AUGUST 1994

ABSTRACT

A heap leach field test was conducted during the 1993-1994 winter season at Carmacks, Yukon Territory. The test was performed to demonstrate the viability of heap leaching Carmacks Copper ores in a sub-Arctic setting. Western Copper is proposing to process ore on a year-round basis. This test was modeled after the successful winter leaching operation of Pegasus Gold at their Zortman, Montana mine. In the latter operation, the leachate distribution system is overlain with approximately one meter of crushed ore. The over layer, plus a variable snow cover, adequately insulate the heap and permit year-round operation.

The test itself utilized an approximately 5 meter diameter crib loaded with a composite of ore from the northern (higher grade) end of the Carmacks Copper deposit. The 250 tonne bulk sample was stacked in the crib to a total height of 7 meters, including one meter of ore on top of the emitter system. This matched the commercial heap height planned for Carmacks Copper at the time the test was started. By insulating the side walls of the crib, lateral heat flux was minimized. Thus, the crib replicated an interior segment of the commercial heap.

Leaching was done at a flow rate that matched those commonly used in industry. Leachate temperature was approximately 21°C, a level achieved with no external heat input other than normal process heat transferred from electrowinning to the leachate via solvent extraction.

An analysis of the test results showed that the winter conditions at Carmacks were quite typical of those expected at the mine site. Conditions included ambient temperatures below minus 45°C and an average temperature of minus 13°C.

In terms of leachate flow to and from the crib, the test ran continuously from late September through mid-February. In spite of some flow system problems, leaching continued unabated. There was no freezing in the interior of the crib. Freezing was limited to the insulating ore over layer and a few isolated points high in the crib near the outer walls.

The test clearly demonstrates that year-round heap leaching of Carmacks Copper ore is practical. The heap appears to be adequately insulated by a 1 meter ore layer on top of the emitter system. Normal process heat should be sufficient to maintain a leachate return temperature of approximately 20°C at the heap. However, provisions should be made for supplemental heating in the commercial operation. This would permit recycle of the heated solution if electrowinning goes off-line or if there is a long run of exposed leachate pipeline back to the heaps.

INTRODUCTION

A comprehensive heap leach field test was conducted during the 1993-1994 winter season at Carmacks, Yukon Territory. The test was performed to demonstrate the viability of heap leaching Carmacks Copper ores in a sub-Arctic setting. Western Copper Holdings Limited is proposing to process ore on a year-round basis. The site selected for this study was Carmacks, Yukon Territory, Canada. Carmacks is located 40 kilometers from the Carmacks Copper project site. Thus, the location is anticipated to have sub-Arctic conditions similar to those expected at the proposed mine site.

There is little operative knowledge or published information available for leaching at extreme latitudes where sub-freezing conditions occur continuously for several months. Therefore, the benefits of the sub-Arctic study are obvious. A detailed study will quantify the heat losses from the heap, consequently defining the heat input necessary to maintain a continuous year round operation. Results then permit accurate thermal modelling of a commercial operation. The overall objective of the proposed test work was to demonstrate that leaching during the winter season is practical.

The proposed operational plan for the mine has been patterned after one used by Pegasus Gold at the Zortman heap leach gold mine in Montana. At Zortman, winter operations are maintained by installing drip emitters and burying them under approximately 1 meter of ore. The Zortman mine has successfully operated for several years under extreme winter conditions occasionally approaching those normally experienced at Carmacks.

The field program at Carmacks involved the construction of a highly instrumented, full height segment of a commercial ore heap. Also included were leach solution distribution and collection systems and a small solvent extraction - electrowinning (SX-EW) facility to decopperize and recycle leach solution. Both thermal and metallurgical (leaching) aspects of heap leaching were studied in detail. However, only the thermal aspects are presented and discussed in this report. Metallurgical performance can not be fully assessed until the ore heap is subjected to a detailed post mortem examination. This is scheduled for the summer of 1994, after which time a metallurgical report will be prepared and issued.

Partial funding for the project was provided by the Canadian/Yukon Geoscience Office as part of the Mineral Development Agreement.

DESCRIPTION OF FACILITIES

The ore was leached in a plywood test crib. The crib was octagonal in shape with a centre wall to centre wall diameter of approximately 5 meters and a height of 7.6 meters (Figures 1, 2, 3). The crib was constructed using 2.45 meter long, 7.6 centimeter thick X 20 centimeter wide planks reinforced with steel beams (0.64 centimeter thick X 7.6 centimeter wide). The beams over lapped at the ends and were locked together with 19 millimeter redi-rods inserted through holes in the end of each beam. These rods were joined with connector nuts so that they ran the

