INTRODUCTION:

Assessment has been filed on the 146 Cam Claims until May of 2001. In spite of this, it was decided to do some bedrock geological mapping on and around the claims in an attempt to better understand the rock types and geology of the area. Four samples of rocks collected during the geological mapping were sent to Vancouver Petrographics Ltd. for study (Report in Appendix A).

In the course of doing this work, some rock, soil and stream sediment samples were taken and analyzed. Analysis for mercury at parts per billion levels was started in 1999. In addition, several lines of VLF-EM surveying were performed. This surveying resulted in the location of a structure located west of the adit area (See Bedrock Geology Maps) on the north side of Livingstone Creek. Subsequent grid soil sampling in this area showed the presence of weak gold, but strong mercury, mineralization in the structure. The structure has been called the "Switchback" because it is located at the top of a switchback on a cat road which runs along the north side of Livingstone Creek.

This report has been prepared to describe the 1999 work program and provide conclusions and recommendations for further work on the CAM Claims.

LOCATION, ACCESS AND CLAIMS:

The original 142 CAM Claims were staked in 1997 to cover 5 of the 6 placer creeks which make up the Livingstone placer camp. Mining of these creeks is still occurring 100 years after it began. The CAM Claims are located on NTS Map Sheet 105 E/8 and are centered at approximately Latitude 61^0 19' N; Longitude 134^0 17' W, within the Whitehorse Mining District, Yukon (See Part of Claim Map 105 E/8 Quartz). An additional 4 claims were staked just east of the main block in May, 1998. These claims were staked to protect a trench, called the Ron Trench, excavated that month. The trench exposed a segment of a sheared quartz vein containing copper and gold values. The claims are owned 50% each by Larry W. Carlyle and Max Fuerstner of Whitehorse, Yukon.

The Livingstone Creek area is accessed by a 75-mile winter road from Lake Laberge. Several air strips exist in the Livingstone area so access is usually via fixed-wing aircraft from Whitehorse; approximately 50 air miles to the south southwest. The main Livingstone air strip is 4000 feet long and has had DC-3 and Caribou aircraft landed on it. The extensive placer mining which has taken place in the area has resulted in the presence of cat trails up most of the creeks within the claim block. These trails enable easy access to most areas by all-terrain vehicles.

The claims cover areas which extend from the fault escarpment of the Big Salmon Fault at an elevation of approximately 900 metres (2,950 ft.) to the top of the hills above the headwaters of the creeks at an elevation of approximately

1500 metres (4,920 ft.). The claims are on rounded to steeply sloping hills; the creek canyons have the steepest slopes. Vegetation consists of black spruce, pine, willow and buckbrush.

Claim Information:

CLAIM NAME	GRANT NUMBERS	EXPIRY DATE
CAM 1 - 126	YB 97530 - YB 97655	May 16, 2001
CAM 127 - 142	YC 07943 - YC 07958	May 16, 2001
CAM 143 - 146	YC 08748 - YC 08751	May 19, 2001

REGIONAL GEOLOGY:

The geology and the placer gold deposits of the Livingstone Creek area were first described by McConnell in 1901. Regional geological mapping was carried out by Cockfield, Lees, and Bostock between 1929 and 1934. This work resulted in Map 372 A being issued in 1936. Most of the camp was mapped as Unit 1, Precambrian quartzite, schists, limestone, gneiss, and greenstone. Along the headwaters of most of the creeks, they mapped a sheared granodiorite as Unit 2. This unit is unique and not found elsewhere on the map sheet. Further east they mapped a large zone of peridotite, hornblendite, and serpentine as Unit 10. A small stock of Unit 11, probably a Cretaceous granite, granodiorite, monzonite, or diorite was mapped at the headwaters of Little Violet Creek.

The regional geology was reinterpreted by Tempelman-Kluit in 1977-1979. This interpretation identified the Big Salmon Fault, down which the South Big Salmon River flows and into which the placer creeks drain. During this mapping, Tempelman-Kluit identified the Teslin Fault (4 - 6 miles west of the Livingstone camp) as the ancient western margin of North America. Tempelman-Kluit obtained more accurate age dating for the rocks of the area; and has mapped most of the rocks as Carboniferous and/or Permian dark green, fine-grained amphibolite and amphibolitic greenstone (CP_{Av}). He has mapped Unit CP_{Ag}, a dioritic to quartz dioritic augen amphibole gneiss, in almost exactly the same location as the Unit 2 from the 1936 map.

The rocks west of the Teslin Fault (also known as the Teslin Suture) were pressed against and over the original North America during the Early Cretaceous. His theory postulated that this action would cause the rocks east of the Big Salmon Fault to be raised in reverse faulted thrust blocks.

Tempelman-Kluit's westerly dipping subduction zone with North American rocks in the footwall and accreted arc terrane and oceanic rocks in its hanging wall has been reinterpreted. This reinterpretation, which has been developing from the mid-1980's to 1997, considers the Teslin zone as a zone of ductile thrusting, which includes thrust sheets of North American affinity and accreted rocks that have been complexly folded and displaced northeastward and then folded again. Rather than marking the western limit of rocks of North American origin, the zone is most likely underlain by North American basement that extends westward beneath the Intermontane Belt. Two facts strongly support this model over that of Tempelman-Kluit:

- the same metamorphosed stratigraphies can be traced along a strike length of at least 20 km. This would not be possible in the more chaotic jumble of rock blocks expected from collapsing hangingwall rocks into a subduction zone.
- most of the rocks in the area have green schist or amphibolite grade metamorphism. Rocks in a subduction zone would most probably have eclogite or blue schist grade metamorphism.

