Stockner toothbrush sampler. In 1993, twelve replicate samples were taken at W4 and W8. Six samples were preserved with Lugol's iodine solution and sent to Munro Environmental Consulting, Vancouver, for identification of dominant and subordinate species. Six samples were filtered through a 0.45 μ cellulose acetate filter, buffered with MgCO3 and sent to ASL Laboratories for chlorophyll "a" (ug/cm^2) analysis. Susan Blundell (Hallam Knight Piesold, Project Biologist) collected all samples completed in 1993. Six samples were collected from CC1, CC2, CC3 and CC4 in 1994. These samples were preserved with formalin/Rose Bengal solution and also sent to Munro Environmental Consulting for similar analysis as 1993 samples. In 1994, productivity was measured by analysis of chlorophyll "a" content in 1 litre of water. These samples were filtered through a 0.45 μ cellulose acetate filter, frozen and sent to ASL Laboratories for chlorophyll "a" analysis. J. Himmelright collected all 1994 samples.

Aquatic macroinvertebrate samples for W4 and W8 were collected in late August 1993. Three replicate samples were taken at each site. These samples were taken using a modified Hess sampler (measuring 17" high, 14" in diameter, and having a 250 μ mesh) to a depth of 10 cm. A Surber (0.25 m^2 ,250 μ mesh) sampler was used to collect samples of benthic invertebrates at CC1, CC2, CC3 and CC4. These samples were collected in early August of 1994. Samples were standardized by sampling in riffle areas with similar depth, velocity and substrate types. Samples were stained and preserved with a buffered formalin/Rose Bengal solution and sent to Dr. Charles Low, Victoria, for taxonomic analysis and enumeration. Indices for community dominance, diversity, equatability and richness were applied to the results of these samples.

4.2 Results

Periphyton samples at CC3 (Table 12) contained very little sediment, either fine grit or soft detritus with a small amount of algae mixed in. A colonial chrysophyte, identified as *Hydrurus foetidus*, made up 90 to 100% of the algae. This is a common species in cool streams. Chlorophyll "a" samples from this site showed $<$ 0.04 *u*g/l).

Six benthic samples from this same site collected 151 individuals representing 26 taxa (Table 13). Five percent of collected specimens are considered sensitive, 66% are facultative and 29% are classed as tolerant. The Shannon - Weiner Diversity Index produced a value of 3.27 for this site. The equitability index, which measures the evenness with which individuals are distributed among

sampled taxa, was calculated at 0.69. Richness, a relationship between sample size and number of taxa sampled, was measured at 4.98. Relative abundance of sampled taxa, as measured by the Dominance index, showed a value of 0.17 (maximum value of 1.0 when only one taxa is sampled). A more complete explanation of these indices can be found in Hallam Knight Piésold (1993).

Proctor Gulch, as represented by sample site CC4 (Table 14), showed the highest abundance of algae for all sites sampled. The predominant species in most samples (60 - 100%) was *Microthamnion*, a filamentous green algae. Other species present included *Hydrurus foetidus* (15 - 80% in four samples) and the diatom *Eunotia* (10 - 65% in three samples). Chlorophyll "a" samples produced an average value of 0.05 *u*g/l, indicating that this site has the highest productivity of all sample sites.

Of the 1,182 invertebrates collected from Proctor Gulch, 99.8% are facultative (Table 15), and 0.2% of individuals are tolerant. There are no sensitive species in any of the samples. With only 16 taxa sampled, diversity is low (0.51). Ninety-four percent of all sampled individuals belong to one taxa, producing a very high dominance index value (0.89). Equitability and richness indices were low (0.1 and 1.98 respectively).

Site W8 samples contained small amounts of sediment composed mainly of soft detritus and bacteria. No algae were present in any of the samples. Chlorophyll "a" values were low with an average of 0.024 $u g/cm^2$.

Only 28 individuals representing 12 taxa were collected at W8 (Table 16). Eighty-two percent are facultative. Tolerant taxa make up the remaining 18% Due to the low number of taxa sampled and low diversity value (0.016), the equitability index is also low (0.004). Dominance is low (0.14), indicating fairly equatable numbers of individuals for each taxon sampled. The low numbers of taxa and individuals contribute to a richness measurement of 3.3.

Periphyton samples taken at CC2 (Table 17) contained very little algae. *Achnanthes sp.* and *Synedra rumpens* are the two species of diatoms which comprised 25 - 100% of the samples. *Phormidium sp.*, a filamentous blue-green, made up 75% of two samples. Chlorophyll "a" samples indicate low productivity, averaging < 0.05 *u*g/l.

Six samples of benthic invertebrates contained 362 individuals from 25 different taxa (Table 18). Tolerance classification returned the following results: 33% sensitive, 51% facultative, and 16% tolerant. Diversity, richness and equitability were relatively high (3.27, 4.07 and 0.70 respectively). The dominance index was low (0.15).

Stockner samples from CC1 also contained very little algae (Table 19). Diatoms, dominated by *Achnanthes sp.*, *Synedra rumpens* and *Diatoma anceps*, comprised 90 - 100% of the samples.

Small amounts of green or blue-green algae were also present. Chlorophyll "a" samples showed < 0.043 ug/l, indicating low productivity.

In six Surber samples collected at CC1 there were 871 invertebrates from 35 taxa (Table 20). Eighty-two percent of the taxa were facultative, 12% tolerant and 6% sensitive. The richness index for these samples is 5.02. Diversity and equatability were calculated to be 3.03 and 0.6 respectively. The dominance value was 0.25.

Samples of algae collected at W4 were comprised of 93 - 98% diatoms (Table 21). Small amounts of blue-green and red algae were also present. Chlorophyll "a" was sampled at 0.131 ug/cm^2 for this site.

A total of 1292 benthic invertebrates were collected from this site (Table 22). Fifty-four different taxa were present. Thirty-five percent of the individuals were sensitive, 46% facultative and 19% tolerant. Diversity, equatability, and richness are all high (4.34, 0.75 and 7.4 respectively). The index for dominance gave a low result of 0.078.

4.3 Discussion

Above the outfall of Proctor Gulch, the aquatic fauna of Casino Creek appear quite healthy. This section of the waterway supports at least one species of alga and 26 species of benthic invertebrates. The alga found here (*Hydrurus foetidus*) is typical of cool streams. Of the 26 taxa of invertebrates found here, seven are considered sensitive. The diversity index used in analysis ranks this site third out of the six sample sites. An equitability value of 0.69 indicates an even distribution of individuals/taxa. The low productivity of this location is probably a function of its high altitude (1100 m) and low flow (0.0107 m^3/s).

Proctor Gulch is a very simple, yet interesting, system. Dominated by one type of algae and one species of invertebrate, this creek has a higher productivity than others of comparable size and location (Upper Casino Creek for example). This is likely due to the extreme, stable environment provided by the creek waters. Such an environment will prevent colonization by most life forms, leaving those who can tolerate it to thrive in the absence of competition. In Proctor Gulch, the predominant algae is *Microthamnion*, a type of filamentous green. This green algae belongs to the same family (Chaetophoraceae) as *Stigeoclonium*; an alga that can tolerate high levels of metal (McLean, 1974). As for the invertebrates, 94% of all sampled individuals were of the genus *Eukiefferiella*. This genus belongs to the sub-family Orthocladiinae, a type of grazing chironomid. Many chironomids living in acidic streams and lakes (Hermann, 1990; Wickham *et al.* 1986). With the ample supply of forage provided by the algae in this stream, large numbers thrive in Proctor Gulch.

The presence of algae within Proctor Gulch does raise some possibilities. Ramelow *et al.* (1986) found periphyton to contain higher concentrations of metals than the surrounding sediments. This would indicate that periphyton, such as *Microthamnion*, may provide a sink for metals resulting from ARD. They could also be used as indicator species for potential acid mine drainage.

Site W8 contains no algae. This may be due to adverse, variable conditions such as pH which varies from 3.86 to 4.62. The lack of forage and fluctuating pH may contribute to the lack of invertebrates here. Some invertebrate species have been shown to increase drift intensity when faced with a drop in pH (Radum & Fjellhiem, 1987).

Data collected at site CC2 (in comparison to Upper Casino Creek CC3) seems to indicate recovery of the aquatic fauna. Primary production, as indicated by chlorophyll "a" samples, is higher here than at CC3. Though they are not the same species as in Upper Casino Creek, there are algae growing here. Invertebrate populations appear to have also recovered. Index values calculated for this community approximate those for CC3 samples. There does appear to be a higher density of organisms at this lower site (362 individuals collected versus 151 for CC3).

There is some change at CC1, approximately 2 km downstream of CC2. Chlorophyll "a" samples indicate a slight reduction in primary productivity. Many of the same species of algae are found at CC1 and CC2 although in different amounts. A comparison of index calculations for benthic organisms do show slight variation. This is probably due to two factors; dominance of one taxa (*Synorthocladius sp.*) and the larger number of taxa found at the more downstream site. Density has also increased from CC2 to CC1, with 871 organisms collected (more than twice that sampled at CC2). As compared to CC3, this is a 580% increase in density. This is probably due to a 375 m drop in elevation between these two sampling points.