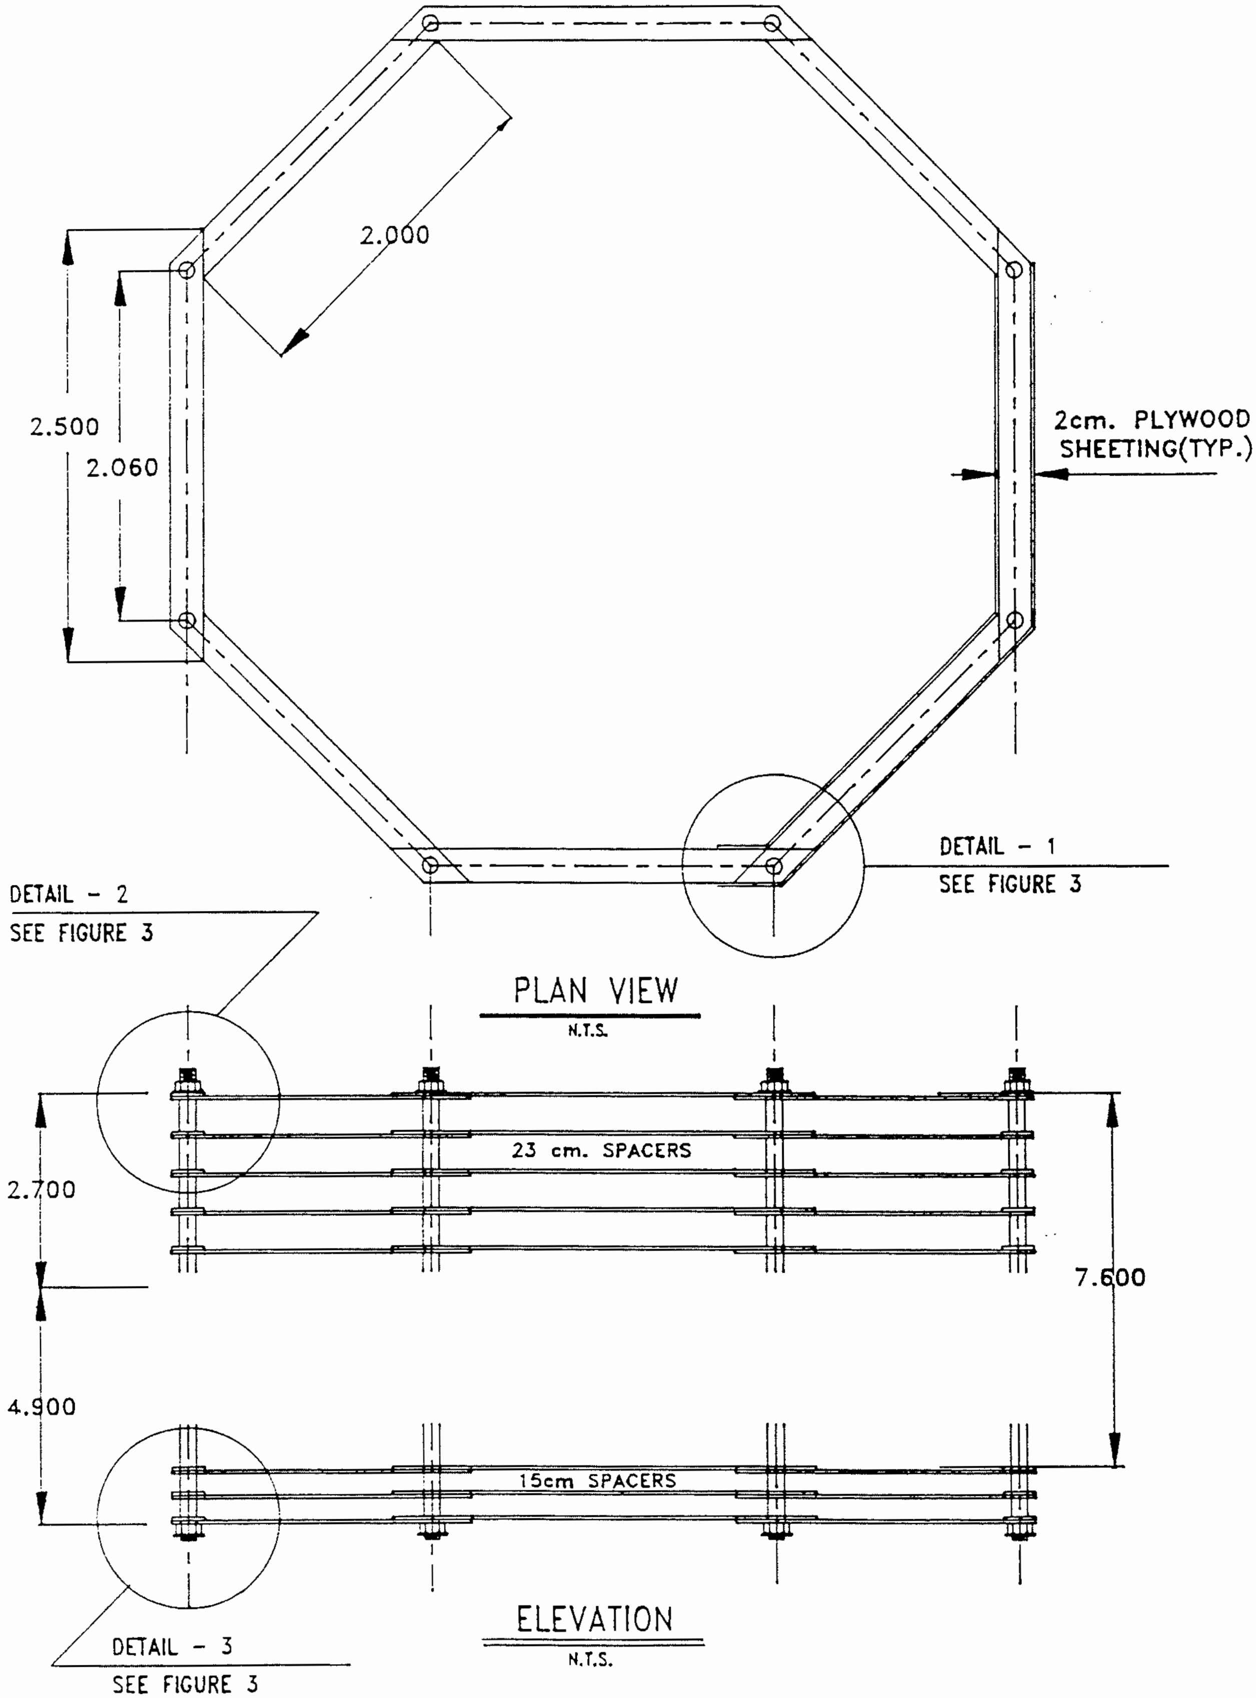

Figure 2: TEST LEACH CRIB DESIGN

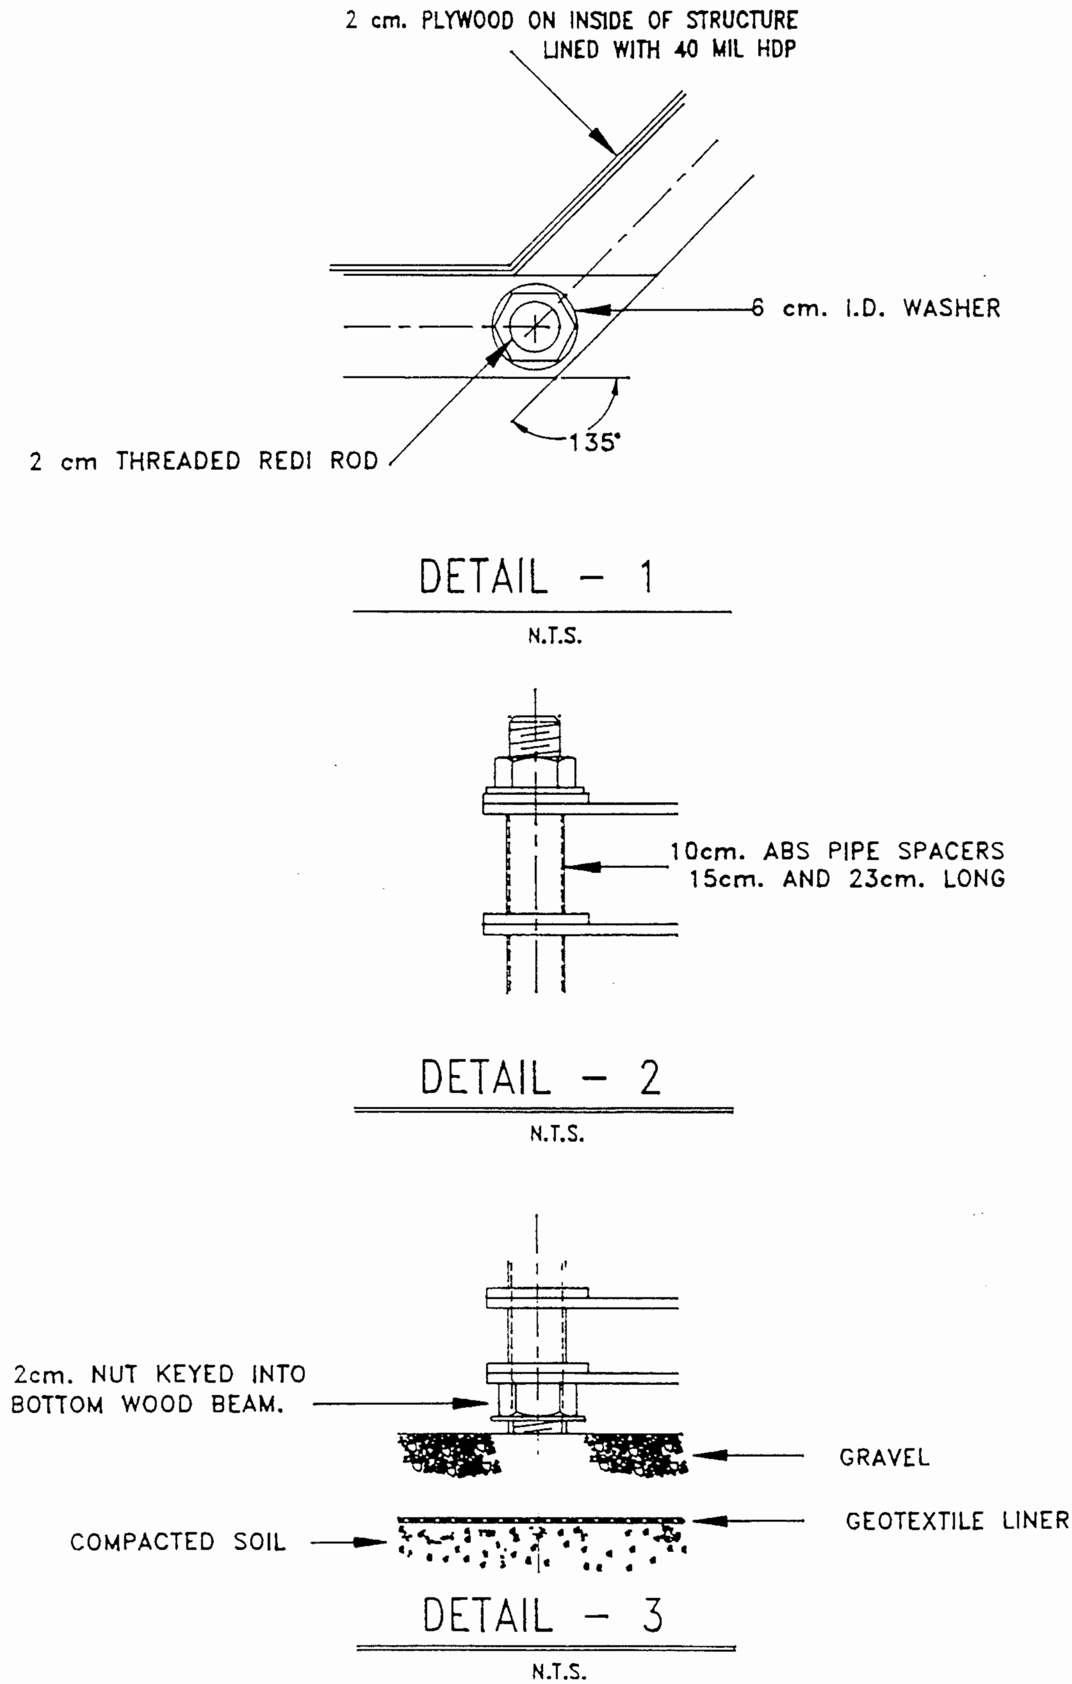

Figure 3: DESIGN DETAILS

full height of the crib. Spacers made from 10 centimeter diameter ABS pipe sections were used to reduce the number of planks needed. Spacers were 15 centimeters high over the bottom half of the crib and 23 centimeters high over the top half. The interior of the crib wall was lined with plywood sheeting, 19 centimeters thick.