In the new model; Devonian-Mississippian granites and Permian intrusives are deformed, while Late Triassic to Early Jurassic plutons are undeformed; this would put the age of deformation and metamorphism between Late Permian and Late Triassic. Proponents of this model, suggest renaming the Teslin Suture Zone, the Teslin Tectonic Zone. Rocks within the Teslin Tectonic Zone are correlated with sedimentary and volcanic rocks of the Yukon Tanana Terrane and oceanic crustal rocks of the Slide Mountain Terrane. Yukon Tanana Terrane rocks range in age from Devonian to Permian. After their deformation and cooling, the Slide Mountain Terrane rocks were emplaced over them along low-angle, post-metamorphic faults. In the Big Salmon Range (just north of Livingstone), the Teslin Tectonic Zone is 20 km. wide. Both Slide Mountain and Yukon Tanana rocks contain steeply dipping fabrics, unlike their counterparts in the rest of the Yukon and Alaska.

The steep north-south striking D'Abbadie fault has generally been taken to represent the eastern margin of the Teslin Zone. It is most probably a narrow zone of brittle deformation reflecting a period of upper crustal normal faulting superimposed on the ductile deformation which had occurred earlier. Last Peak granite has been dated at 98 Ma. and, on the basis of contact and structural

relationships, is interpreted to have intruded while the D'Abbadie fault zone was active. Dextral shearing and gentle NW plunging of the stratigraphy are also believed to have occurred at this time.

PROPERTY GEOLOGY:

Previous mapping in the Livingstone Creek area had, for the most part, been done on a scale of 1: 250,000. More detailed work was needed in order to direct future exploration. Bedrock geological mapping at 1:50,000 scale was carried out by Carlyle to better locate geological contacts and faults in the area of the CAM Claims. Mapping was difficult due to the scarcity of outcrop; outcrop was restricted to ridge tops, steep south-facing slopes and gullies created by faults cross-cutting the ridges. Outcrop exposure was probably less than 15%.

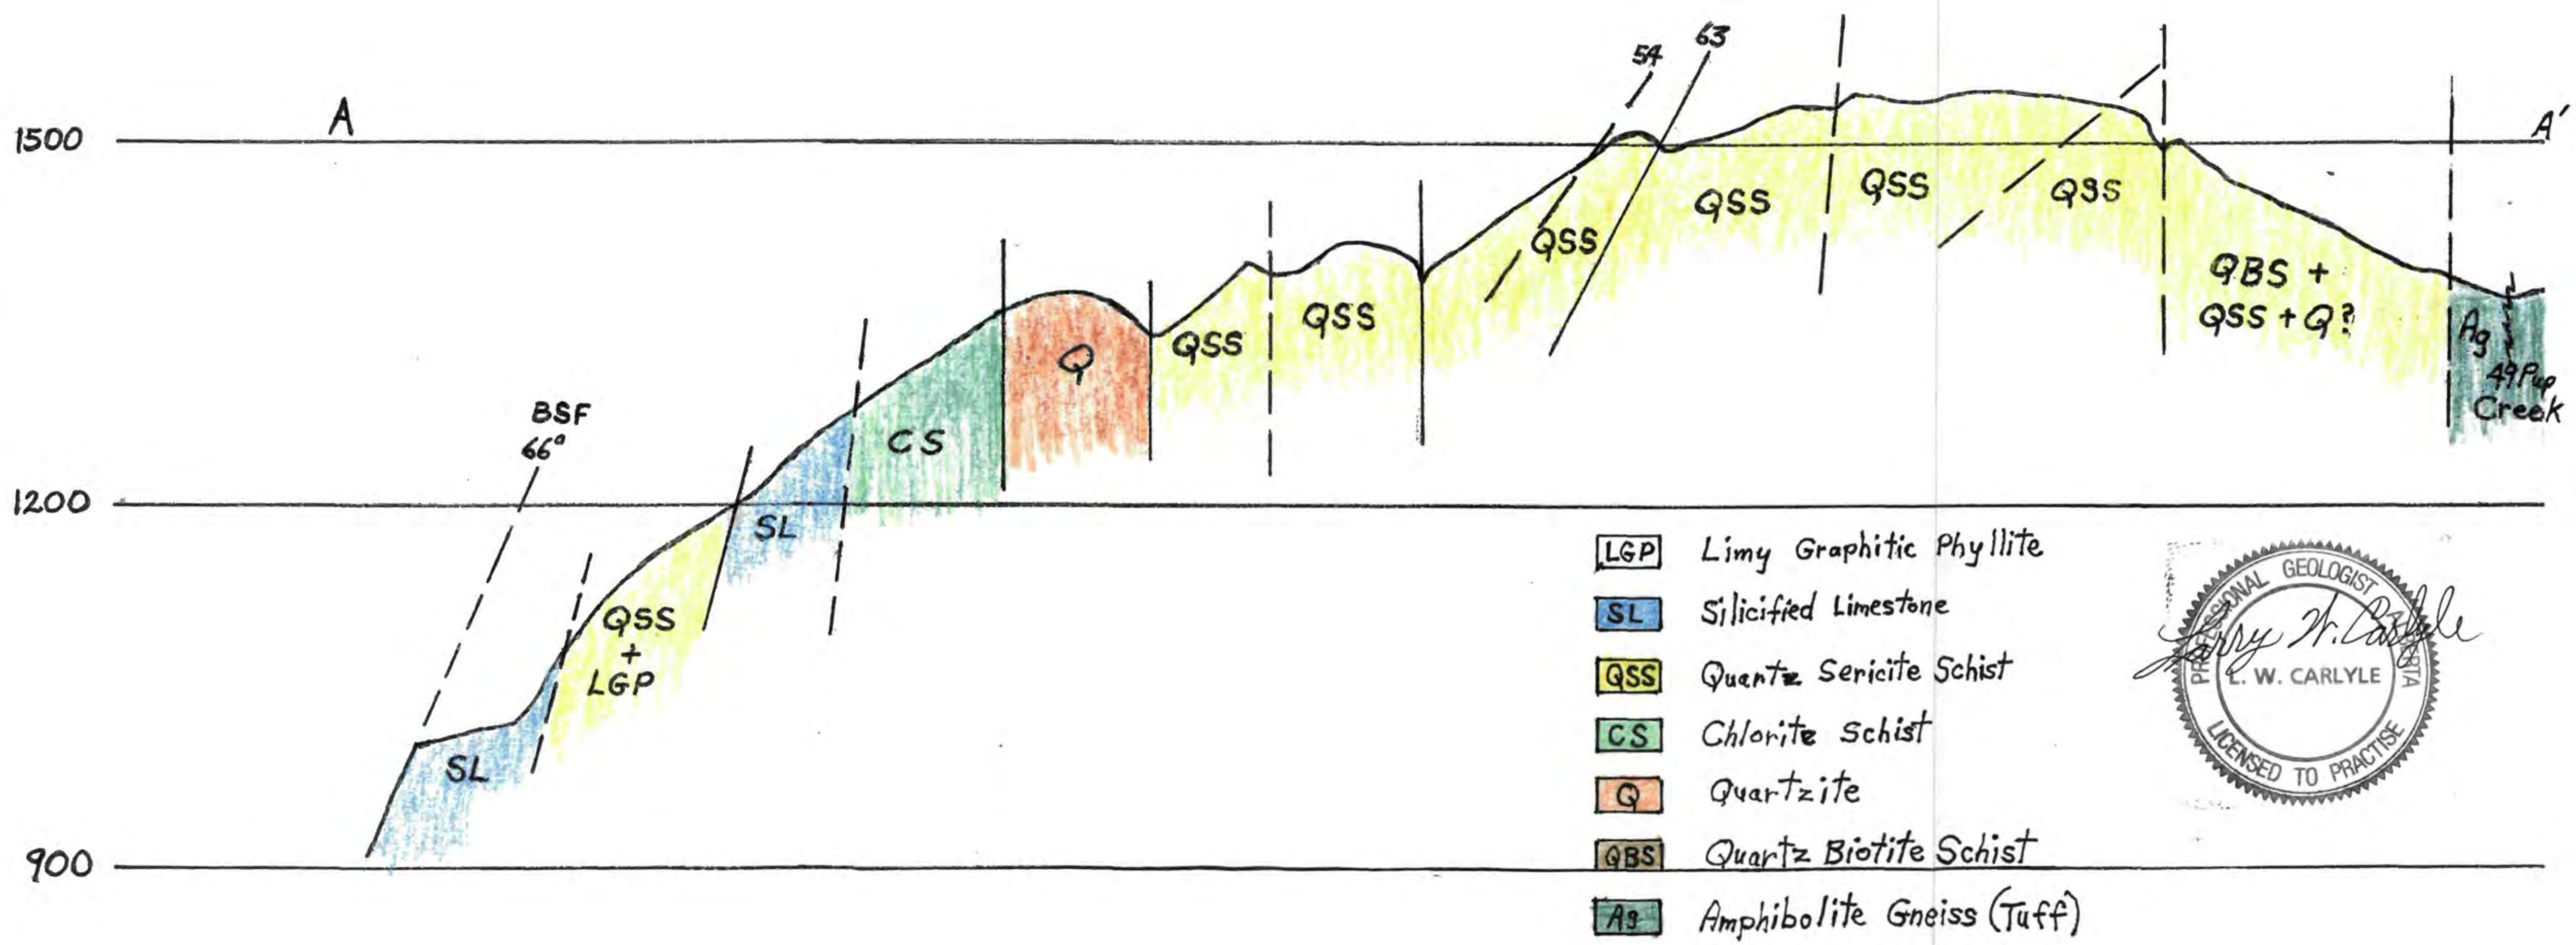
Most of the rocks mapped in the area appear to be metamorphic equivalents of near-shore sub-aqueous, beach, and sub-aerial sedimentary rocks.