At the most downstream site (W4), primary production is much higher than immediately below the outfall of Proctor Gulch. Comparisons to other locations within the stream are difficult due to differences in sampling techniques. Algae here at W4 seem a little more abundant as compared to more upstream sites. There are large differences in the benthic communities between this station and upstream locations. There is a much higher density and a significant increase in the number of taxa found. Index calculations show increases in diversity, equatability, and richness of the benthic community this far downstream. This may be due to the influx of Bryanelsen Creek which confluences with Casino Creek between sites CC1 and W4. At this confluence, Bryanelsen is almost as large as Casino and nearly doubles the flow. The marked decrease of metal in stream sediments at W4 (Table 10) may also contribute to the success of the benthic community.

5.0 SOILS & VEGETATION

5.1 Methods

In order to investigate the possible effects of Proctor Gulch on the soils of Casino Creek, soil sample data (collected in 1992 by Archer Cathro and Assoc. Ltd) are pooled into one of three categories:

Proctor Gulch
Upper Casino Creek (above Proctor Gulch confluence)
Lower Casino Creek (below Proctor Gulch confluence)

For each data set, an average, standard deviation, maximum and minimum are reported (Tables 1-3).

It is difficult to draw direct conclusions as each data pool represents a different sampling density. However, trends can be recognized and possible causes and effects suggested.

Vegetation and soils are intimately linked and so are analyzed together. In the analysis of soil data, particular attention is paid to those elements which are important to plant life. A list of plant species was compiled for each soil region. Data for these lists were collected by visual inspection of a selected site within each area. There were 5 vegetation sites, three of which were in Lower Casino Creek:

CC1 (7 km downstream of Casino Creek-Proctor Gulch confluence)
CC2 (5 km downstream of Casino Creek-Proctor Gulch confluence)
Site #7 (represents Casino Creek-Proctor Gulch confluence, completed in 1993 by S. Blundell, HKP).

These sites are spread between the Proctor Gulch outfall and the confluence of Casino Creek with Dip Creek.

5.2 Results

Proctor Gulch:

At the site selected for vegetation description of Proctor Gulch, 13 plant species were identified (Table 1). Most of the plants were indicators of a poorly drained, acidic site. Only one species , birch - leaved spirea, has a broad ecological tolerance (inhabiting moist and dry sites).

The results of soil sampling are presented in Table 2. These results represent 26 samples covering 1.4 km of creek length.

Upper Casino Creek:

Seventeen plant species were identified at Upper Casino Creek (Table 3). Again , most of the plants were indicators of a wet, acidic environment. A few species (bog blueberry, prickly rose, cinquefoil and fireweed) point to a rocky or gravel substrate.

Soil sample results are presented in Table 4. These results were drawn from 17 samples covering 1.8 km of creek length.

Lower Casino Creek:

At the vegetation site immediately below the Proctor Gulch/Casino Creek confluence (Table 5) 22 species of plants were identified. Again, most species are indicators of a poorly drained site. (MacKinnon et. al., 1992).

At site CC2, 5 km downstream of Proctor Gulch, 13 species of plants were identified (Table 6). Indications are of a sub-alpine, poorly drained site. This site appears to have more willow (*Salix sp.*) than previous sites both in terms of species present and total cover.

Vegetation plot CC1 (Table 7) contained fourteen species, all indicating a wet site. Stunted black spruce (*Picea mariana*) indicate permafrost. This site is 7 km downstream of Proctor Gulch.

Soil sample results are shown on Table 8. These numbers were calculated from the results of 69 samples taken between Proctor Gulch and Meloy Creek, totalling 5.6 km of creek length.

5.3 Discussion

The three nutrients required in large amounts by plants are phosphorous, nitrogen and potassium. Since soils collected on the Casino property were not analyzed for nitrogen, no information as to its abundance and distribution is available. Potassium values are relatively constant. Phosphorous values peak in a gossan in Proctor Gulch; values elsewhere are low and constant (refer to graphs in Appendix A).

Those nutrients required in trace amounts (micronutrients) are more dynamic in their distribution, possibly a consequence of leaching from Proctor Gulch. A good example is aluminium. Within the gulch itself, aluminium in soil is low ($1.76 \pm 0.62\%$). In Upper Casino Creek, values are somewhat higher ($2.53 \pm 0.70\%$). Aluminium peaks immediately downstream of Proctor Gulch

and then returns to lower values farther down the creek (see graphs in Appendix A). This pattern could be due to the leaching of aluminium from the soils of Proctor Gulch followed by deposition as the pH climbs back to near neutral levels in Casino Creek. If this is the case, water quality data should show high levels of aluminium within Proctor Gulch itself which decrease with distance from the confluence of the two creeks. This trend is seen in the water quality data (see graphs in Appendix B).

The same pattern occurs with cobalt and magnesium. Concentrations are high in samples taken near the bottom of Proctor Gulch but drop rapidly downstream.

Copper and molybdenum show a different pattern. Relatively high values appear in Upper Casino Creek and the gossan zone of Proctor Gulch (likely associated with the lithology), dropping to lower, more constant values in Lower Casino Creek (refer to graphs in Appendix A). Proctor Gulch does not appear to be significantly affecting the soil distribution of these elements.

Calcium values are variable along Casino Creek (graph, Appendix A). In general, there seems to be a steady increase from high to low elevation. Proctor Gulch itself has low calcium levels (probably a result of years of leaching) but it is difficult to say whether or not soil calcium is affected downstream of the confluence. There is no "deposition peak" as with cobalt or magnesium; calcium levels appear to rise continuously from the source to the outfall of Casino Creek. Although soil calcium is definitely being affected within Proctor Gulch, outside the gulch it appears more uninfluenced.

Soil zinc levels seem strongly influenced by the acid drainage coming out of Proctor Gulch. A sharp increase in zinc levels immediately downstream of Proctor Gulch indicates deposition, likely triggered by the rise in pH. If this zinc loading is the result of leaching by acidic water, water quality data should show high concentrations of zinc in Proctor Gulch which decrease downstream. The graph in Appendix B shows this trend.

Manganese, iron, and sodium distributions do not appear to be affected by Proctor Gulch. A Gossan zone within the gulch is high in iron and low in sodium. Otherwise, sampled areas contain relatively constant amounts of these two elements. Manganese is low in Proctor Gulch (refer to graphs in Appendix A). However Proctor Gulch values are relatively constant. The apparent lack of a deposition peak for these three elements may to due to a more gradual deposition rate or higher solubility. Random variation in soil sample values may then mask any noticeable effect.

There were no soil data for nitrogen, silicon, sulphur, boron and chlorine, therefore, the distribution of these elements cannot be discussed adequately. Also not available was soil texture data. Since soil texture may be as important as soil chemistry in determining plant distribution, it is impossible to conclude that differences in vegetation are solely the result of the acid rock drainage from Proctor Gulch.

The acidic stream is likely to affect plant life in some way. Species composition is visibly different between Upper Casino Creek (Table 3) and Proctor Gulch (Table 1). In Proctor Gulch, there is an increase in the abundance of Wild Rhubarb (*Polygonum alaskanum*) and Scrub Birch (*Betula glandulosa*). The amount of willow (*Salix* sp.) is noticeably less. Since the two sample sites are less than 100 m apart, variability in environmental parameters such as elevation and gradient is minimal. The acid rock drainage is suspected to affect soil chemistry. Soil texture, combined with a slight variation in aspect, may also contribute to the difference in vegetation.

It cannot be definitely concluded that Proctor Gulch is affecting plant nutrient distribution. All soil data does show randomness. Trends, interpreted here as the effect of Proctor Gulch, may actually be random. There is also the question of sample collection. There is no way of knowing whether or not soil was collected from stream sediments, creek banks or some distance from the creek. Obviously, samples at a distance from the creek are less likely to be influenced by the creek itself.

The apparent increase in diversity between Upper Casino (CC3) and the first Lower Casino site (Site 7) is a function of sampling technique. Vegetation surveys in 1993 (Site 7) were much more detailed than in 1994. Soil chemistry at Site 7 may be affected by Proctor Gulch; this site is near the deposition zone created by the acid stream. There is a minor variation in elevation (25 m from CC3 to Site 7) but gradient and aspect are relatively constant. Variation in vegetation is not so visibly obvious as in the comparison of CC4 and CC3.

It is more difficult to compare the Lower Casino vegetation sample sites. The large distances between these three sites (7 km between all three) and a 450 m drop in elevation probably have greater effect on the vegetation than acid drainage from Proctor Gulch. There is little visible difference between these sites.

In conclusion, the acidic waters of Proctor Gulch may be affecting vegetation along the gulch itself. Visibly different plant distribution, combined with soil chemistry data, provide some evidence for this. It is more difficult to conclude that acid rock drainage is affecting the plants along Casino Creek. The deposition of nutrients immediately downstream of the confluence may be having some effect on plant life. In addition, metal loadings to soils may influence soil invertebrate survival which would in turn affect vegetation. Other factors such as elevation, gradient and aspect are probably more important in determining the characteristics of the vegetation near Casino Creek.