Due to the large extent of a commercial heap, horizontal heat flux will be minimal except around the outer edge of the heap. This condition was simulated in the crib by placing fibreglass insulation (R32) between the beams and covering the entire crib with plastic sheeting. An additional 5 centimeters layer of Styrofoam insulation (R20) was placed over the sheeting and a second layer of sheeting was placed over the Styrofoam. The total insulating value of the insulation layers and sheeting was estimated to be approximately R60.

Prior to construction of the crib, the area was covered with 30-mill thick HDPE sheeting. This was supported on both sides with geotextile fabric. About 15 centimeters of crushed rock was placed on top of the liner and sloped to a lined event pond. The liner provided secondary solution containment. After erecting the crib, the edge of the liner was raised and dirt was packed underneath to provide a diversion/containment berm around the crib.

In order to simulate in-pile impoundment of leach solution, a 2 meter high cup shaped PVC liner was installed in the bottom of the crib. A 0.6 meter deep flooded zone was maintained by installing a slotted standpipe through the liner. In an emergency, the PVC cup could provide storage for all leach solution in the crib. The upper crib walls were lined with HDPE sheeting to direct solution flow to the PVC cup.

In the latter stages of the test, make-up water was drawn from the flooded zone. By November 20 (DAY 54) the reservoir had been completely drawn down and was maintained at this level for the rest of the test.

A array of temperature probes (sensors) was located in the crib, in the underlying soil, and other ambient locations to determine: heat/loss (gain) into the air and ground, lateral heat loss through the crib walls, solar flux on the side of the crib, and ambient conditions. In total, 48 sensors were installed and connected to six 8-channel data loggers. Details on the sensor locations are given in Table 1 and Figure 4. The data loggers were set to record temperatures every five minutes and report an hourly average.

PVC piping was used to move solution in and out of the pile. Loading of the crib was stopped to allow installation of an irrigation header along the west wall of the crib after ore reached the 6 meter level. Drip emitter piping was connected to the header every 50 centimeters. There was a 45 centimeter spacing between emitters. Variable flow emitters were installed to allow flexibility in the solution application rates. A duplicate header and irrigation lines were installed in the event of a failure of the primary line. All exterior piping was heat traced and insulated. A plan view of the irrigation system is included in Figure 4. The bottom drain was also located along the west wall.

DESCRIPTION OF LEACH MATERIAL

A 250 tonne bulk ore sample was excavated from three trenches, representative of the ore at the north end of the deposit. This is the higher grade portion of the deposit and accounts for the bulk of recoverable copper. The number of trenches sampled was minimized in favour of increased sample depth to obtain unweathered ore. A minimum of 4 meters of bedrock was blasted and removed before mining the samples. The samples were excavated from a 1.5 meter wide cut blasted across the full width of the ore zone exposed in the bottom of each trench.

Ore from each trench was segregated and transported to the test site in Carmacks. The ore was reduced to minus 2.5 centimeters with a portable two stage closed circuit crusher. A representative metallurgical sample was cut from each trench and shipped to Vancouver where it was sieved into five fractions, weighed and analyzed. The results are as follows:

	TRENCH T91-20		TRENCH T910-21		TRENCH T91-02	
SIEVE FRAC.	**WEIGHT** %	**Cu** %	**WEIGHT** %	**Cu** %	**WEIGHT** %	**Cu** %
-3/4 + 1/2	17.97	0.68	23.00	0.80	22.7	0.92
-1/2 + 3/8	12.3	0.78	15.7	0.86	14.8	0.96
-3/8 + 1/4	13.4	0.86	13.9	0.93	14.4	1.02
-1/4 + 6 MESH	14.4	1.06	14.1	1.05	14.4	1.12
-6 MESH	41.9	1.42	33.3	1.91	33.7	2.06
AVERAGE		1.08		1.23		1.35

Three methods of sampling were used to establish the ore grade in each trench: compositing the blast hole cuttings, chip sampling the trench walls, and size analysis of crushed sample splits (see table above). Assays were then performed on appropriate samples.

TRENCH #	**DRILL CUTTINGS**	**CHIP SAMPLE**	**METALLURGICAL SAMPLE**
T91-20 (800N)	1.20	1.50	1.08
T91-21 (1200N)	1.48	1.64	1.23
T91-02 (1700N)	1.25	1.53	1.35

These values are somewhat lower than those obtained from blast hole cuttings and chip samples. Therefore, confirmation of the ore grade must await final sampling of the leached material in the crib. However, the grade is expected to be near 1.3% copper.

Metallurgical testing had previously demonstrated that acid preconditioning improves leaching efficiencies. Therefore, batches of ore were blended in a cement truck proportionate to the sample weights mined from each trench. Concentrated acid and water in a 1:1 ratio, were added to the ore as it was being loaded into the truck. A total of 15 kilograms of acid was added per

TABLE 1

tonne of ore. The ore was mixed for three to five minutes and dumped onto an inclined conveyor which lifted the ore to the top rim of the crib.

In order to reduce compaction or breakup of the preconditioned material, drop off from the end of the conveyor was held to less than 3 meters. The walls of the crib and conveyor were raised in 1.2 meter lifts as the crib was being filled. Ore was dropped against the east wall of the crib. The surface of the pile was allowed to build up at the natural angle of repose. This is similar to an actual operation where the ore is dumped on the top edge of a new lift and allowed to cascade down the open face. After the leachate distribution system was installed, an additional 1 meter of ore was added to the top of the pile. Eventually, a layer of snow also accumulated on top of the ore.

Lakefield Research supplied a SX-EW pilot plant which was used to decopperize the pregnant leach solution (PLS) prior to recirculation back into the pile. The solvent extraction portion employed a 2 X 2 circuit of extraction and strip mixer-settlers. The electrowinning cells comprised three tanks, each containing four stainless steel cathodes and five lead anodes. The electrodes were one quarter commercial size and weighed approximately 15 kilograms each. Copper was harvested manually by lifting the cathodes from each cell and peeling the copper off the sides. PLS was pumped into a 2000 litre storage tank. A solution inventory was maintained between 375 litres and 750 litres. Raffinate flowed by gravity from the extraction cells into the first of three 200 litre leachate tanks. Tank #1 had a bottom drain which allowed entrained organic to collect at the top of the tank. Tank #2 was fitted with instrumentation to control acid additions. Leachate was pumped from the third tank back to the top of the ore pile. Lean organic recycled to the extraction stage contained considerable entrained electrolyte. This was sufficient to keep the pH of the raffinate at less than 1.5 when combined with acid pickup from transfer reactions in the extraction stages. Hence, no additional acid was required.

A flow sheet for the SX-EW circuit is provided in Figure 5. The circuit and its operation will be discussed in more detail in the metallurgical report to be issued later.

OPERATION OF FACILITIES

As described above, the ore was pre-acidified before being loaded into the crib. Heat from acid hydration and reaction with the ore raised the temperature of the preconditioned material to about 35°C. The crib took four days to load during which time the top of each lift was exposed to freezing conditions through the evenings. The core temperature of the pile was still equilibrating between 27°C and 30°C at the time the irrigation was initiated.

Irrigation started on September 27, 1993 (DAY 0). Solution breakthrough at the bottom of the crib occurred 20 hours later. The SX-EW pilot plant was started as soon as sufficient PLS became available. The SX-EW plant was shut down on December 16, 1993 (DAY 80). However, heated leach solution was circulated through the pile until February 8, 1994 (DAY 134) and temperatures monitored until February 15, 1994 (DAY 141). Thermal conditions were monitored throughout the 141-day test by recording the temperature data using