During mapping, special attention was paid to the following:

- Evidence for intrusive-related gold mineralization in stocks and plugs mapped by earlier geologists.
- Evidence for Carlin-type gold mineralization, which could be a source for some of the placer gold.
- Evidence for the existence of east-west striking faults down which some of the creeks may flow.

X-Section Looking N along ridge between Livingstone and Summit Creeks

SCALE 1:50,000



The intrusive stocks and plugs located within the area mapped by Cockfield, Lees, and Bostock (1936) were not found.

In spite of the straight and narrow courses of the creeks as they flow west through the Big Salmon Fault (BSF) and drain into the South Big Salmon River valley; no evidence was found to demonstrate that the creeks were following faults.

Only evidence of some characteristics considered to be important for the formation of Carlin-type deposits were located during the mapping (See Conclusions).

PROFESSIONAL GEOLOGIST W. CARLYLE ALBERTA LICENSED TO PRACTISE

Rock Units Used for Mapping:

LGP	Limy Graphitic Phyllite (possibly an argillite)
L & SL	Limestone and Silicified Limestone
QSS	Quartz Sericite Schist (resembles Klondike Schist)
CS	Chlorite Schist (frequently has small magnetite crystals)
Ag	Amphibolitic Gneiss (taken from Tempelman-Kluit)
Q	Quartzite (strongly resembles United Keno Hill Quartzite)
QBS & QBg	Quartz Biotite Schist and Quartz Biotite Gneiss
Sk	Calcium Silicate skarns
P	Pyroxenite (?)
Dyke	Dark grey to black, fine-grained, unmetamorphosed intrusive