6.0 CONCLUSION

Proctor Gulch appears to affect Casino Creek in several different ways. It is possible that soils and vegetation may be influenced by the acidic stream. A comparison of plant life on Upper Casino Creek and Proctor Gulch would seem to indicate that this is the case. For the more downstream sites, it is difficult to interpret differences in vegetation being due to acid rock drainage. Elevation, gradient and aspect are probably more important influences on the distribution of vegetation along Casino Creek. The influence of Proctor Gulch on the water quality of Casino is much more obvious. As far as 7 km downstream of the outfall, loadings of copper and iron, which may be due to Proctor Gulch, can still be found. Metal loadings to sediments are probably also due the metal-rich waters of Proctor Gulch. The influx of Bryanelsen Creek is probably the dilution factor responsible for reducing these concentrations to the "safe" levels found at the mouth of Casino Creek. Aquatic fauna also appear influenced by Proctor Gulch although the effects are not as easily defined as those for water. The sharp increase in abundance and diversity found at the outfall of Casino Creek (as compared to CC1, 6 km upstream) is likely due in part to the extra aquatic habitat provided by Bryanelsen Creek. By further diluting Casino Creek, Bryanelsen also serves to change water and sediment quality. Significant effects on algae and invertebrates cannot be demonstrated. For the upstream sites, the results are ambiguous. Diversity returns to pre-acid values; abundance does increase with a decrease in elevation, with the exception of the sample site immediately downstream of Proctor Gulch. The lack of benthos and algae here may be due to acid rock drainage. However, this cannot be concluded without further investigation.

ACKNOWLEDGEMENTS

This work was funded by Pacific Sentinel Gold Corporation and Hallam Knight Piésold Ltd. I thank the staff of both organizations for their support. I recognise the help of Don Karasiuk, Jenifer Hill and Bob Hallam. I thank them for the editing suggestions and assistance in publishing.

TABLE 5
CASINO PROJECT
LOWER CASINO CREEK VEGETATION, SITE #7

Gradient: 15°

Altitude: 914 m (3000 ft)

Observations:

Transect situated below Casino Creek/Proctor Gulch confluence. Proctor Gulch has a low pH, ranging from 3.2 to 4.5, sediments are orange indicating a high iron (and other metals) content. Most of the Black spruce trees were stunted (may be due to permafrost).

Species present:

Black spruce (*Picea mariana*)
Scrub birch
Sweet coltsfoot
Labrador tea (*Ledum groenlandicum*)
Northern Labrador Tea (*Ledum palustre*)
Tall Lungwort (*Mertensia paniculata*)
Bog blueberry (*Vaccinium uliginosum*)
Sphagnum moss
Rock worm lichen
Tufted wheat grass
Many bladed, short, bending grass
triangular stem with three inflourescenses (Sedge sp.)
Labrador lousewort (*Pedicularis labradorica*)
Mountain heliotrope (*Valeriana capitata*)
Pink mountain-heather (*Phyllodoce empetriformis*)
moonshine lichen
waxpaper lichen
old man's beard
Reindeer lichen
Freckled lichen (*Peltigera aphthosa*)
Pixie cup lichen
Cloudberry

Most common:

Scrub birch 20%
Black spruce 10%
Labrador tea 15%
Northern Labrador Tea 5%
Vaccinium sp. 7%
Sphagnum moss 35%
Mertensia 5%
Bent grass 5%
Pink mountain-heather 5%
Reindeer lichen 5%
Cloudberry 3%

This report has been prepared by Nautilus Environmental Company Inc. based on data and/or samples provided by our client and the results of this study are for their sole benefit. Any reliance on the data by a third party is at the sole and exclusive risk of that party. The results presented here relate only to the samples tested.

1.0 INTRODUCTION

Nautilus Environmental conducted freshwater sediment toxicity tests for Palmer Environmental Consulting Group on a sample identified as W18. The sample was collected on July 28, 2014 and delivered to the laboratory in Burnaby, BC on July 30, 2014. The sample was transported in two 4-L plastic pails and was received at a temperature of 7.5°C. The sample was stored in the dark at 4 ± 2°C prior to testing.

A 28-d *Hyalella azteca* and a 10-d *Chironomus dilutus* survival and growth test was conducted on the sample. This report describes the results of these toxicity tests. Copies of laboratory data sheets and printouts of statistical analyses for the tests are provided in Appendices A and B. The chain-of-custody form is provided in Appendix C.

2.0 METHODS

Methods for the toxicity tests are summarized in Tables 1 and 2. Testing of the survival and growth of *H. azteca* followed procedures described in USEPA (2000) including modifications that have recently been proposed by the *Hyalella azteca* Advisory Group, which is coordinated by Chris Ingersoll of USGS. Testing of survival and growth of *C. dilutus* was performed according to procedures described by Environment Canada (1997).

Statistical analyses were performed using CETIS (Tidepool Scientific Software, 2013). Ammonia levels were monitored at the start and end of the test. The ammonia concentrations in the overlying water of the samples and control were measured by ALS Environmental, Burnaby and are provided in Appendices A and B.

Table 1. Summary of test conditions: *Hyalella azteca* survival and growth test.

Test organism	*Hyalella azteca*
Test organism source	Aquatic BioSystems, Fort Collins, CO
Test organism age	7 – 8 days old
Test type	Static-renewal
Test duration	28 days
Test vessel	375 mL glass container
Test volume	100 mL sediment; 175 mL overlying water
Test replicates	5 laboratory replicates per sample
Number of organisms	10 per replicate
Control water	Moderately-hard synthetic water prepared by addition of salts to dechlorinated municipal water. Containing ~28 mg/L Cl and supplemented with 0.02 mg/L Br.
Test solution renewal	Overlying water replaced twice per day
Test temperature	23 ± 1°C
Feeding	1 mL of YCT daily to each container. Tetramin daily, with amounts increasing weekly: Week 1: 0.5 mg, Week 2: 0.75 mg, Week 3: 1 mg, Week 4: 1.5 mg in each test container.
Light intensity	500 to 1000 lux at water surface
Photoperiod	16 hours light/8 hours dark
Aeration	Gentle aeration throughout test
Test protocol	Modified from USEPA (2000)
Statistical software	CETIS (2013)
Test endpoint	Survival and dry weight
Test acceptability criteria for controls	Mean control survival of ≥80% survival
Reference toxicant	Sodium chloride

Table 2. Summary of test conditions: *Chironomus dilutus* survival and growth test.

Test organism	*Chironomus dilutus*
Test organism source	Aquatic BioSystems, Fort Collins, CO
Test organism age	3rd Instar
Test type	Static
Test duration	10 days
Test vessel	375-mL glass containers
Test volume	100 mL sediment; 175 mL overlying water
Test replicates	5 laboratory replicates per treatment
No. of organisms	10 per replicate
Control water	Moderately-hard synthetic water prepared by addition of salts to dechlorinated municipal water
Test solution renewal	None
Test temperature	23 ± 1°C
Feeding	6.0 mg Tetramin in 1.5 mL suspension per replicate daily
Light intensity	500 – 1000 lux at water surface
Photoperiod	16 hours light/8 hours dark
Aeration	Gentle aeration thoughout test
Test protocol	Environment Canada (1997), EPS 1/RM/32
Statistical software	CETIS (2013)
Test endpoint	Survival and dry weight
Test acceptability criteria for controls	Mean control survival ≥70% survival and ≥0.6 mg/worm dry weight
Reference toxicant	Potassium chloride

3.0 RESULTS

There were no effects on survival or dry weight of either *H. azteca* or *C. dilutus* (Tables 3 and 4). Measured ammonia concentrations in the overlying water are summarized in Tables 5 and 6.

Table 3. Results: *Hyalella azteca* survival and growth test.

Sample ID	Mean ± SD	
	Survival (%)	Dry Weight (mg)
Control Sediment	94.0 ± 5.5	0.43 ± 0.11
W18	92.0 ± 8.4	0.37 ± 0.19

SD = Standard Deviation.

Table 4. Results: *Chironomus dilutus* survival and growth test.

Sample ID	Mean ± SD	
	Survival (%)	Dry Weight (mg)
Control Sediment	92.0 ± 13.0	2.04 ± 0.26
W18	88.0 ± 11.0	2.04 ± 0.16

SD = Standard Deviation.

Table 5. Ammonia concentrations in the 28-d *H. azteca* sediment toxicity test.

Sample ID	Ammonia (mg/L N)	
	Day 0	Day 28
Control Sediment	<0.005	0.202
W18	<0.005	0.0557

Table 6. Ammonia concentrations in the 10-d *C. dilutus* sediment toxicity test.

Sample ID	Total Ammonia (mg/L N)	
	Day 0	Day 10
Control Sediment	0.0150	3.00
W18	<0.005	1.30

4.0 QA/QC

The health histories of the test organisms used in the exposures were acceptable and met the requirements of the test protocols. The tests met control acceptability criteria and water quality parameters remained within ranges specified in the protocols throughout the tests. Uncertainty associated with these tests is best described by the standard deviation around the mean.