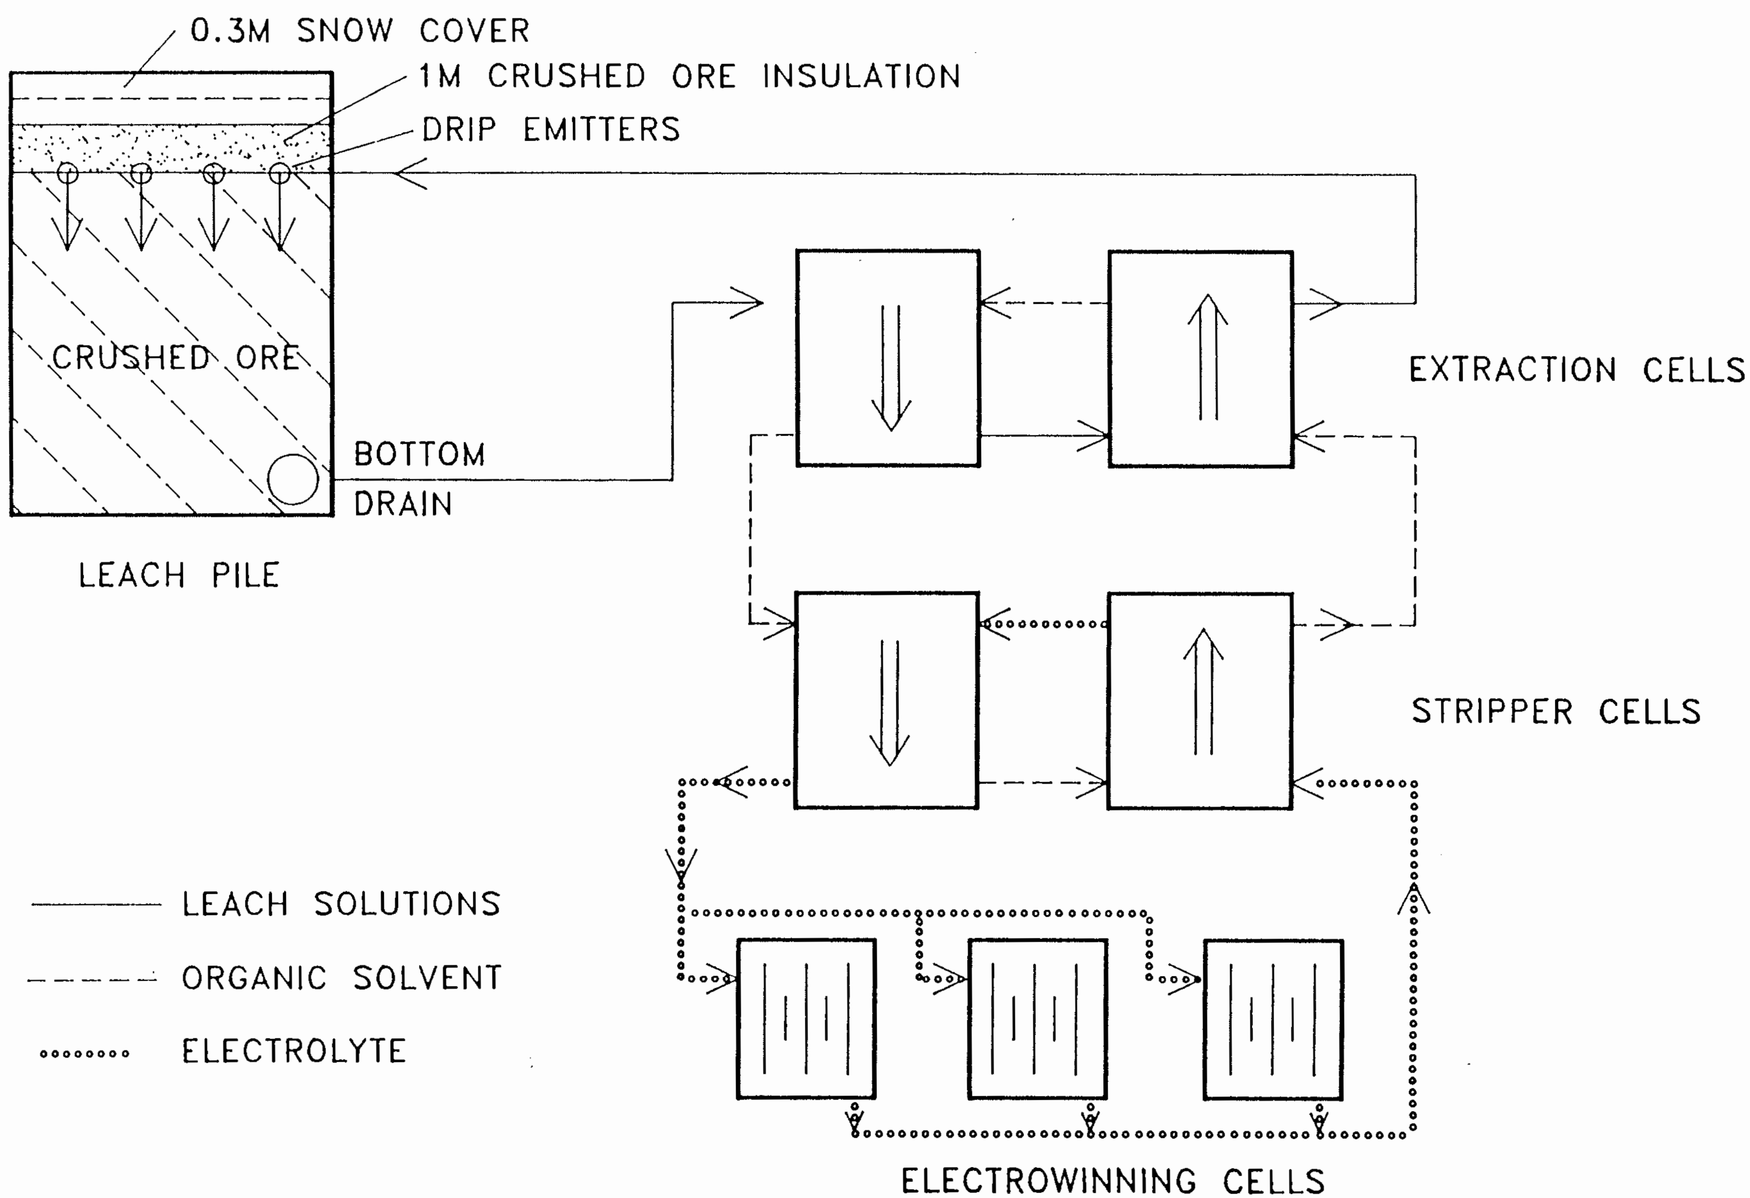

Figure 5: PILOT PLANT FLOW SCHEMATIC

the array of sensors. Other than the limited solar flux, the only heat input to the crib was in the leach solution recirculated back to the emitter system. Over the duration of the test this heat input averaged 720 to 1,000 Kcal per hour.

During the first 80 days of the test, there was no direct heating of the leachate. Only the electrolyte was heated to maintain an electrolyte solution temperature of 35°C. Electrolyte heating in commercial electrowinning plants is done to achieve optimum current densities and cathode quality. Heat was transferred from the electrolyte, through the organic into the leachate. This process heat transfer was sufficient to raise the average leachate temperature to 21°C from the average PLS temperature of 18°C.

When the SX plant was shut down, after December 16 (DAY 80), a heater in the leachate tank was used to maintain the solution temperature, simulating continued operation of the SX plant. Recirculation of the heated solution continued until February 8, 1994 (DAY 123) when the test was terminated. Temperature data was collected through February 15, 1994 (DAY 141) to follow the cool down of the system.

Every effort was made to minimize the lateral heat flux as this will approach zero in a commercial operation, except around the extreme edges of the heap. The lateral heat loss in the test was greatly reduced, however, there was some limited effect on the sides of the crib. Significant heat losses were attributed to solutions flowing from the crib and vertical fluxes into the soil below the crib and upward through the ore and snow layers above the emitters.

PRESENTATION OF DATA

Figures 6 through 9 include the ambient temperatures from temperature sensor C8.0 mounted above the top of the crib. This sensor is the highest and is affected more by wind than any other sensor. However, all seven ambient sensors tracked within a degree of each other. After the last week in November the temperatures (high, low, average) dropped below freezing and averaged minus 13°C for the remainder of the test.

Temperature data from the Faro area, 200 km east of Carmacks, was analyzed to determine the average conditions of the 6-year period 1985-1990. The Yukon Weather Centre (YWC) of Canadian Weather does not track conditions in Carmacks. According to YWC, Faro and Carmacks are very similar environments. Indeed, at minus 13.3°C, the daily average temperature for Faro during the 1985-1990 period is virtually identical to the minus 13.0°C seen at Carmacks during the 1993-1994 field test.

During the test period there was a close correlation between Carmacks and an average winter at Faro. Taking into account a warm spell in December and a cold snap in January at Carmacks, the temperatures at the two locations tracked within a few degrees of each other. The variance between daily high and low temperatures at Faro and Carmacks was particularly close.

Leach solution was detected outside the base of the crib in late December. The leak was traced to the point where the feed line for the header penetrated the crib. Here the pipe was melted by heat tracing which had shorted due to acid attack. Consequently, only the west side of the crib was being irrigated. During repair it was found that the heap had subsided about 45 centimeters or 7.5% and several irrigation lines had pulled away from the header. Leach pile settlement is quite normal during the initial leach cycle. The irrigation lines were re-attached to the header and normal flow was established on January 18 (DAY 113) which resulted in a sudden temperature rise detected by most thermistor probes.