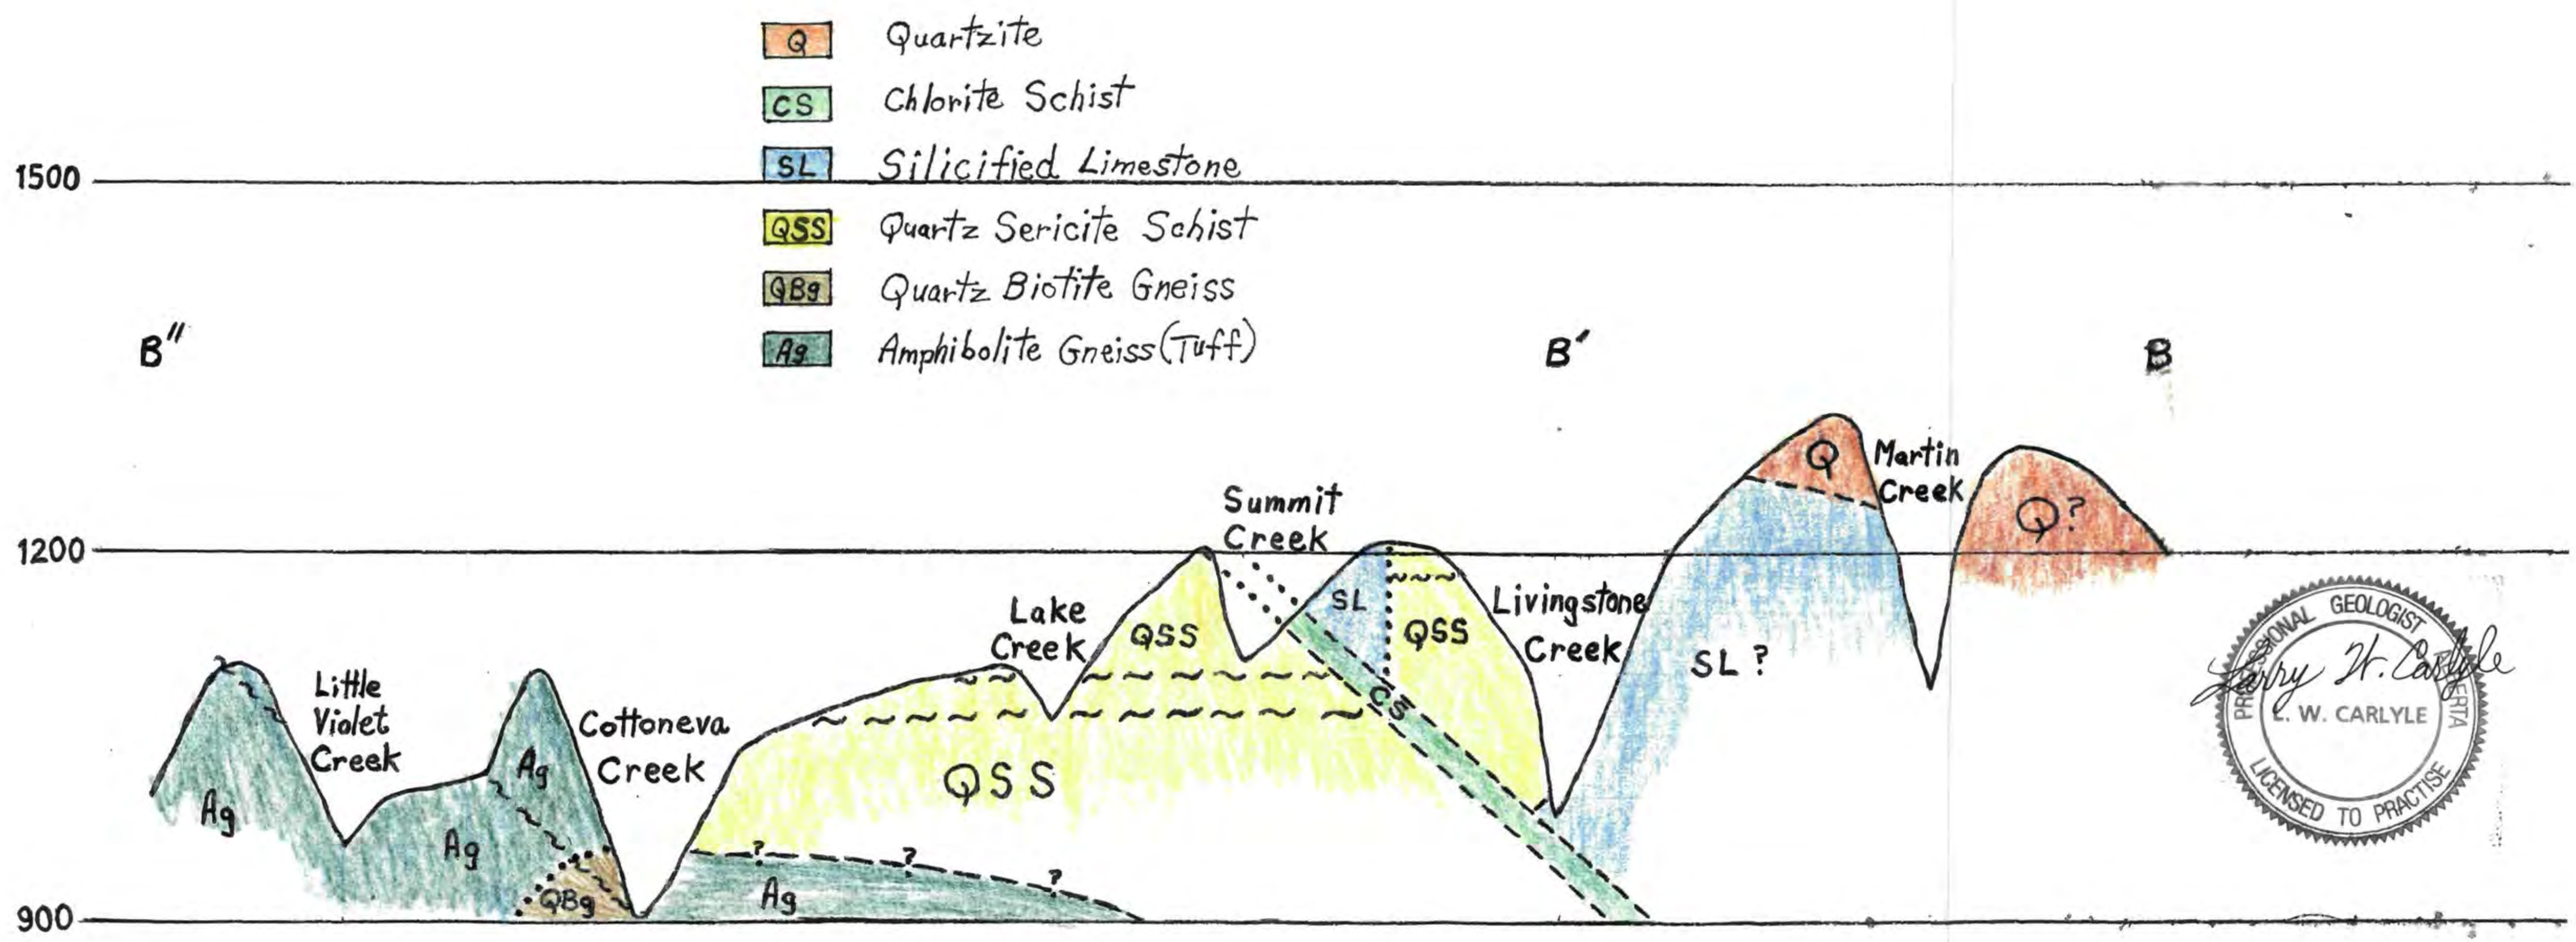
Rock Descriptions:

Limy graphitic phyllite (LGP) is a dark grey to black, fine-grained, schistose to slightly blocky phyllite. It is variably limy; having small white calcite lenses and caliche to having none at all. On schistose surfaces it has a satiny appearance.

Limestone (L) is light grey to white, blocky to schistose, with light brown iron oxide in fractures and on surfaces. It occasionally has white calcite lenses and generally reacts weakly to vigorously to 10% HCl. Contains < 1% pyrite crystals, usually oxidized.

X-SECTION LOOKING E ACROSS BSF
APPROX. 450m E OF BSF

SCALE 1:50,000



Silicified Limestone (SL) is the same as the limestone but appeared to have had significant amounts of silica added.

Quartz Sericite Schist (QSS) is strongly schistose, white to light brown-yellow iron oxide coated quartz-carbonate. Frequently reacts to 10% HCl and has caliche along fractures. Generally contains < 1% pyrite crystals, usually oxidized. The petrographic analysis has demonstrated that the limestone, silicified limestone, and the quartz sericite schist (Samples 1 and 3 – Appendix A) are probably all metamorphically recrystallized quartz-carbonate rocks. They contain very little sericite; what was considered to be sericite is most likely limonite. The silica, which was thought to have been added to the limestone, is most probably an original constituent. In spite of this petrographic clarification, the original rock designations will be maintained for the sake of clarity among property workers.

Chlorite Schist (CS) is a dark olive green, fine-grained schist. It frequently contains small euhedral magnetite crystals and possibly is the metamorphic equivalent of a basalt. The magnetite crystals appear to be strongest along the eastern contact of the zone and may represent the bottom of the original bed.

Amphibolitic Gneiss (Ag) is a light to dark green, laminated, quartz-feldspar-hornblende gneiss. Petrographic analysis (Sample 2 – Appendix A) suggests it may have originally been a felsic to intermediate tuff.

Quartzite (Q) is a fine-grained, blocky, black quartzite with small lenses of fine-grained white quartz. It is most probably intercalated with the limestone and quartz sericite schist, in bands of less than 10 metres in width. Some light grey quartzite has been seen in the placer excavations, probably representing alteration after metamorphism.

Quartz Biotite Schist (QBS) and Quartz Biotite Gneiss (QBg) are medium-grained, laminated quartz and biotite rocks of uncertain origin. The composition of both rocks seems to be similar and the schist or gneiss designation was determined by their textural appearance. They may have an intrusive origin but this is not clear. They have been seen most frequently near the contact between quartz sericite schist and amphibolitic gneiss. They may, therefore, represent an alteration zone between these rocks.

Calcium Silicate Skarns (Sk) have only been seen north of Little Violet Creek next to the Big Salmon Fault (BSF) [See Geological Maps]. They occur in irregular zones of garnet, actinolite, tremolite (?), and diopside skarn intercalated with amphibolitic gneiss. The zones may represent limestone lenses caught in the gneiss and subsequently altered.

Rock Descriptions (Continued):

Pyroxenite (?) (P) is an anhedral, occasionally botryoidal, black to dark green rock assumed to be composed of pyroxene minerals. It has only been seen west of the relatively fresh but strongly sheared limestone on the north face of Mendocina Creek canyon (See Geological Mapping).

Dyke is a dark grey to black, fine-grained intrusive containing large (up to ¾ inch) altered k-feldspar phenocrysts and smaller (up to ½ inch long) hornblende phenocrysts. Petrographic analysis (Sample 4 – Appendix A) indicates the dyke rock is quartz-free of monzonitic composition and is unmetamorphosed. Dykes have only been seen in Livingstone and Summit Creeks and on the ridge between the two creeks. Where the dykes have been mapped, they have fault contacts with the country rocks; suggesting that they were emplaced after metamorphism was complete.

VLF – EM SURVEYING:

Five lines of VLF-EM surveying were done:

1. Summit Falls Road: To get an idea of the depth of fill within the Big Salmon Fault (BSF). The survey indicated that the fault is deepest approximately 75 metres east of the Livingstone Creek road. (See profile)

2. Old Sawmill Site: To get an idea of the depth of fill within the Big Salmon Fault. The survey indicated that the fault is deepest approximately 50 metres east of the Livingstone Creek road (See profile).

3. Livingstone Creek Road: To get an idea of the depth of fill within the Big Salmon Fault and get an indication of the number of faults which cross the road. The BSF seems to be deepest against the hill at the west end of the survey. Several cross-faults seem to cut the road. They seem to be stronger and more numerous as the BSF is approached.

4. Adit Road: To get an indication of the number of cross-faults which cut the road. Only one was discovered at approximately 125 metres east of the top of the switchback. Weak gold mineralization was discovered at this location by later grid soil sampling.