Results of the reference toxicant tests conducted during the testing program are summarized in Table 7. The results of the tests fell within the acceptable range for organism performance of mean and two standard deviation based on previous results obtained by the laboratory with these tests. Thus, the sensitivity of the organisms used in the tests was considered to be appropriate.

Table 7. Reference toxicant results.

Test Species	Endpoint	Historical Mean (2 SD Range)	CV (%)	Test Date
H. azteca	Survival (LC50): 5.3 g/L NaCl	4.4 (3.0 – 6.7)	22	September 5, 2014
C. dilutus	Survival (LC50): 4.0 g/L KCl	6.0 (3.9 – 9.2)	24	August 15, 2014

SD = Standard Deviation, LC = Lethal Concentration, CV = Coefficient of Variation.

APPENDIX B – *Chironomus dilutus* Toxicity Test Data

Chironomus dilutus Sediment Test Summary Sheet

Client: PECG
Work Order No.: 14594

Start Date: 15-Aug-14
Set up by: KJL/JW

Sample Information:

Sample ID: W18
Sample Date: 28-Jul-14
Date Received: 30-Jul-14
Sample Volume: 2x 4L

Test Organism Information:

Species: *C. dilutus*
Supplier: Aquatic Biosystems, CO
Date received: 14-Aug-14
Age or size (Day 0): 3rd instar

KCl Reference Toxicant Results:

Reference Toxicant ID: CT32
Stock Solution ID: n/a
Date Initiated: 15-Aug-14

96-h LC50 (95% CL): 4.0 (3.1 - 5.4)

96-h LC50 Reference Toxicant Mean and Range: 6.0 (3.9 - 9.2) CV (%): 24

Test Results:

Sample ID	Survival ± SD (%)	Average Dry Wt. ± SD (mg)

1.0 INTRODUCTION

Nautilus Environmental conducted sub-lethal toxicity tests for Palmer Environmental Consulting Group (Palmer) on a sample identified as W18-1 supplemented with a number of constituents of interest to achieve two mixtures (Mixture 1 and Mixture 2) specified by Palmer. The sample was collected on September 30, 2014 and delivered to the laboratory in Burnaby, BC on October 2, 2014. The sample was transported in two 20-L plastic containers and was received at a temperature of approximately 3.0°C. The sample was stored in the dark at 4 ± 2°C prior to testing. The following sub-lethal toxicity tests were conducted on the sample:

- *Ceriodaphnia dubia* survival and reproduction
- 72-h algal (*Pseudokirchneriella subcapitata*) growth inhibition

This report describes the results of these toxicity tests. Copies of laboratory data sheets and printouts of statistical analyses for each test are provided in Appendices A and B. Analytical results are provided in Appendix C and the chain-of-custody form is provided in Appendix D.

2.0 METHODS

Mixture 2, referred to here as the 100% test concentration, was prepared using W18-1 as the base water supplemented with $CaSO_4*2H_20$, KCl, $MgCl_2*6H_20$, $MgSO_4*7H_20$, Na_2SO4 and NaF along with metal stock solutions of $CdCl_2$, $CuCl_2$, $Na_2SeO_4*10H_20$, $Na_2MoO_4*2H_20$ and $MnCl_2*4H_20$ to achieve targeted ion concentrations. Mixture 1 was prepared by diluting Mixture 2 to 77% using unspiked W18-1 site water for dilution. Additional dilutions were also tested.

Methods for the toxicity tests are summarized in Tables 1 and 2. Testing was conducted according to procedures described by Environment Canada (2007a and 2007b). Statistical analyses for all tests were performed using CETIS (Tidepool Scientific Software, 2013).

Table 1. Summary of test conditions: *Ceriodaphnia dubia* survival and reproduction test.

Test organism	*Ceriodaphnia dubia*
Test organism source	In-house culture
Test organism age	<24 h old neonates produced within 12 h
Test type	Static-renewal
Test duration	7 ± 1 day
Test vessel	20 mL test tube
Test volume	15 mL
Test replicates	10 test replicates per treatment
No. of organisms	1 per replicate
Control water	20% Perrier water
Test solution renewal	Daily
Test temperature	25 ± 1°C
Feeding	*Pseudokirchneriella subcapitata* and YCT
Light intensity	100 to 600 lux at water surface
Photoperiod	16 hours light/8 hours dark
Aeration	None
Test protocol	Environment Canada (2007a), EPS 1/RM/21
Statistical software	CETIS (Tidepool Scientific Software 2013)
Test endpoint	Survival and reproduction
Test acceptability criteria for controls	≥80% survival; ≥15 young per surviving control producing three broods; ≥60% of controls producing three or more broods
Reference toxicant	Sodium chloride

Table 2. Summary of test conditions: *Pseudokirchneriella subcapitata* growth inhibition test.

Test organism	*Pseudokirchneriella subcapitata* (Strain CPCC #37)
Test organism source	In-house culture, obtained from Canadian Phycological Culture Center, and originally isolated from Nivelta River, Norway.
Test organism age	4 to 7 day old culture in logarithmic growth phase
Test type	Static
Test duration	72 hours
Test vessel	Microplate
Test volume	220 µL
Test replicates	4 test replicates per treatment; 8 replicates for control
No. of organisms	10, 000 cells/mL
Control water	Deionized water with nutrients added
Test solution renewal	None
Test temperature	24 ± 2°C
Feeding	None
Light intensity	3600 to 4400 lux
Photoperiod	24 hours light
Aeration	None
Test protocol	Environment Canada (2007b), EPS 1/RM/25
Statistical software	CETIS (Tidepool Scientific 2013)
Test endpoint	Algal cell growth inhibition
Test acceptability criteria for controls	> 16-fold increase in number of algal cells; CV ≤ 20%; no trend when analyzed using Mann-Kendall test
Reference toxicant	Zinc

3.0 RESULTS

Targeted and measured values of constituents in Mixture 1 (77% sample) and Mixture 2 (100% sample) are provided in Table 3. Iron, silicon and bicarbonate were not added to the W18-1 water, since the concentration that was already present in this water already exceeded the target concentrations for Mixtures 1 and 2. Uranium was not added because this constituent was not available since protocols were not in place in the laboratory for safe handling of this material. Other than these materials, the measured concentrations were in good agreement with the target concentrations

Table 3. Targeted and measured values of constituents in the mixtures.

Constituent	W18-1	Mixture 1 (77%)		Mixture 2 (100%	
		Targeted (mg/L)	Measured (mg/L)	Targeted (mg/L)	Measured (mg/L)
Hardness	70.1	495	512	642	659
SO_4	20.8	441	441	573	581
HCO_3 [1]	75.8	54.5	82.6	70.8	84.1
Cl	5.5	13.7	15.8	17.8	18.8
F	0.03	0.78	0.68	1.02	0.87
Cd	<0.00005	0.00050	0.00055	0.00065	0.00066
Ca	19.0	182	186	236	242
Cu	0.0012	0.0174	0.0167	0.0226	0.0199
Fe [1]	0.055	0.0057	0.067	0.0074	0.0970
Mg	5.5	10.0	11.4	13.0	13.1
Mn	0.004	0.702	0.691	0.912	0.883
Mo	0.001	0.100	0.113	0.130	0.146
K	<2	1.8	2.0	2.3	2.3
Se	<0.0010	0.0030	0.0035	0.0040	0.0046
Si [1]	5.4	3.55	5.67	4.62	5.62
Na	3.2	15.6	16.7	20.2	20.4
U [2]	0.0027	0.0210	0.00280	0.0273	0.00283

[1] Measured value exceeded target value because this constituent already contained the measured amount upon receipt.
[2] Uranium was not added to the mixture.

Results of the toxicity tests conducted on the Mixture prepared in sample W18-1 are summarized in Tables 4 and 5. No adverse effects were observed on *C. dubia* survival or reproduction; the LC50, IC25 and IC50 were each >100%. In the 72-h *P. subcapitata* toxicity test, a reduction in cell yield was observed relative to the unspiked W18-1 sample, resulting in an IC25 of 74.9% sample. However, cell yield was greater than in the laboratory water control in all test concentrations. Thus, there was no adverse effect in the test concentrations relative to the laboratory control performance.

Table 4. Results: *Ceriodaphnia dubia* survival and reproduction test.

Concentration (% v/v)	**Survival (%)**	**Reproduction (mean ± SD)**
Lab Control	100	24.5 ± 2.3

IC25 (95% CL)	74.9 (57.1 – 85.2)	>100
IC50	>100	>100

SD = Standard Deviation, IC = Inhibition Concentration, CL = Confidence limits.

4.0 QA/QC

The health history of the test organisms used in the exposures was acceptable and met the requirements of the Environment Canada test protocols. The tests met all control acceptability criteria and water quality parameters remained within ranges specified in the protocols throughout the tests. There were no deviations from the test methodologies. Uncertainty associated with these tests is best described by the standard deviation around the mean and/or the confidence limits around the point estimates.

Results of the reference toxicant tests conducted during the testing program are summarized in Table 6. Results for these tests fell within the range for organism performance of mean and two standard deviation range, based on historical results obtained by the laboratory with these tests. Thus, the sensitivity of the organisms used in these tests was appropriate

Table 6. Reference toxicant test results.