In relation to the highly variable ambient temperature, the heap showed much greater thermal stability. Note that the heap had sufficient heat capacity so that it only responded to seasonal and not daily fluctuations in ambient conditions. Periods of extreme cold lasting 7 to 10 days had limited or no effect on most probes.

Temperatures within the crib had a much greater sensitivity to the temperature of the irrigating solution than to external conditions. Leachate temperatures were consistently between 20°C and 22°C up to January 10 (DAY 100) at which time the temperature was increased to 30°C. This was done to reduce the amount of time required to return the pile to the approximate temperature when the header severed. Leachate temperatures were maintained at these levels until January 27 (DAY 122) when they were returned to 21°C. PLS temperatures were consistent throughout the test, varying between 14°C to 20°C. The warming trend in the pile continued even after the temperature of the leachate was reduced.

Temperature probes located 0.15 meters above the crib bottom showed a consistent decline in temperature. The probes 45 centimeters in from the walls were all approaching or slightly below freezing. These temperatures reflect frost penetrating through the soil under the sides of the crib. The central probe was the same temperature as the underlying soil.

At 3.0 meters above the crib bottom, probes against the north, south and east walls measured the chilling affect around the sides. By the end of the test, temperatures in these areas slowly decayed to slightly above or below freezing. Variations in the slopes of the curves correspond to both high and low ambient temperature spikes. After January 13 (DAY 108) the temperatures were consistently within 3°C of freezing.

On the west sides of the crib, up to December 17 (DAY 81), probe W 3.0 was consistent, varying up to 2°C above or below 20°C. This corresponds with the temperature of the leachate being pumped back on top of the pile. On Day 81, the measured temperature began to drop to an eventual low of 6.3°C on January 8 (DAY 104) at which time the temperature began to recover. This dip in the temperature profile reflects the time between the leaking of solutions outside of the crib and repair of the header.

Probe C 3.0 measured a steady drop in the core temperature from a high of 28°C at the start of the test to 18°C some 21 days later. From October 18 (DAY 21) until December 1 (DAY 65) the temperature at the core of the pile varied within 1°C of 18°C. After December 1, the temperature began to slowly drop as a result of the lack of irrigation. Ambient temperature spikes appeared to have little or no effect on the slope of the curve. Re-establishing the irrigation also had no effect on the temperature profile.

At 5.5 meters above the crib floor, 0.5 meters below the emitter lines, temperatures generally had similar trends as at 3.0 meters. Inflection in the curves caused by ambient air temperature swings were more dramatic. As with the deeper sections of the pile, the north, south and east sides slowly dropped to below freezing until the header was repaired.

Within five days after irrigation was re-established both the north and south probes began warming and eventually reached temperatures around 6°C. The east side of the crib did not show any sign of warming, indicating a lack of irrigation.

Temperatures measured at the centre of the pile closely reflected those of at the 3.0 meter level up until January 18 (DAY 113), after which time they steadily rose. The measured temperatures reached a low of 6.7°C before climbing back to a high of 20.5°C where they remained until the irrigation was shut off.

The probe against the western wall, W 5.5, had a similar profile to the one described for the 3.0 meter level. Daily temperature swings were more dramatic, corresponding mainly to daily temperature variations of the incoming leachate.

At 6.5 meters above the crib floor, 0.5 meters above the emitters, temperature profiles closely reflected those of the underlying material. The difference being that minimum temperatures observed were 7°C cooler than at 5.5 meters and the edges of the pile were frozen by November 23 (DAY 57). As before, when irrigation was re-established this layer began to warm, although the edges of the pile remained slightly below freezing.

At the centre of the pile, temperatures cooled to just above freezing before warming to 8.9°C. The slope of the warming portion of the profiles are shallower than those at 5.5 meters. The area around the western probe was excavated on December 28 (DAY 92). The bottom of the pit was covered with insulation, however, this probe was exposed to ambient air for the duration of the test.

Comparison of the above data indicates that the outside edges of the pile were subjected to lateral cooling even though the crib walls were well insulated. It is assumed that this lateral heat loss had minimal effect at the centre of the pile. As a result, only temperature profiles for the central string of thermistors are presented in Figures 6 through 8.

Temperature profiles for probes C.15, C 3.0, C 5.5 and ambient are shown in Figure 6 and for C 5.5, C 6.0, C 6.5 and ambient in Figure 7. These are expected to be typical of a commercial heap where irrigation is interrupted and then re-started. Note that between October 1 and December 1 the profiles are fairly flat reflecting the long term seasonal temperature variations.