5. Ditch: To get an indication of the number of cross-faults which cut the ditch. Three or four weak crossovers were located (See chart) but have not been followed up.

ROCK SAMPLING:

Only 17 rock samples were taken during the year. Most of these samples were again primarily from the area being placer mined at the base of Livingstone Creek canyon (See 1999 Rock & Stream Sediment Samples Map and Rock Sample Chart). Most of the samples taken from the Livingstone canyon area were to investigate the potential for Carlin-type mineralization.

The most significant of the rock samples taken during the geological mapping were L99 – 4 and L99 – 8. L99 – 4 is orange-brown iron oxide fracture fillings in grey fine-grained quartzite with minor white, weakly vuggy quartz lenses and up to 1% pyrite which returned 113 ppb. gold. This sample was taken from the ridge in the area of the headwaters of 49 Pup Creek and may indicate that the structure believed by Friedrich and Stroink to pass through this area may exist. L99 – 8 was taken from the top of a ridge west of the headwaters of May Creek. It is a highly iron oxided, vuggy quartz vein containing slightly limy, amphibolite inclusions and no visible sulphides. It returned only 22 ppb. gold but 148 ppm. arsenic. This may indicate mineralization associated with the strong N-S striking fault believed to run up May Creek and across the headwaters of Livingstone Creek.

Grab samples L99 – 14 and 15 of amphibolite gneiss containing quartz and hematite in fractures from the adit area returned gold assays of 369 ppb. and 579 ppb. respectively (See Rock Sample Table). These values, in addition to the high-grade mineralization already exposed in the area, indicate that more work, possibly including diamond drilling, is needed at this site.

SOIL SAMPLING:

Soil sampling was done at three sites during 1999.

Adit Site:

Additional sampling extended the expected strike length of the adit structure by a further 100 metres both uphill and downhill from that exposed during 1998 (See gold, copper, and arsenic plots included). Some significant mercury analyses (up to 800 ppb.) were obtained from some of the 1999 samples. Mercury was not plotted since the earlier samples had not had it determined at this precision.

Switchback Site:

3 lines of soil samples were taken over a structure discovered by a VLF-EM survey done along the Adit Road (See 1999 Soil Sample Locations Map). Weak coincident anomalies in gold, copper, and arsenic (See sample plots) outline a weak structure in the area. A zone of high mercury analyses occur slightly SE of the weak structure (See sample plots).

Livingstone Canyon:

Soil samples done along the north ridge of Livingstone Creek in 1997 started at the first claim line which is 450 metres upstream from the bottom of the canyon. Extending the sampling to the bottom of the canyon both on the north and south sides of the canyon could demonstrate the presence of structures cross-cutting the area (See 1999 Soil Sample Locations Map). The analyses in gold were as high as 46 ppb. and were associated with weak values in mercury, arsenic, and copper. The values, although occasionally interesting, were too low and too erratic to clearly demonstrate the existence of structures (See Soil Sample Chart).

CONCLUSIONS:

Only evidence of some characteristics considered important for the formation of Carlin-type deposits were located during the mapping.

1. Proximity to a buried continental margin.

   Many of the Carlin deposits are aligned east of the buried continental margin in Nevada. This is thought to reflect a fundamental deep crustal structural control on ore deposition. Stevens and Erdmer, de Keijzer and Williams, and others have suggested that the rocks presently in the Livingstone area have been ramped onto the North American craton with the craton's margin being west of Livingstone near the Teslin River.

2. Complex folding and faulting, perhaps in more than one phase, make up the geological history.

   Strong folding and faulting has been recognized at Livingstone since its discovery. There have been at least two periods during which rocks were ramped onto the North American craton; Devonian to Permian sedimentary and volcanic rocks of the Yukon Tanana Terrane and Permian to Mississippian oceanic crustal rocks of the Slide Mountain Terrane.

3. Mineralized bodies are frequently localized adjacent to steep faults.

   All of the placer bearing creeks at Livingstone run through the Big Salmon Fault near, or at their base. This fault, therefore, could be the main host fault for a Carlin-like system. High gold values obtained from soil samples near the fault on both the north and south ribs of Livingstone canyon (See soil sample chart) would re-enforce this thought. The mapping done during 1999 shows that there are numerous faults running sub-parallel to the Big Salmon Fault. Earlier writers have indicated that these faults have dextral strike-slip motion, and evidence from this study indicates they are normal faults. Steep faults with normal displacement are common within Carlin-type systems. These smaller faults at Livingstone appear more prevalent closer to the Big Salmon Fault and many of them cut through the most prospective silicified limestone and quartz-sericite schist rock types.

4. Impure carbonates are the most common host rocks.

   Petrographic analysis of what were believed to be silicified limestone and quartz-sericite schist are, in fact, metamorphically recrystallized quartz-carbonate rocks whose most likely origin was a silty or cherty dolomite. Only 0.5 % – 2.0 % sericite was found in the samples.

5. Mineralization is not obviously part of a zoned magmatic-hydrothermal system (not necessarily associated with a stock).

   Although intrusive rocks were mapped by earlier workers in the area, none were recognized during this study. However, several zones of quartz-biotite schist (QBS) and quartz-biotite gneiss (QBg), in the current mapping were likely previously identified as intrusive rocks. During the 1999 work, these rock types were considered to be neither extensive nor continuous enough to be stocks or plugs. Their location suggests that they may be contact or alteration zones between the rocks mapped as quartz-sericite schist (QSS) and amphibolite gneiss (Ag) [See geological map].

   The only large intrusive recognized in the area is the mid-Cretaceous batholith located near Mt. Black approximately 14 -17 kms. (10 - 12 miles) southeast of Livingstone Creek. A smaller, but similar, intrusive has been mapped north of the headwaters of Dycer Creek.