Test Species	Endpoint	Historical Mean (2 SD Range)	CV (%)	Test Date
C. dubia	Survival (LC50): 2.1 g/L NaCl	1.9 (1.4 – 2.5)	16	October 22, 2014
	Reproduction (IC50): 1.8 g/L NaCl	1.4 (1.0 – 2.0)	18	
P. subcapitata	Growth (IC50): 24.2 µg/L Zn	25.4 (14.8 – 43.4)	31	October 3, 2014

SD = Standard Deviation, CV = Coefficient of Variation, LC = Lethal Concentration, IC = Inhibition Concentration.

1) Mean survival of first generation controls is ≥80 %
2) At least 60% of controls have produced three broods within 8 days
3) An average of ≥15 live young produced per surviving female in the control solutions during the first three broods.
4) Invalid if ephippia observed in any control solution at any time.

WQ Ranges:

T (°C) = 25 ± 1; DO (mg/L) = 3.3 to 8.4 ; pH = 6.0 to 8.5

Test Organism Information:

Broodstock No.: 092614B
Age of young (Day 0): <24-h (within 12-h)
Avg No. young in first 3 broods of previous 7 d: 32
Mortality (%) in previous 7 d: 10
Individual female # used ≥8 young on test day: 23~~4~~, 25, 27, 29, 30

NaCl Reference Toxicant Results:

Reference Toxicant ID: Cd119
Stock Solution ID: 14Na07
Date Initiated: Oct 22/14

Reference Information

Test Method References:

ALS Test Code	Matrix	Test Description	Method Reference**
ALK-COL-VA	Water	Alkalinity by Colourimetric (Automated)	EPA 310.2
This analysis is carried out using procedures adapted from EPA Method 310.2 "Alkalinity". Total Alkalinity is determined using the methyl orange colourimetric method.			
ANIONS-CL-IC-VA	Water	Chloride by Ion Chromatography	APHA 4110 B.
This analysis is carried out using procedures adapted from APHA Method 4110 B. "Ion Chromatography with Chemical Suppression of Eluent Conductivity" and EPA Method 300.0 "Determination of Inorganic Anions by Ion Chromatography".			
ANIONS-F-IC-VA	Water	Fluoride by Ion Chromatography	APHA 4110 B.
This analysis is carried out using procedures adapted from APHA Method 4110 B. "Ion Chromatography with Chemical Suppression of Eluent Conductivity" and EPA Method 300.0 "Determination of Inorganic Anions by Ion Chromatography".			
ANIONS-SO4-IC-VA	Water	Sulfate by Ion Chromatography	APHA 4110 B.
This analysis is carried out using procedures adapted from APHA Method 4110 B. "Ion Chromatography with Chemical Suppression of Eluent Conductivity" and EPA Method 300.0 "Determination of Inorganic Anions by Ion Chromatography".			
HARDNESS-CALC-VA	Water	Hardness	APHA 2340B
Hardness (also known as Total Hardness) is calculated from the sum of Calcium and Magnesium concentrations, expressed in CaCO3 equivalents. Dissolved Calcium and Magnesium concentrations are preferentially used for the hardness calculation.			
MET-TOT-ICP-VA	Water	Total Metals in Water by ICPOES	EPA SW-846 3005A/6010B
This analysis is carried out using procedures adapted from "Standard Methods for the Examination of Water and Wastewater" published by the American Public Health Association, and with procedures adapted from "Test Methods for Evaluating Solid Waste" SW-846 published by the United States Environmental Protection Agency (EPA). The procedures may involve preliminary sample treatment by acid digestion, using either hotblock or microwave oven (EPA Method 3005A). Instrumental analysis is by inductively coupled plasma - optical emission spectrophotometry (EPA Method 6010B).			
MET-TOT-LOW-MS-VA	Water	Total Metals in Water by ICPMS(Low)	EPA SW-846 3005A/6020A
This analysis is carried out using procedures adapted from "Standard Methods for the Examination of Water and Wastewater" published by the American Public Health Association, and with procedures adapted from "Test Methods for Evaluating Solid Waste" SW-846 published by the United States Environmental Protection Agency (EPA). The procedures may involve preliminary sample treatment by acid digestion, using either hotblock or microwave oven, or filtration (EPA Method 3005A). Instrumental analysis is by inductively coupled plasma - mass spectrometry (EPA Method 6020A).			

** ALS test methods may incorporate modifications from specified reference methods to improve performance.

The last two letters of the above test code(s) indicate the laboratory that performed analytical analysis for that test. Refer to the list below:

Laboratory Definition Code	Laboratory Location
VA	ALS ENVIRONMENTAL - VANCOUVER, BRITISH COLUMBIA, CANADA

Chain of Custody Numbers:

1

GLOSSARY OF REPORT TERMS

Surrogate - A compound that is similar in behaviour to target analyte(s), but that does not occur naturally in environmental samples. For applicable tests, surrogates are added to samples prior to analysis as a check on recovery.
mg/kg - milligrams per kilogram based on dry weight of sample.
mg/kg wwt - milligrams per kilogram based on wet weight of sample.
mg/kg lwt - milligrams per kilogram based on lipid-adjusted weight of sample.
mg/L - milligrams per litre.
< - Less than.
D.L. - The reported Detection Limit, also known as the Limit of Reporting (LOR).
N/A - Result not available. Refer to qualifier code and definition for explanation.

Test results reported relate only to the samples as received by the laboratory.
UNLESS OTHERWISE STATED, ALL SAMPLES WERE RECEIVED IN ACCEPTABLE CONDITION.
Analytical results in unsigned test reports with the DRAFT watermark are subject to change, pending final QC review.

CASiNO

Casino Kinetic Testwork 2014 Update for Ore, Waste Rock and Tailings

Project No. J862-6
15 December 2014

LORAX ENVIRONMENTAL
2289 Burrard Street
Vancouver, BC, V6J 3H9
Canada
1-604-688-7173

Executive Summary

CASINO

Executive Summary

The Casino kinetic test program evaluates the metal leaching and acid rock drainage (ML/ARD) potential of waste rock, tailings and ore samples in support of the geochemical assessment for the Casino Project. A total of 53 kinetic tests have been undertaken for the Casino Project, which includes saturated columns, unsaturated columns, humidity cells and field weathering bins. Additional data has continued to be collected for a number of kinetic tests discussed in the 2013 Kinetic Test Update report and/or the 2013 Casino Source Term Development report. This report presents the results for the laboratory kinetic tests up to September 2014. The most relevant findings are summarized here.

Final Stabilized Metal Leaching Rates

- 95^{th} percentile concentrations in saturated column tests were used to estimate the source term for the saturated impoundment. Concentrations produced by column experiments have generally decreased with time.
- Geochemical loading rates measured in neutral and acidic pH waste rock humidity cells were used to predict pit wall and unsaturated waste rock source terms. The latest available data (Cycles 49-65) were applied at the time of source term development. Since this time, final geochemical loading rates have decreased by on average 20% (Cycles 69-79).
- Geochemical loading rates measured in tailings humidity cells and unsaturated columns were used to estimate loading rates for the tailings embankment and beach. Closure source terms were predicted using HYP tailings kinetic tests Col6 and T7. Now, an additional 50 cycles of data is available. Overall, the geochemical loading rates have decreased by an average of 14% and 29% in Col 6 and T7, respectively. Specifically, sulphate loading rates have decreased 40% and 75% in these kinetic tests. Conversely, there are several elements which have shown increased loading rates. The most significant of these increases is Cu in Col 6, which increased by 51% and Mo in T7 which increased by 107%.

Temperature Effects

Kinetic oxidation rates are temperature sensitive so temperature effects must be considered when relating laboratory loading rates to field conditions. At the time of source term development, data was available from one kinetic test (T1) which had been moved from a room temperature environment to a 4°C environment after rates had stabilized. Since the time of initial source term calculations, a number of other kinetic tests were moved from

room temperature to 4°C environment to provide further information regarding temperature affects. The updated kinetic test data generally shows that the assumptions related to site temperature effects on metal leaching rates that were applied during the source term development are of sound basis. That is, acidic metal leaching rates are more sensitive to temperature then that of neutral metal leaching rates and oxide CAP is generally not as sensitive to temperature affects as sulphidic SUP or HYP rock types.

1. Introduction

CASINO

1. Introduction

1.1 Introduction

A series of laboratory and field based kinetic tests have been conducted to evaluate the acid rock drainage and metal leaching potential (ML/ARD) for waste rock, tailings and ore that will be produced during mine operations at Casino Mining Corporation's (CMC) Casino Project in the Yukon. The primary objective of this report is to provide an update of the ongoing kinetic test program presented in Lorax 2013c in order to determine if the Casino source term predictions (Lorax, 2013b) require revising. This report presents an update of the static and kinetic test results of kinetic tests completed, and ongoing, since March 2013. It also provides an evaluation of the effect of temperature on leachate quality for those tests that were moved from 22 ºC to 4 ºC storage.

1.2 Geology

The Casino deposit is a large gold-copper-molybdenum (Au-Cu-Mo) porphyry deposit that occurs in the Yukon Crystalline Terrane. A more detailed description of the site geology and can be found in Lorax (2013a,b,c).