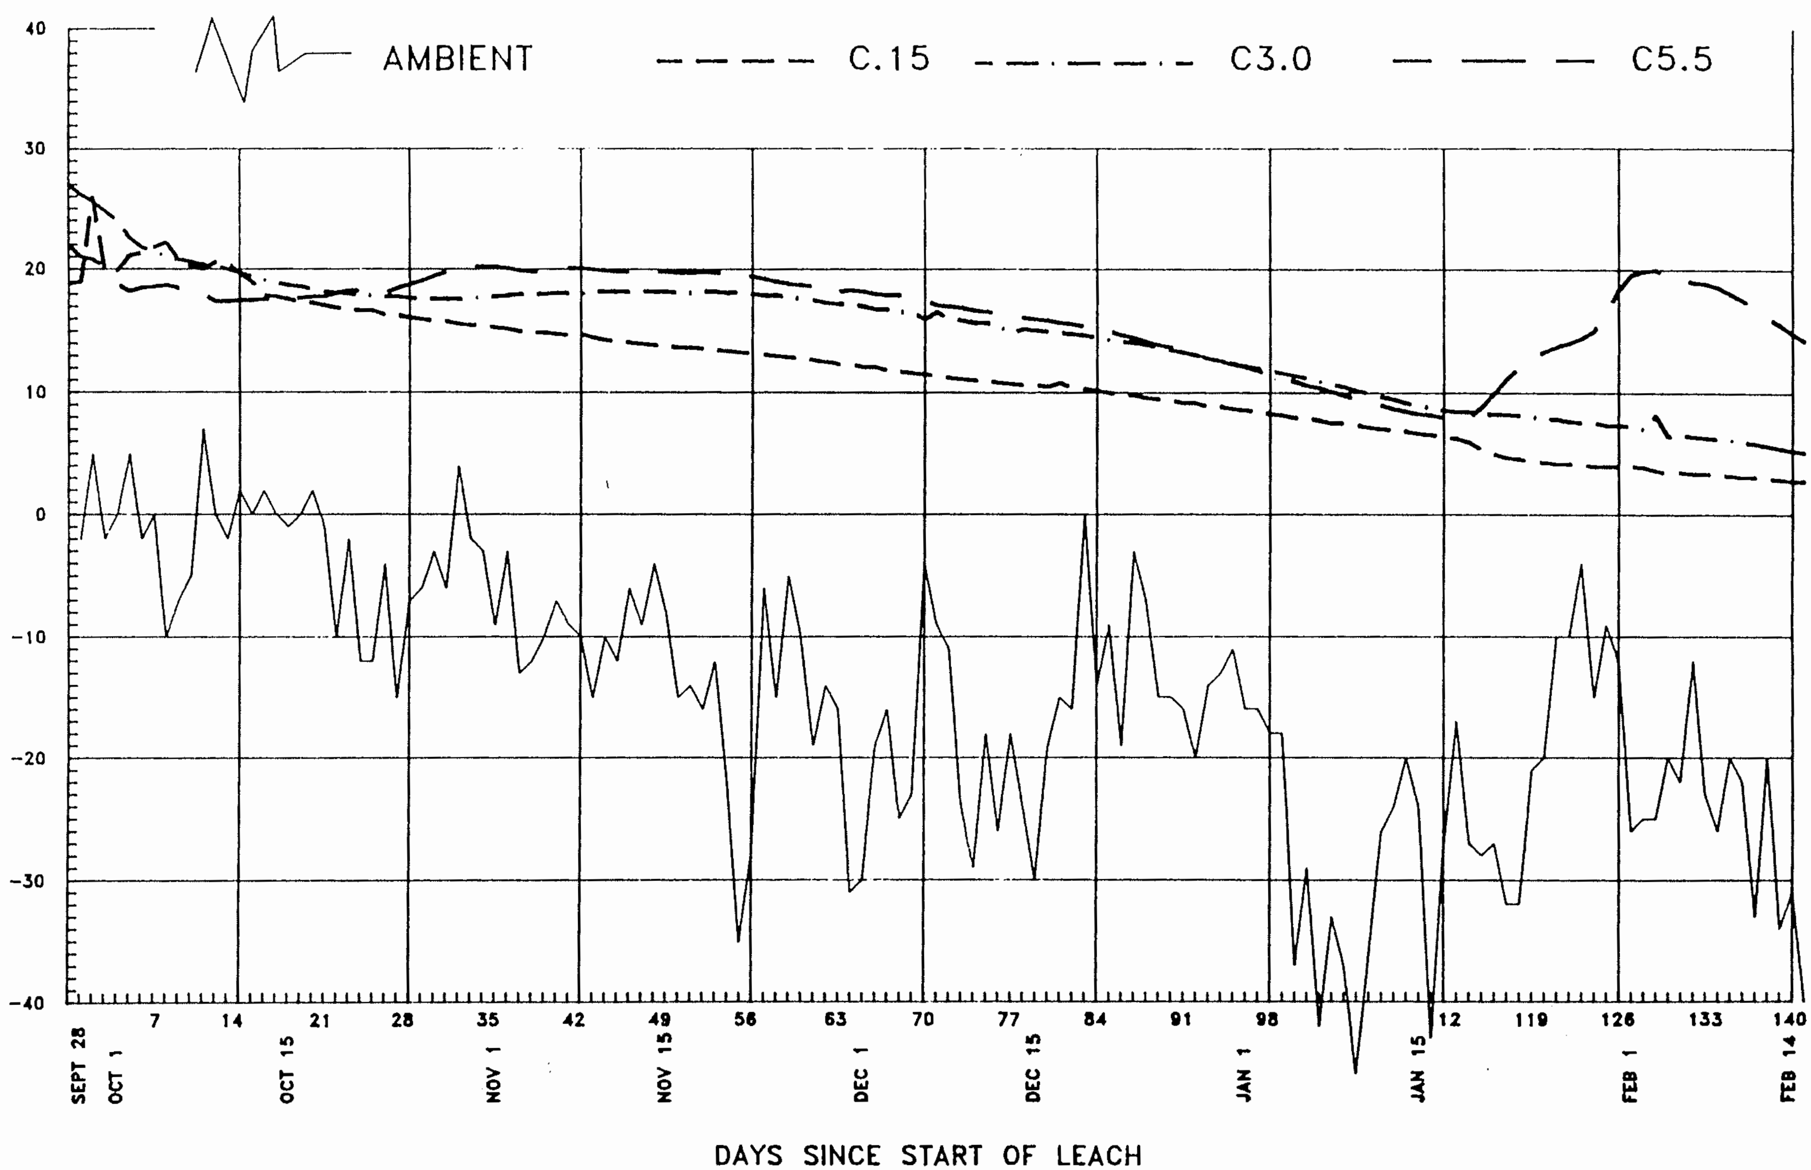

Figure 6: LEACH PILE TEMPERATURE PROFILES BELOW THE DRIP EMITTERS

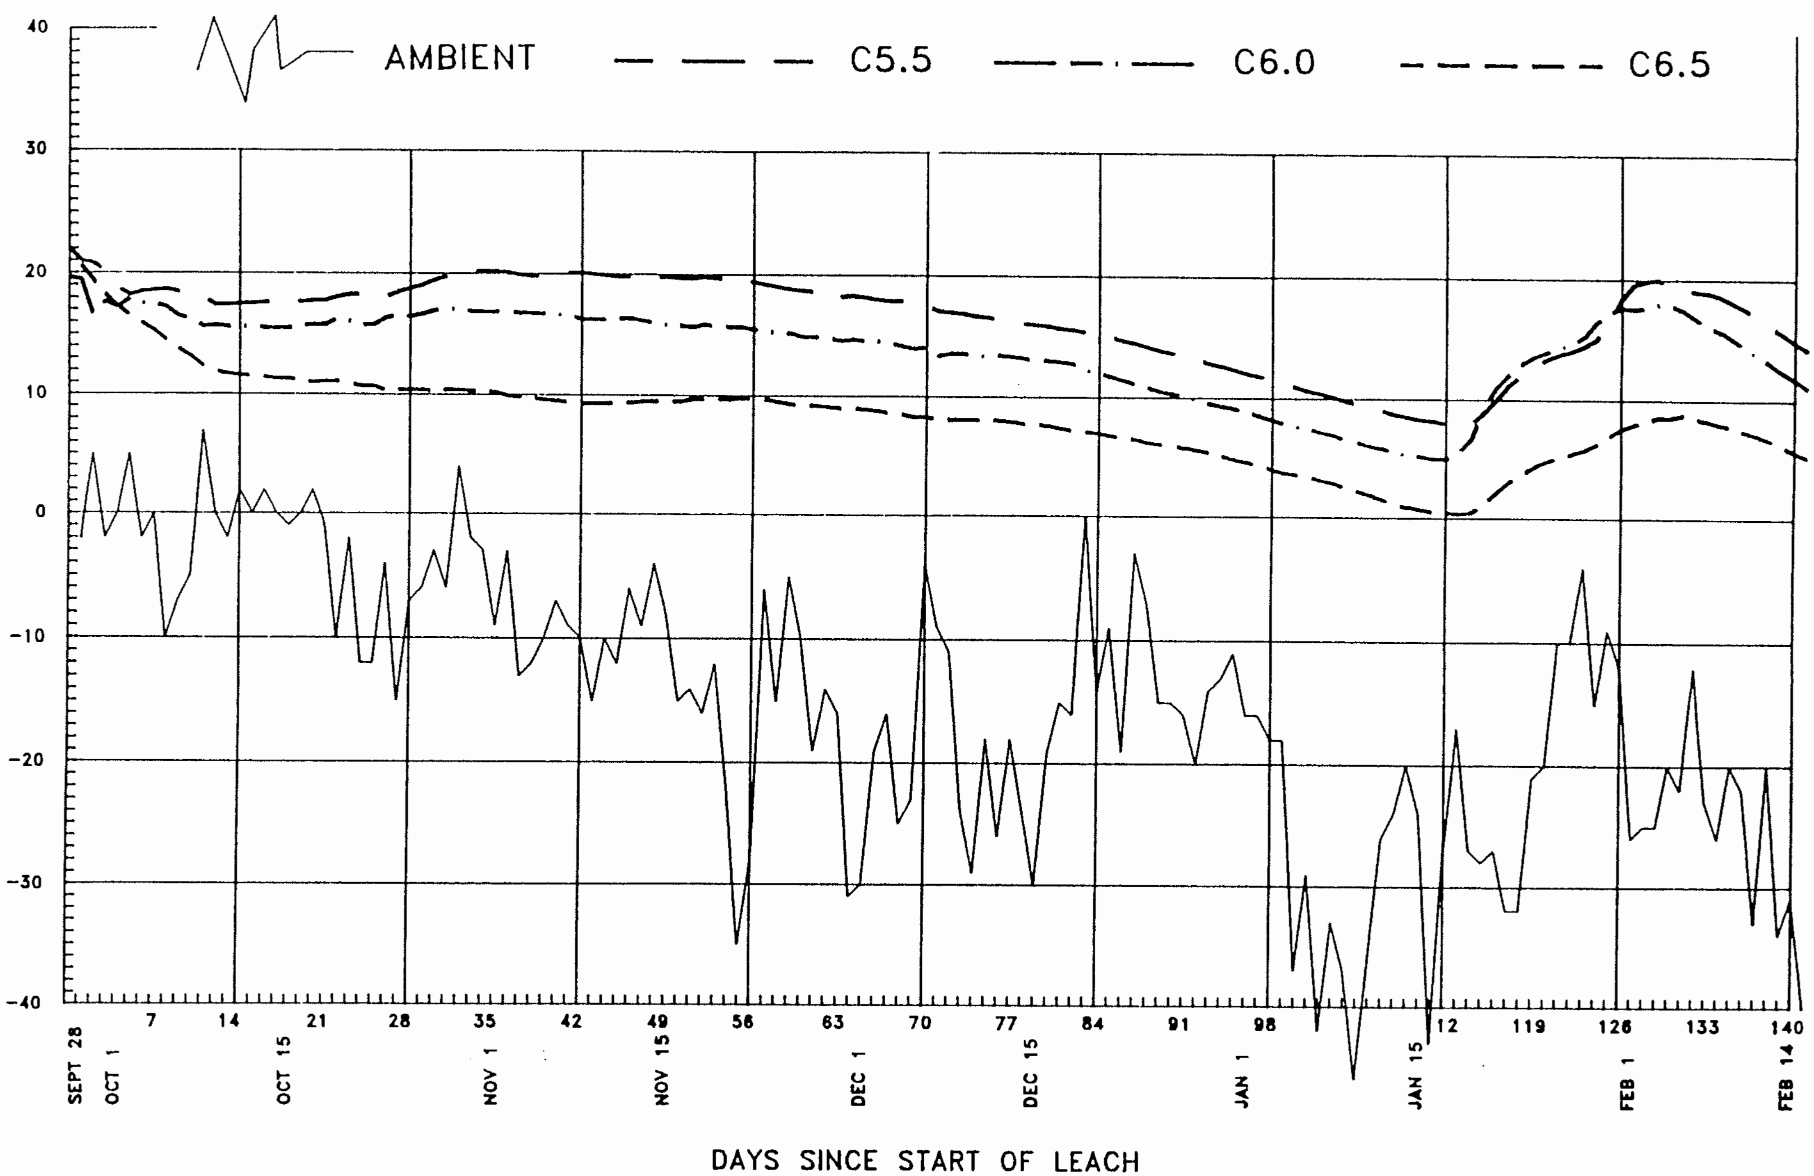

Figure 7: LEACH PILE TEMPERATURE PROFILES WITHIN 0.5M OF THE DRIP EMITTERS

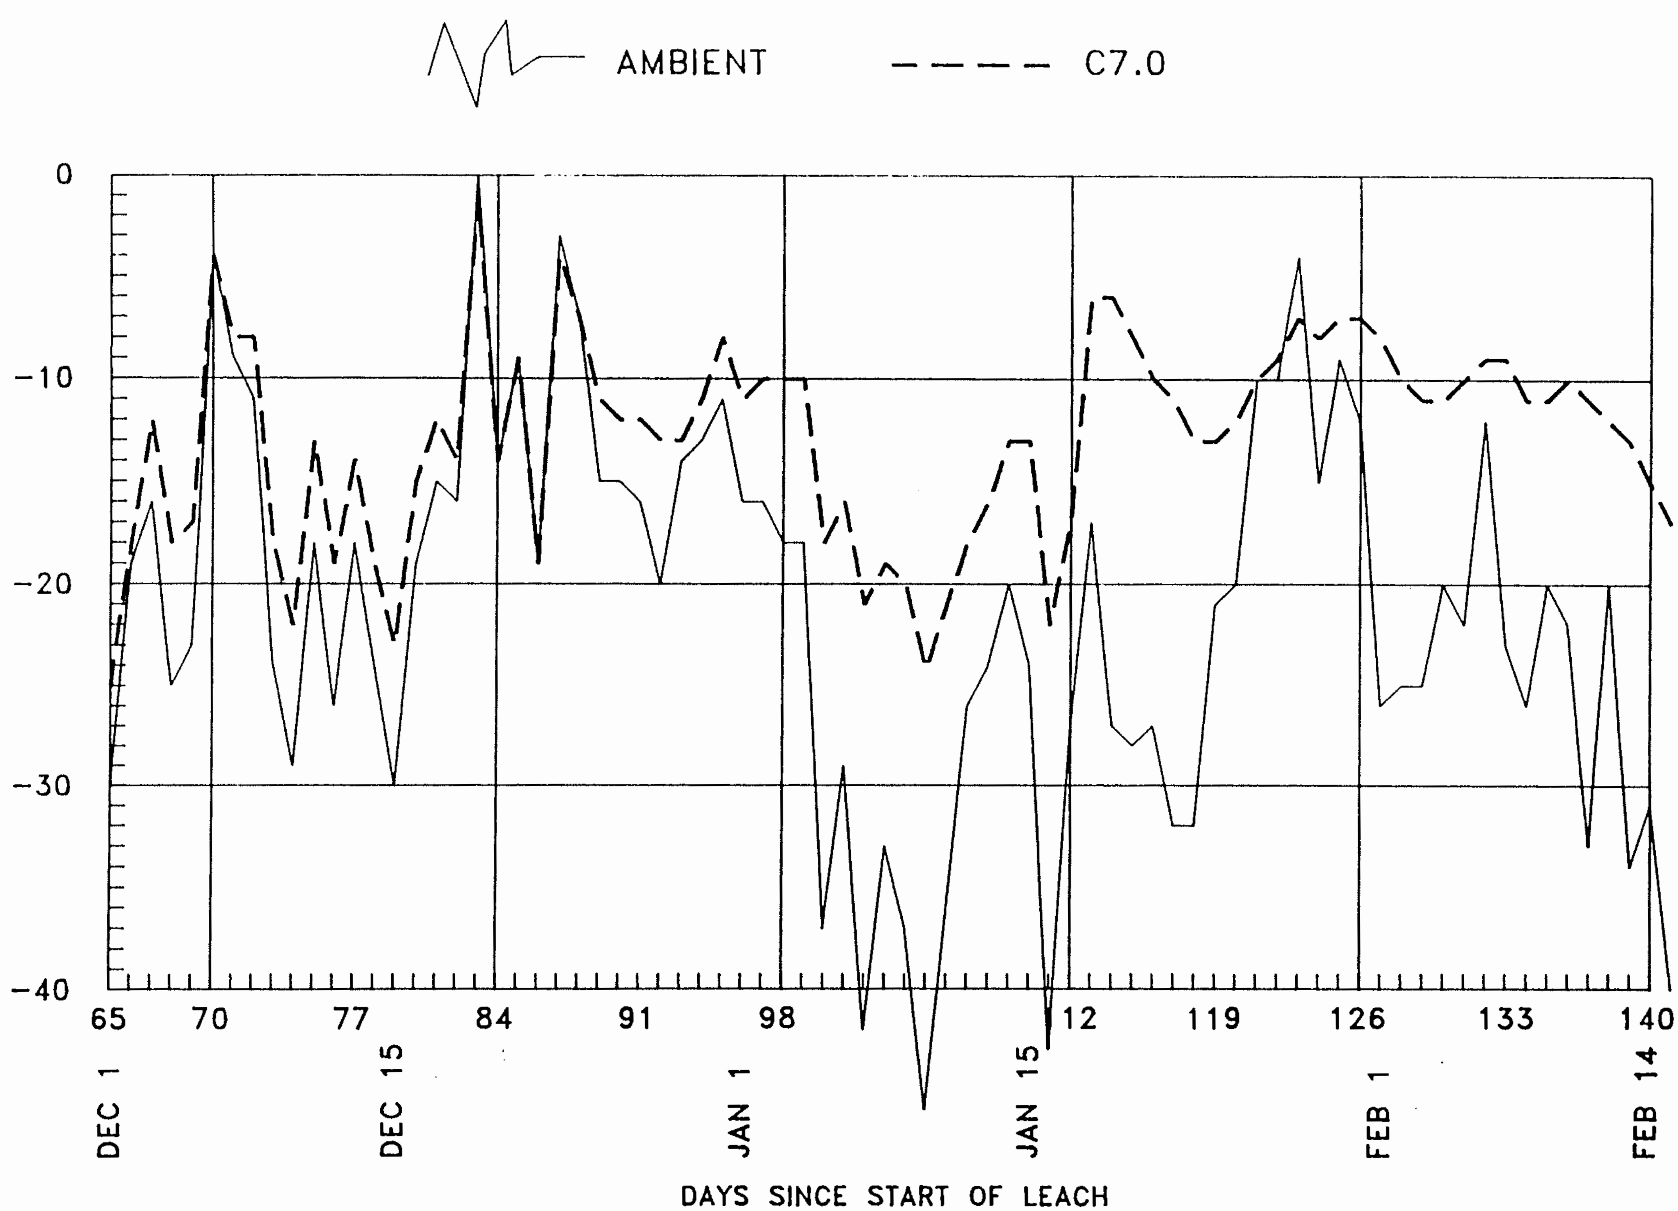

Figure 8: COMPARISON OF TEMPERATURES ABOVE AND AT BOTTOM OF SNOW COVER

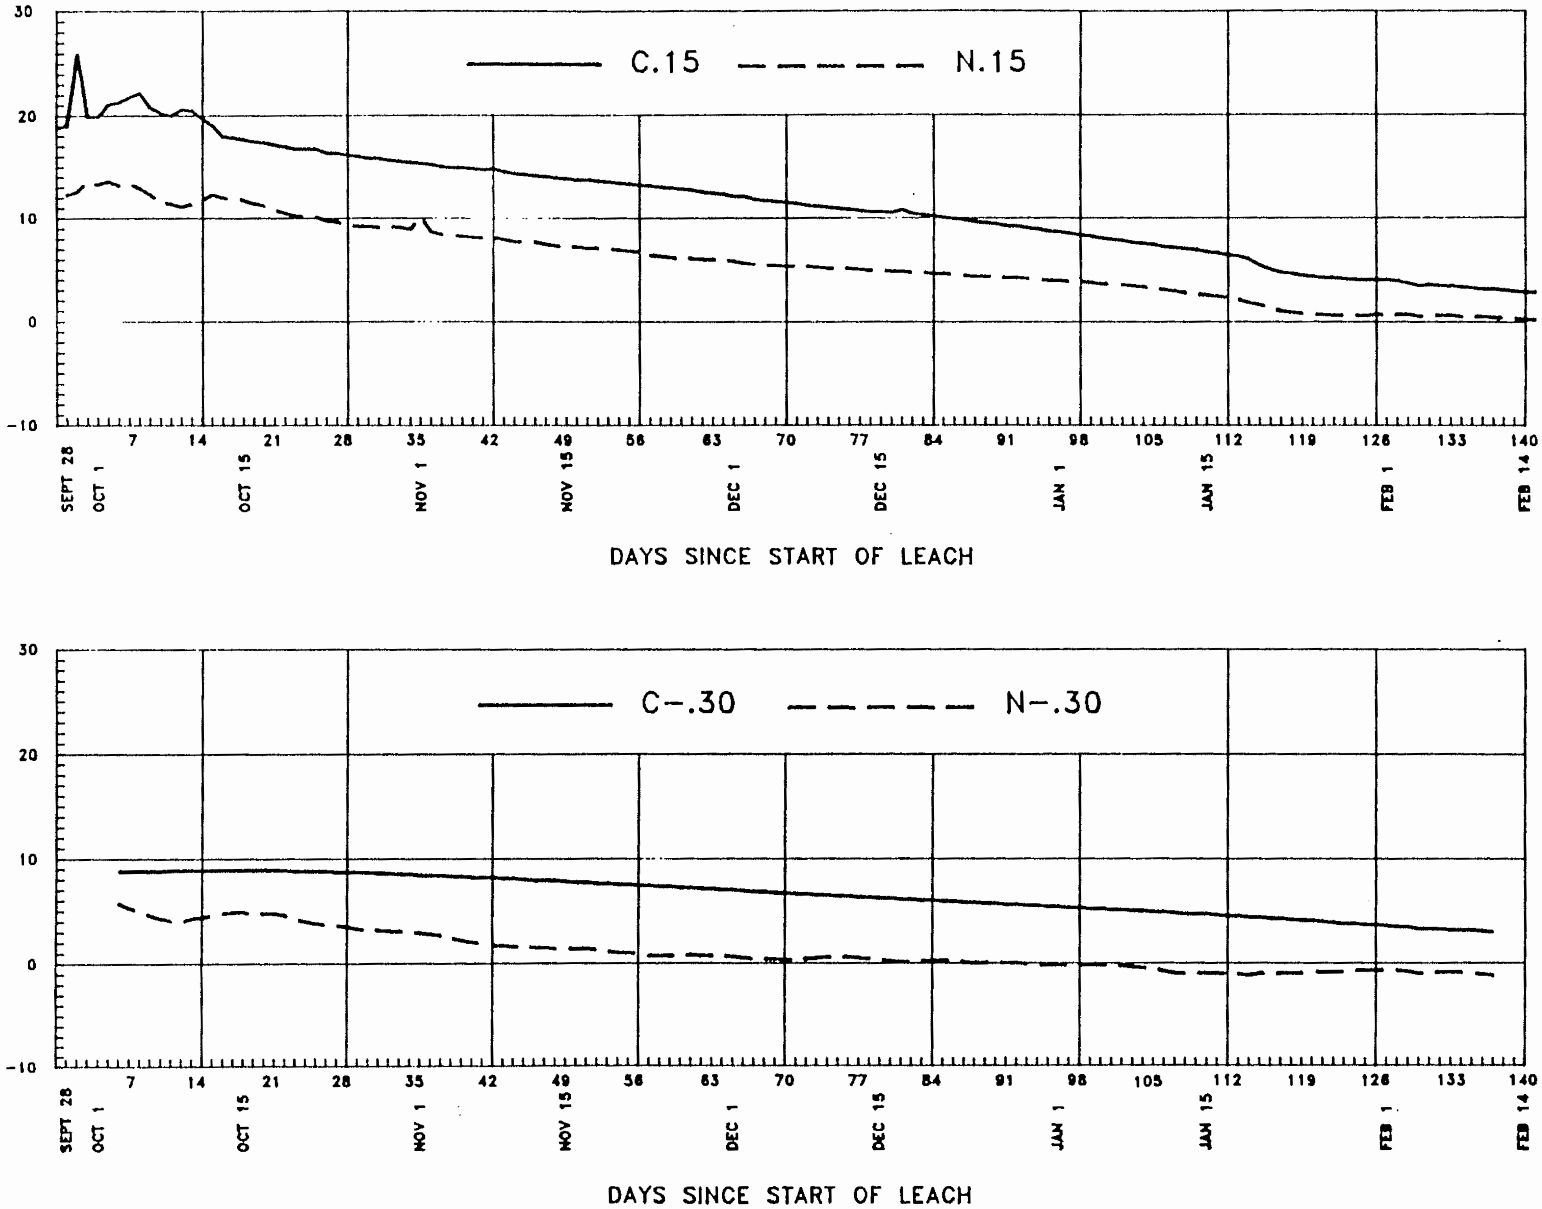

Figure 9: COMPARISON OF TEMPERATURES AT THE BASE OF THE LEACH PILE AND IN THE UNDERLYING SOIL

A permanent layer of snow did not accumulate on top of the pile until December 7 (DAY 71). The snow smoothed out the daily temperature variations as well as providing insulation. When the snow reached a thickness of 30 centimeters, the difference in temperatures between ambient air and the bottom of the snow averaged 8°C to 10°C. During periods of extreme temperature lows, this difference was as much as 20°C (-25.4°C vs - 45.2°C). Conversely, during an unseasonably warm period, the bottom of the snow layer was 3°C to 5°C cooler than ambient air. These profiles are shown in Figure 8.

Ground temperatures below the centre and north edge of the crib are shown in Figure 9. Temperatures at the base of the crib were equilibrating with those of the underlying soil. Presumably, as additional heat transferred into the soil these basal temperatures would slowly begin to rise.

CONCLUSIONS

The winter weather conditions in Faro and Carmacks were demonstrated to be similar. The daily average temperature during the test at Carmacks tracked closely with the average daily temperature over a six year period from Faro. This shows that the winter experienced in Carmacks was typical of the area in terms of severity.