6. Many mineral deposits are beneath caps of siliciclastic or volcanic rock.

At Carlin, structural traps and reactive sedimentary rocks are believed to control ore deposition. Ore is confined to a host fault system, or is spread laterally in calcareous silty rocks, or in a combination of these structural and stratigraphic settings. At Livingstone, structural traps such as fold hinges or thrust faults were not recognized; however, if the amphibolite gneiss lies above the quartz-sericite schist and its protolith is a felsic to intermediate tuff as the petrography suggests; a stratigraphic trap may exist. Southwest-northeast oriented cross-sections through the area have shown the typical "anticlinal" aspect exhibited by many Carlin-type deposits (See Cross-Section).

7. The common presence of dykes is considered to be evidence of magmatic activity.

Unmetamorphosed, quartz-free, feldspar-hornblende porphyry dykes of monzonitic composition have been located in Livingstone and Summit Creeks. The fact that these dykes are unmetamorphosed suggests they are related to an intrusion which post-dates the metamorphism, possibly the mid-Cretaceous batholith mentioned earlier.

Discussion of Carlin-type Mineralization at Livingstone:

1. Much of the placer gold recovered from Livingstone Creek has associated magnetite. This suggests the existence of a magnetite skarn in the area – such a skarn has not been found to the present time.

2. Although the placer gold recovered from the 1999 excavations within the calcareous units is generally much finer than that usually recovered, it is far larger than the micron-sized gold of Carlin deposits. It also seems to be located within narrow iron-rich clay fillings in the cracks and joints of the rock and not within the rock itself – this suggests a hydrothermal origin to the gold.

3. Many Carlin-type deposits are located below thrust faults and within zones of brecciation – neither thrust faults nor breccia zones have been recognized on the property.

4. The short course on thermal aureole gold deposits (TAG) at the 1999 Whitehorse Geoscience Forum demonstrated that several of the Carlin-like characteristics discussed above are also present in TAG deposits. This suggests that this model should also be considered at Livingstone Creek.

RECOMMENDATIONS:

1. Exploration of the structure(s) in the adit area should be intensified. The high-grade values obtained from the 1998 trenches, the high-grade values obtained from the amphibolite gneiss samples L-14 & 15 (See Rock Sample Table), and the strike length extension of the structure(s) both uphill and downhill by the soil sampling done during the year; make this a high priority.

2. Grid soil sampling follow-up of newly discovered VLF-EM targets should be continued. The use of this technique to discover a new mineralized structure at the switchback on the adit road demonstrates the importance of this procedure.

3. Continuing to investigate for Carlin-type deposits at Livingstone should become an important pursuit.

4. The TAG (thermal aureole gold) deposit model should also be investigated since they have some of the same characteristics as Carlin deposits. Characteristics such as: a preference for calcareous rock units, several phases of fault reactivation, and an "anticlinal" aspect.

STATEMENT OF QUALIFICATIONS

I, LARRY W. CARLYLE, do certify:

1. That I am a professional geologist; resident at 74 Tamarack Drive, Whitehorse, Yukon Y1A 4Y6.

2. That I hold a B. Sc. Degree in geology from the University of British Columbia (1970).

3. That I am a Fellow of the Geological Association of Canada (F - 4355).

4. That I am a Registered Professional Geologist in the Association of Professional Engineers, Geologists, and Geophysicists of the Province of Alberta (41097).

5. That I have practiced my profession as a mine and exploration geologist for over twenty years.

6. The conclusions and recommendations in the attached report are based on work I performed or supervised on the property, and on a review of the references cited.

DATED at Whitehorse, Yukon, this 26th day of January, 2000.

SAMPLES:

4 rock samples, numbered 1 to 4, were submitted for sectioning and petrographic examination.

Field names given in the covering letter are as follows:

Sample 1. Quartz sericite schist
Sample 2. Amphibolite gneiss
Sample 3. Silicified limestone
Sample 4. Dyke

Typical portions of each sample were prepared as standard thin sections.

SUMMARY:

Samples 1 and 3 are metamorphically recrystallized quartz-carbonate rocks of uncertain origin (most likely silty or cherty dolomite). Sample 3 is an evenly fine-grained intergrowth of the two minerals, in roughly equal proportions, whereas Sample 1 has a higher dolomite/quartz ratio, shows banded grain-size variations, and is patchily impregnated with limonite. Both rocks contain low proportions of accessory sericite.

Sample 2 is a fine-grained, laminated, quartzose amphibolite. It consists dominantly of a poikiloblastic intergrowth of fresh plagioclase and quartz with wispy intercalations of mafic minerals - principally hornblende plus lesser epidote. The abundance of quartz, and relatively low proportions of mafics, suggest that its protolith may have been a felsic-intermediate tuff.

Sample 4 is an unmetamorphosed, quartz-free porphyry of monzonite composition. Its texture is consistent with minor intrusive origin. It exhibits partial sericitization of plagioclase, and epidote-chlorite-carbonate alteration of hornblende.

J.F. Harris Ph.D. (604) 929-5867

SAMPLE 1: SILICEOUS DOLOMITE

Estimated mode

Quartz	25
Carbonate	70
Sericite	2
Chlorite	trace
Limonite	3

The sectioned portion of this sample (see off-cut) shows banded compositional differentiation, defining apparent folded bedding. One component band in this sequence has an unetched, grey appearance. The adjacent one is buff-coloured. An imperfect laminar foliation which appears to cross-cut the banding may represent an axial plane cleavage.

Thin section examination shows that the rock is composed dominantly of carbonate, with intergrown quartz and minor sericite as accessories. The carbonate is unreactive to dilute HCl, and is probably dolomite or ankerite.

The macroscopically prominent grey band and the adjacent buff-coloured band are much less clearly distinguishable in the thin section. The former is not quartz (as it might appear), but consists of a varigranular, interlocking aggregate of carbonate as anhedral grains 30 - 300 microns in size, with quartz (of similar grain size) occurring as disseminated, individual, equant grains, strings and lenses, and small clumpy segregations. This unit contains only traces of sericite, as tiny individual sub-oriented flakes and rare concentrated wisps.