The mineralization zones identified in the core of the Casino deposit include:

- Leached oxide cap zone (CAP);
- Supergene (SUP) Zone (Supergene Oxide (SOX) + Supergene Sulphide (SUS)); and
- Hypogene Zone (HYP).

1.3 Test Program Overview

A total of 53 kinetic tests have been undertaken for the Casino Project, including:

- Waste rock: 11 saturated columns, 5 unsaturated columns, 10 humidity cells, and 8 field bins;
- Tailings: 6 saturated columns, 4 unsaturated columns (including 2 composed of CAP heap leach residue), and 7 humidity cells; and
- Ore: 2 humidity cells.

This report provides an update for the 15 kinetic tests that are ongoing or have additional data since March, 2013:

- Waste rock: 4 saturated columns, 2 unsaturated columns, 10 humidity cells; and,
- Tailings: 2 saturated columns, 1 unsaturated, and 2 humidity cells.

The description and details for the Casino Project kinetic testing are summarized in Table 1-1 and Table 1-2. Additional information can be found in Lorax documents (2008, 2010, 2013a,b,c).

Table 1-1:
Summary of waste rock kinetic tests for the Casino Project.

Kinetic Test Type	Sample ID	Sample Selection Rational	Sample Description		Test Details

Notes: Only samples that are either ongoing or have end dates after March-2013 are reported herein with the exception of unsaturated columns Col 7 and Col 8. The data for those two columns will be provided in a separate report addressing the heap leach pile. The kinetic tests reported on in this report are shaded grey.

1.4 Errata

During preparation of this report, reviews of previous reports found that, in some cases, the units for Hg concentrations and loadings were presented erroneously.

The report Casino_Kinetic Testwork_Update_Final_updated 18th December, 2013 was reviewed in detail with the following findings:

- The units for Hg were presented as µg/x or mg/x in the report. However, the values are consistent with the units given in each table with the exception of Table 4-41. In that table, the Hg units are listed as ug/L. However, in some columns of the table, Hg is reported as <0.01 (µg/L), but in other columns it is reported as <0.00001. The values <0.00001 are actually in units of mg/L.
- The Hg loading values listed in tables of Appendix E: Unsaturated Kinetic Test Results, represent µg/kg not mg/kg.
- The Hg loading values given in the figures in Appendix E represent µg/kg, not mg/kg.

The source term calculations were checked and it was found that the conversion from µg/L to mg/kg was done correctly. The loading values for Hg presented in the report, Casino Geochemical Source Term Development_FINAL, are correct. Therefore, the error is a presentation error and does not affect the source term values. The units for Hg loading rates have been corrected to mg/kg for the tables presented in this report.

2. Saturated Column Results

CASiNO

2. Saturated Column Results

Saturated kinetic tests with new data since the 2013 kinetic test report and/or the 2013 Source Term Development report (Lorax 2013b,c) are listed in Table 2-1.

Table 2-1:
Saturated tests with new data since the 2013 kinetic test report

Kinetic Test ID	Mineralization Zone	Details / Notes	Start Date	End Date
Waste Rock				
Sat Col 12	25% HYP 75% acidic SUP	Layered acidic SUP and HYP (upper and lower ports sampled)	12-Jul-12	13-Feb-14

Sat Col 11	85% SUP, 15% HYP	Pyrite concentrate with 21% slimes	28-Jul-11	6-Jun-13
Sat Col 16	100% HYP (87% IXWR, 13% IXPP)	Pyrite rougher whole tailings	01-Mar-13	12-Feb-14
Sat Col 17	100% HYP (87% IXWR, 13% IXPP)	Pyrite concentrate	01-Mar-13	12-Feb-14

The composition of the saturated column leachate is controlled by the flushing of water soluble oxidation products and reductive dissolution of reducible phases (*i.e.*, Fe and Mn oxides). Peak concentrations are generally observed during the first pore volume that is flushed through the columns, although concentrations of some parameters have been observed to increase or remain constant with time. In the saturated TMF, flushing of one pore volume will take in excess of 100 years. During this time, waste rock and tailings will impart a concentration on drainage water which is best represented by the peak concentrations observed in the saturated columns. The 95th percentile concentrations in saturated column data was used for the source term development (Lorax 2013b). The 95th percentile was calculated from the current data set and compared against the values used in the source term development to assess if there has been a significant difference in concentrations since the source term development. Column leachate trends for selected analytes over time are shown in Appendix A (Figures A-1 and A-2). The comparison is provided in Table B-1 (Appendix B) and the complete dataset is provided in Appendix C.

Analytes that were consistently below detection for a test column (*e.g.*, NO_3, NO_2, Be, Bi, Cr, Hg, P, Ag, Sn, Ti, Zr) in the data set were excluded from the assessment. Table 2-2 provides the summary statics from the comparison; negative values indicate that, overall, the current 95th percentile values are less than the values used in the source term development. Therefore, the source term values are considered conservative. The statistics are based on the complete analysis suite (the average of the relative differences of all analytes above detection) except for pH because a lower pH used in the source term development is considered conservative. In all cases, the pH has increased with time, typically by 5 to 10%, with the exception of the lower port of Sat Col 14, which has increased by 39%, going from a pH of 3.35 to a pH of 5.88 (Table 2-2). This increase in pH is accompanied by an increase in alkalinity values. That is, the largest increase in the 95th percentiles, 141% (Table 2-2), is from the alkalinity values. The 95th percentile for sulphate concentrations decreased in all the saturated columns by a maximum of 31% (Table B-1). The overall relative differences are negative, meaning the current 95th percentile values are typically less than the values used in the source term development.

Two saturated tailings columns (Sat Col 16 and Sat Col 17) were initiated in early 2013, and results were not available by the cut-off date for reporting in the 2013 Casino Kinetic test Update (Lorax, 2013c). Results for these columns are included alongside other saturated tailings columns in Figures A-3 and Figure A-4. These saturated columns contain pyrite rougher tailings (Sat Col 16) and pyrite concentrate (Sat Col 17) from the 2012 pilot plant. These tailings samples were produced exclusively from HYP ore. Most of the existing saturated tailings columns were composed of a mixture of SUP and HYP. The pH of these two columns is similar to the 83% Hyp (Sat Col 8) and 85% Sup (Sat Col 10 and 11) columns, as is alkalinity and dissolved Fe. The sulphate concentrations from both columns are still trending downward and are now <1.0 mg/L for Sat Col 16 and 10 mg/L for Sat Col 17 (similar to Sat Col 8 and Sat Col 10 stabilized values). The rapid depletion of sulphate in column drainage is presumably related to production of H_2S, which was detected in concentrations as high as 0.76 mg/L and 0.089 mg/L in Sat Col 16 and Sat Col 17, respectively. The dissolved metals concentrations eluting from these two columns are frequently below detection (*e.g.*, Cd, Cu, Pb, Se and Zn). The As and Mo concentrations are very similar to Sat Col 1 (60% HYP). Therefore, when HYP ore is the primary mill feed, the tailings are expected to have similar, or slightly lower, metal leaching potential than when mixed mill feeds are running. It is unclear why these samples provided more favorable conditions for SO_4 reduction and H_2S production. This may be related to the relatively high dissolved organic carbon content (DOC), with concentrations ranging from 45 mg/L to 125 mg/L in Sat Col 16 and Sat Col 17, while DOC remained below 10 mg/L in other tailings columns (Sat Col 1, 8, 10 and 11).

Table 2-2:
Summary statistics for saturated columns showing relative difference between the 95th percentile used in the source term development and the current 95th percentile.

Relative difference	6%	-80%	-25%	-14%	-14%	-94%	94%
Sat Col 16							
Current	8.66	<0.0001	615				
Relative difference	5%	NS	-2%	-2%	9%	-28%	126%
Sat Col 17							
Current	8.20	0.0004	1376				
Relative difference	9%	62%	-4%	-3%	7%	-94%	116%

Notes: Negative values indicate that the current 95th percentile value is less than the 95th percentile used for the source term development.
"NS" means difference is Not Significant because both medians are less than 5 x's the reporting limit.

3. Unsaturated Kinetic Test Update

CASiNO

3. Unsaturated Kinetic Test Update

3.1 Waste Rock

Unsaturated waste rock kinetic tests with new data since the 2013 Kinetic Test Report Update and/or the 2013 Source Term Development Report are listed in Table 3-1.

Table 3-1:
Unsaturated waste rock kinetic tests with new data since the 2013 kinetic test report.

	Kinetic Test ID	Sample Description		Details of Test		
		Lithology	Details / Notes	Start Date	Terminated	Temperature change to 4ºC
CAP	Col 1	WR	Low S, duplicate of FB2	27-Jan-10	26-Feb-14	No change
	Col 2A	85% WR, 5%IX, 5%MX, 5%PP	Moderate S	27-Jan-10	on-going	No change
HYP	HC3	PP	Neutral pH, high S	29-Nov-12	25-Feb-14	4-Jun-13 Cycle 79
	HC4	WR	Neutral pH, high S	29-Nov-12	25-Feb-14	
	HC5	PP	Neutral pH, moderate S	29-Nov-12	25-Feb-14	
	HC6	WR	Neutral pH, moderate S	29-Nov-12	25-Feb-14	
	HC7	50% IX, 50% MX	Neutral pH, moderate S	29-Nov-12	25-Feb-14	
	HC8	MX	Acidic paste pH	29-Nov-12	on-going	4-Mar-14 Cycle 118
	HC9	PP	Carbonate depleted	29-Nov-12	on-going	No change
	HC10	WR	Acidic paste pH	29-Nov-12	on-going	4-Mar-14 Cycle 118
SUP	HC11	WR	Neutral SUP	29-Nov-12	25-Feb-14	4-Jun-13 Cycle 79
	HC12	WR	Acidic SUP	29-Nov-12	on-going	4-Mar-14 Cycle 118

Notes: The CAP unsaturated columns were trickle leached and the SUP and HYP humidity cells were flood leached; temperature for each test maintained between 22°C and 24°C unless otherwise specified; sampling was/is conducted weekly without sample preparation prior to flushing. No initial flushing was conducted.

Column leachate trends for selected analytes over time are shown in Appendix A (Figures A-5 to A-8). Table 3-2 provides the summary statics from the comparison; negative values indicate that the stabilized final values are less than the values that were used in the source term development. The percent difference calculation is not an appropriate comparison when both values are near detection limits considering analytical precision. The BC Field Manual (MOE, 2013) states that relative percent difference is not a meaningful comparison

if both values are less than 5 times the detection limit. Therefore, if both the values used in the source term development and the current values are less than 5 times the analytical reporting limit (Table B-1) the relative difference is deemed Not Significant. The comparison is provided in Table B-2 (Appendix B) and the complete dataset is provided in Appendix C.

Table 3-2:
Summary statistics for the relative difference between values used in the source term development and the final, stablized leaching rates: Unsaturated waste rock.

	pH	Cu	SO_4	All analyses combined			
	s.u.	mg/kg/wk	mg/kg/wk	Median	Mean	Min	Max
Col 1							
22°C Median	4.97	0.05	1.50				
Relative Difference	-4%	-10%	-45%	-13%	-37%	-508%	10%
Col 2a

H7							
22°C Median	7.40	0.0011	10.44				
Relative Difference	1%	-5%	-12%	-12%	-15%	-71%	37%
HC8							
22°C Median	2.91	0.40	80.84				
Relative Difference	-10%	-84%	38%	16%	10%	-111%	108%
HC10							
22°C Median	3.24	1.19	56.25				
Relative Difference	2%	-29%	-20%	-26%	-30%	-121%	7%
HC11							
22°C Median	6.82	0.0009	4.40				
Relative Difference	-3%	-60%	NS	-19%	-19%	-95%	46%
HC12							
22°C Median	3.41	0.36	18.70				
Relative Difference	-8%	-96%	-20%	-32%	-32%	-98%	64%

Notes: The 22°C median represents the median of the last five complete analysis sets at a temperature of 22°C. The relative difference represents the difference between the median values used in the source term and the median from the last 5 complete analyses at a temperature of 22 °C (pH values excluded). "NS" means difference is Not Significant because both medians are less than 5 x's the reporting limit. Negative values mean the current median is less than the median used in the source predictions.

The pH did not change by more than 20% and in most tests remained relatively constant (Table 3-2). The final copper and sulphate loading rates either decreased or did not change significantly between values currently observed and those used in source term development. Updating source terms with currently observed values would reflect the general decline in stabilized loading rates, resulting in generally lower geochemical loading rates used in source terms.

3.2 Tailings

Unsaturated tailings kinetic tests with new data since the 2013 Kinetic Test Report Update and/or the 2013 Source Term Development Report are listed in Table 3-3.

Table 3-3:
Unsaturated tailings kinetic tests with new data since the 2013 kinetic test report.

Kinetic Test ID	Mineralization Zone	Operational Procedure						
		Start Date	Terminated	Temperature change to 4ºC	Mass (kg)	Flushing Rate/ Weekly Input (mL)	Leach Procedure	Sample Prep for Flushings
Whole Tailings								
T4	60% HYP, 40% SUP	15-Dec-09	on-going	4-Mar-14 Cycle 220	1	500	Flood	Stirred
Depyritized Pyrite Rougher Whole Tailings								
T7	HYP	5-Mar-13	on-going	No change	1	500	Flood	Stirred
Depyritized Pyrite Rougher Tailings Sands (>75 µm)								
Col 6	HYP	19-Dec-12	on-going	No change	5.0	300	Trickle	None

Notes: Temperature for each test is maintained between 22°C and 24°C unless otherwise specified.

Column leachate trends for selected analytes over time are shown in Appendix A (Figures A-9 and A-10). Table 3-4 provides the summary statistics from the comparison; negative values indicate that the current stabilized final values are less than the values that were used in the source term development. If both the values used in the source term development and the current values were less than 5 times the analytical reporting limit the relative difference was deemed Not Significant. The comparison is provided in Table B-3 (Appendix B) and the complete dataset is provided in Appendix C.

The pH remained relatively constant (Table 3-4). The final loading rates have declined for most parameters compared to what was used in source term development as shown in the 'all analyses combined' results in Table 3-4. One significant result is that Cu leaching rates for Cu have increased in Col 6. Other loading rates which increased in this kinetic test were of Cd, Co, Mn, Mg and Ni. The cause of these increases is unclear, as pH and alkalinity have remained stable and most other parameters (*e.g.*, sulphate) have declined over this time period.

Table 3-4:
Summary statistics for the relative difference between values used in the source term development and the final, stabilized leaching rates: Unsaturated tailings.

	pH	Cu	SO_4	All analyses combined			
	s.u.	mg/kg/wk	mg/kg/wk	Median	Mean	Min	Max
Col 6							
22°C Median	7.95	0.0005	1.04				
Relative Difference	2%	51%	-40%	-7%	-14%	-107%	51%
T4							
22°C Median	7.72	0.0003	25.20				
Relative Difference	2%	NS	11%	-17%	-14%	-36%	11%
T7							
22°C Median	7.91	0.0003	3.92				
Relative Difference	3%	NS	-75%	-36%	-29%	-101%	107%

Notes: The 22°C median represents the median of the last five complete analysis sets at a temperature of 22 °C. The relative difference represents the difference between the values used for the source term development and the median from the last 5 complete analyses at a temperature of 22 °C (pH values excluded). Negative values mean the current median is less than the median used in the source predictions

4. Temperature Dependence

CASiNO

4. Temperature Dependence

The oxidation rate of Casino mine waste is influenced by temperature. Laboratory tests are typically conducted at room temperature (~22°C) while the average ambient temperature at the Casino mine site is near 1°C. Therefore, the rate of sulphide oxidation observed in kinetic test work likely overestimates field conditions. To assess and address the influence of temperature on oxidation rates, 12 humidity cells were moved from room temperature to a cold room maintained at 4°C. The cycle at which the temperature was changed is marked for all applicable test cells in their respective Figures (Appendix A).

4.1 Acid Generation

Briefly, it has been found that the kinetic rate of pyrite oxidation can generally be described by an Arrhenius relationship:

$$k = Ae^{-Ea/RT}$$

where k is the reaction rate, A is the pre-exponential factor, Ea is the activation energy, R is the noble gas constant, and T is the temperature in Kelvin. The pre-exponential factor is a constant, with a value of 9.28×10^{-14} mole m^{-2} s^{-1}. The Ea of a reaction can be derived from the slope of the Arrhenius relationship (1000/T versus log k) and estimates of sulphide oxidation activation energies based on the results from each of the humidity cells (Table 4-1).

The activation energy can be somewhat variable due to chemical differences in pyrite composition. The range of Ea values reported in the literature is 39 KJ mol^{-1} to 88.0 KJ mol^{-1} (Lowson, 1982). Activation energy values calculated for the 12 kinetic tests ranged from 4 to 69 KJ mol^{-1} with a mean of 43 KJ mol^{-1}. This average value is consistent with the Ea observed in T1 of 44 KJ mol^{-1} which was applied to source term calculations. The temperature sensitivity of sulphide oxidation assuming an activation energy of 44 KJ mol^{-1} is plotted in Figure 4-1.

Three tests (Col 2A, HC6 and HC10) have notably lower activation energy estimates. From the data plots (Figures A-5 and A-7), it appears HC10 and possibly HC6 may not have reached steady-state sulphate leaching rates before the temperature was decreased. The unsaturated column Col2A contains oxide CAP waste rock which only contains trace quantities of pyrite, with jarosite being the primary host of sulphur. Sulphate release from this material is poorly described by sulphide oxidation kinetics.

Table 4-1:
pH, sulphate and activation energy of sulphide oxidation in Casino unsaturated humidity cells.

		21°C		4°C		Ea
ID	**Mineralization**	**pH**	**SO_4**	**pH**	**SO_4**	**KJ mol^{-1}**

					Mean	**43**

Notes: Sulphate loadings in mg/kg/week; T1 values from Lorax (2013c).