The buff-coloured unit differs principally in being of finer grain size, typically in the range 10 - 80 microns. It also contains slightly more abundant sericite, mainly concentrated as thin, semi-continuous schlieren with intergrown traces of chlorite. Its colour is apparently partly due to the presence of more or less abundant disseminated specks of dark brown material - most likely limonite.

Macroscopic examination of the thin section shows irregular and sub-parallel zones of speckled brown pigmentation (developed in both units). Microscopic examination shows that these are concentrations of limonite as rims to carbonate grains, and as intergranular pockets. The latter could be pseudomorphous after original disseminated pyrite - now oxidized by the effects of surface weathering.

This rock appears to be a siliceous dolomite - now more or less deformed and recrystallized. The present distribution of the quartz is consistant with origin as a clastic or chemically precipitated (chert) impurity in an enivronment of sedimentary carbonate deposition. There is no petrographic evidence to support a volcanic origin.

SAMPLE 2: **QUARTZOSE AMPHIBOLITE**

Estimated mode

Quartz	30
Plagioclase	45
Hornblende	14
Epidote	7
Chlorite	2
Muscovite	1
Garnet	trace
Apatite	trace
Opaques	1

The off-cut of this sample shows an undisturbed laminar foliation? defined by parallel strings of a fine-grained white-etched component alternating with dark and/or unetched material.

In thin section the rock is found to be made up of a granoblastic aggregate of colourless minerals, with thin, laminar, mafic-rich intercalations.

The colourless minerals consist of an intergrowth of quartz and untwinned plagioclase in uncertain proportions. Grain size ranges from 0.05 mm to 1.0 mm or more, and poikiloblastic textures are widespread. Much of the plagioclase occurs as relatively coarse, parallel-oriented, ovoid to sub-prismatic grains, sieved with smaller grains of quartz and, to a lesser degree, tiny grains of mafics. The plagioclase appears water-clear and totally fresh. Thin laminae composed largely of quartz alternate with thicker plagioclase-rich zones.

The fabric is clearly a product of metamorphic recrystallization, though the texture may reflect original porphyritic or volcaniclastic character.

The principal mafic constituent is a strongly pleochroic (straw-coloured to dark green) variety of hornblende, as slender, well-oriented grains up to 0.5 mm in length. These occur partly as dispersed individuals, but mainly concentrated as parallel swarms and as thin schlieren (up to 0.3 mm or so in thickness).

The commonest accessory is epidote, occurring in distinctive manner as tiny discrete granules 10 - 150 microns in size, in close spatial association with the hornblende.

Other minor components of the mafic assemblage are sporadic flakes of muscovite and chlorite, and specks of opaques (probably mainly Fe-Ti oxides). A single small porphyroblast of garnet was noted.

All the mafic constituents appear fresh, and apparently co-exist in equilibrium.

SAMPLE 3: **QUARTZ-DOLOMITE ROCK**

Estimated mode

Quartz	40
Carbonate	59
Sericite	0.5
Limonite(?)	trace

This sample is of closely similar character to Sample 1, but is texturally more homogenous and free of limonite impregnations.

It is of simple mineralogy, consisting of an intergrowth of non-reactive carbonate (probably dolomite) and quartz, plus traces of accessory sericite.

The rock consists dominantly of an equigranular intergrowth of quartz and carbonate, in approximately equal proportions, as anhedral grains 30 - 100 microns in size.

This assemblage locally gives way to crudely laminar or lenticular zones, up to 1 or 2 mm in thickness, in which dolomite is strongly dominant over quartz and exhibits coarser grain size (in the range 0.1 - 0.5 mm). The coarser dolomite is sometimes lightly speckled with brown (limonitic? bituminous?) inclusions.

Sericite is very minor overall. It occurs as rare, thin schlieren, and as individual, sub-oriented, intergranular flakes in one local zone of the fine quartz/dolomite aggregate.

The origin of this rock is uncertain. The present fabric is probably one of recrystallization - most likely of an original silty or cherty dolomite of sedimentary origin. There is no positive evidence to support the suggestion that the quartz component is of introduced (silicification) origin.

SAMPLE 4: **MONZONITE PORPHYRY**

Estimated mode

Plagioclase	4
Sericite	8
K-feldspar	60
Hornblende	17
Epidote	4
Chlorite	1
Carbonate	5
Apatite	trace
Opaques	1

This sample differs compositionally from the others of the suite in having a major content of K-feldspar (see yellow cobaltinitrite stain on the off-cut), and in exhibiting a non-foliated, prominently porphyritic, primary igneous texture.

Thin section examination shows that the rock consists of occasional coarse phenocrysts of altered plagioclase, plus abundant smaller phenocrysts of partially altered mafics, in a groundmass of K-feldspar and minor plagioclase.

Scattered, rounded to sub-prismatic phenocrysts of original plagioclase, 2 - 6 mm in size, show strong pervasive alteration to fine-grained sericite, plus lesser epidote and carbonate. Some of them have inclusions (remnants?) of K-feldspar.

The mafic phenocrysts, typically 0.1 - 0.5mm in size, are euhedral-subhedral hornblende. These show varied degrees of alteration (ranging from essentially nil to total) to epidote, carbonate and chlorite.

Scattered clumps of opaques (not well represented in the thin section) appear from the off-cut to be mainly sulfides (pyrrhotite?).

The phenocrysts occur scattered, with random orientation, through a microgranular groundmass of grain size 10 - 100 microns, composed essentially of K-feldspar and lesser turbid plagioclase. It also incorporates minor mafics and small pockets of carbonate (totally altered mafics?).

The sectioned area includes an area of about 2x2 cm in which the groundmass shows a much lower K-spar/plagioclase ratio, and small mafic phenocrysts are notably abundant. This appears to be a xenolith.

This rock is quartz-free, and is clasifiable as monzonite. It appears unmetamorphosed. Its texture is consistent with a minor intrusive (dyke rock).

APPENDIX B

ANALYTICAL CERTIFICATES