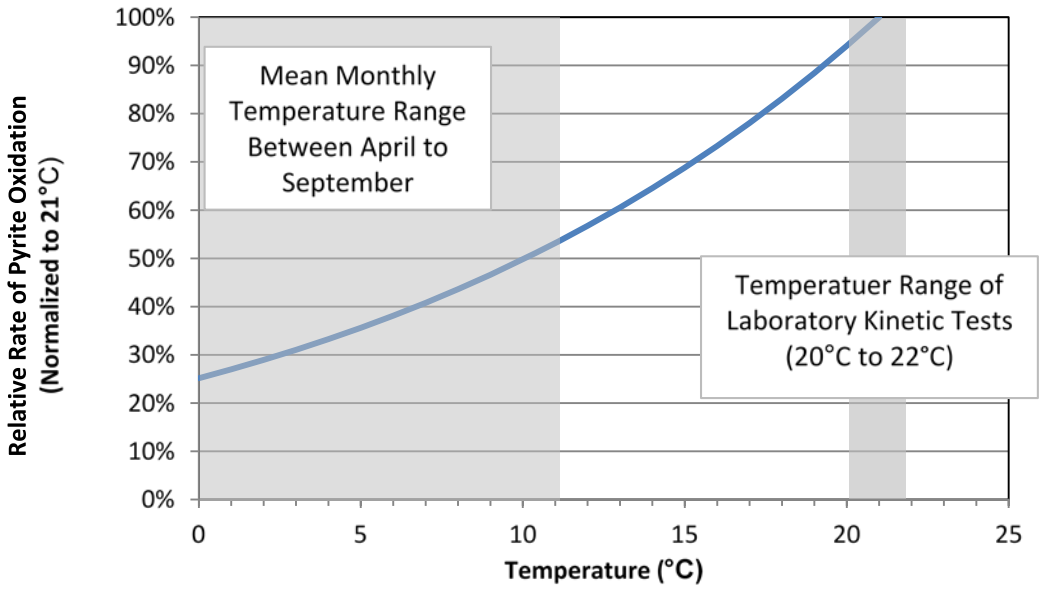

Figure 4-1: Influence of temperature on pyrite oxidation rate in Casino tailings normalized to activation energy of 44 KJ mol^{-1}.

4.2 Metal Leaching Rate

The effect of temperature on metal release rates was evaluated by considering the ratio of the median loading rate from the last 5 complete analyses at 4°C to the median loading rate from the last 5 complete analyses at 22°C.

The leaching rate of most metals decreased when the humidity cells were moved from 22°C to 4°C as indicated by the geometric means of the ratios (4°C/22°C) of the datasets being <1 (Appendix B). The difference in metal leaching rates between 4°C and 22°C is presented in Table 4-2 to Table 4-5. These tables group temperature effects by weathering state (acidic vs. neutral) and material type (tailings, waste rock, oxide cap). These tables also compare the difference in metal leaching rate between 22°C to 4°C observed in recent test work with scaling factors based on results from humidity cell T1 used in source term predictions. In general, test results show that metal leaching rates in acidic waste rock are much more temperature sensitive than in neutral pH waste rock and tailings, and oxide CAP is generally not as temperature sensitive as sulphidic HYP or SUP. For most elements, the temperature scaling factors applied to source terms generally fall within the range observed in the updated kinetic test work.

Table 4-2:
Comparison of temperature scaling factor (rate at 4°C/ rate at 22°C) applied to neutral pH waste rock with recent results from neutral pH waste rock humidity cells.

Element	Scaling Factor Applied to Source Term	HC3	HC4	HC5	HC6	H7	HC11
Sulphate	0.33	0.29	0.17	0.31	0.54	0.28	NS

5. Static Testing of Kinetic Test Material

CASiNO

5. Static Testing of Kinetic Test Material

The static testing results from pre- and post-kinetic testing for tests that have been terminated since the 2013 reports (Lorax 2013b,c) are provided in Appendix D.

The paste pH in the lower layers of saturated columns 12 and 14 (acidic SUP) increased from 4.0 to 4.3 and from 4.0 to 5.1, respectively. The neutral upper layers of those columns (HYP) decreased by no more than 0.6 pH units from the original paste pH of 8.2. The paste pH in Sat Col 15 (neutral SUP) remained essentially the same, with a pre-test value of 7.7 and a post-test value of 7.8. The paste pH in the neutral humidity cells dropped in all cells by ~1 pH unit (*e.g.*, from a paste pH of 8.4 to 7.7).

Total inorganic carbon concentrations generally remain the same or are slightly lower post-test in both the saturated and unsaturated tests. Likewise, post-test non-sulphate sulphide is slightly lower or remains the same (within error) as pre-kinetic test values in the saturated and unsaturated tests. The NPR values for Sat Col 6 drop slightly post-kinetic testing, but remain above an NPR value of 2.0. The NPR for all remaining tests remained essentially the same.

Metals concentrations generally are similar pre and post kinetic testing, within the natural heterogeneity that may be expected for this material.

6. Summary

CASiNO

6. Summary

Kinetic test data that have been acquired since the previous reporting cut-off date, March 2013, (Lorax, 2013b,c) has been compiled in this report and the kinetic test leaching trends have been evaluated to determine if recalculating the source terms is required. The most relevant findings are summarized here.

Final Stabilized Metal Leaching Rates

- 95^{th} percentile concentrations in saturated column tests were used to estimate the source term for the saturated impoundment. Concentrations produced by column experiments have generally decreased with time. As such, re-calculating 95^{th} percentile values with the updated data results in lower concentrations.
- Geochemical loading rates measured in neutral and acidic pH waste rock humidity cells were used to predict pit wall and unsaturated waste rock source terms. The latest available data (Cycles 49-65) were applied at the time of source term development. Since this time, geochemical loading rates have decreased by on average 20% between Cycles 69-79.
- Geochemical loading rates measured in tailings humidity cells and unsaturated columns were used to estimate loading rates for the tailings embankment and beach. Closure source terms were predicted using HYP tailings kinetic tests Col6 and T7. At the time of source term development the kinetic tests had not been running for very long, and the last two cycles available for Col6 and T7 were applied to the source term (cycles 28-30 and cycles 15-17, respectively). Now, an additional 50 cycles of data is available. A comparison of loading rates used in source term development with recent loading rates shows that the geochemical loading rates have generally decreased by an average of 14% and 29% in Col 6 and T7, respectively. Specifically, sulphate loading rates have decreased 40% and 75% in these kinetic tests. However, there are several notable elements which have shown increased loading rates in recent data compared to that which was used in source term development. The most significant of these increases are Cu in Col 6, which increased by 51% and Mo in T7 which increased by 107%.

Temperature Effects

Kinetic oxidation rates are temperature sensitive so temperature effects must be considered when relating laboratory loading rates to field conditions. At the time of source term development, data was available from one kinetic test (T1) which had been moved from a

room temperature environment to a 4°C environment after rates had stabilized. The temperature effects on metal leaching rates observed in this humidity cell, along with supporting data from literature sources, was used to scale acid generation and metal leaching rates. Since the time of initial source term calculations, a number of other kinetic tests were moved from room temperature to 4°C environment to provide further information regarding temperature affects. The assumptions applied to source term development (which this additional test work was initiated to support) include:

- Under neutral conditions, mineral solubility will effect metal loading metal loading rates. Neutral SUP and HYP loading rates are scaled based on observed variation from stabilized rates at laboratory and site temperatures.
- Under acidic conditions, the influence of oxide mineral solubility and metal adsorption will be less significant than under neutral pH. Acidic SUP and HYP loading rates are scaled based on a site-specific Arrhenius relationship.
- Metal leaching from CAP material is driven by oxide dissolution which is expected to not be as sensitive to temperature affects as sulphide oxidation. Therefore, oxide CAP leaching rates were not adjusted to account for temperature affects.

The updated kinetic test data generally shows that these assumptions are of sound basis. That is, acidic metal leaching rates are more sensitive to temperature then that of neutral metal leaching rates and oxide CAP is generally not as sensitive to temperature affects as sulphidic SUP or HYP rock types.

Notes: Units in mg/L; Allalinity as mg $CaCO_3$/L; Blue text indicates analytes that were below detection; NS means "Not Significant"; highlighted texts indicates concentrations that have increased since the source term was developed.
Values which exceed CCME aquatic life guidelines shaded in blue, values exceeding Metal Mining Effluent Regulations: MMM guidelines in italic, values exceeding MCS are in bold text, values exceeding MGS are highlighted in yellow.

Comparision of the 95th percentile concentration values used in the 2013 source term development and current 95% percentile concentrations

Notes:
1. Units in mg/kg; Alk. = Alkalinity as $CaCC_3$.
2. Values in Blue represent elements that were consistently below detection.
3. "NS" means difference is Not Significant because both medians are less than 5 x's the reporting limit

Notes:
Units in mg/kg; Alk. = Alkalinity as $CaCC_3$.
2. Values in Blue represent elements that were consistently below detection.
3. "NS" means difference is Not Significant because both medians are less than 5 x's the reporting limit; gray shading + italic text indicates analyte concentrations that are within 5 x's the reporting limit.
4. Highlighted cells indicate an increase in dissolved metal/metaloid production rate at 4°C.