The heap appeared to be a well behaved thermal system that responded normally to variations in heat flux. With the insulated sides, the heat flow was predominantly vertical into the air above and the underlying soils below. Lateral heat loss was monitored in the form of chilling along the sides of the crib. In a commercial operation, freezing would be restricted to the outside edges of the leach pile. Consequently, the conclusions of this study are drawn from the centre thermistor string which was relatively unaffected by lateral heat loss.

In the first half of the test, temperatures inside the pile varied only 2°C or 4°C. In fact between October 11 (DAY 14) and November 8 (DAY 42) core temperatures were on a steady increase. Continued drop in the ambient temperature reversed this trend. The pile did not begin to cool rapidly until irrigation was stopped by the break of the header. When irrigation was restored, temperatures quickly rose to their original levels. The rate of increase in the temperature was in part a reflection of an increase in the leachate temperature. When the leachate temperature was lowered, the warming trend continued until temperatures in the pile equilibrated with those of the leachate. Rates of cooling, similar to those during the time of no irrigation, were measured during the last seven days of the test when irrigation was stopped in preparation for plant decommissioning.

The exception to this trend were the temperature profiles at the base and 3 meters above the base of the crib. As seen on Figure 8, temperatures at the base of the leach pile equilibrated with those of the underlying soil. Emplacement of the leach pile prevented those soils from freezing except along the perimeter of the pile where frost crept in from the sides. The lack of warming at probe C 3.0 was presumably a result of restricted solution flow. Analysis of the post mortem pile inspection will be required to confirm this.

Figures 5 and 6 show that in the areas of active irrigation frost penetration into the top of the pile will be less than 0.5 meters if the drip emitters are 1 meter below surface. If irrigation is interrupted the surface of the pile will cool. Once irrigation is re-established, temperatures will return to levels experienced before the break in irrigation.

Freezing on the sides of the pile is not expected to exceed 4 to 5 meters. This is inferred from probe C 3.0 which is 4 meters below the top of the pile. At this point the temperature appears to be unaffected by ambient conditions. Even during periods of no irrigation, the slope of the curve was unchanged. Areas under active irrigation will experience less frost penetration into the sides than areas which are not.

Thawing of frozen areas in the pile may be achieved by irrigation. Areas on the sides of the crib froze due to lateral heat loss. The zone immediately below the header thawed once irrigation was re-established. Temperatures at the 3 meter level were slowly warming at the end of the test and presumably would have thawed.

This test demonstrated that the leaching procedures used by Pegasus Gold at the Zortman mine are applicable to sub-Arctic conditions. Burying drip emitters is an effective leach solution delivery system. Frost will not penetrate below the level of the emitters. A 30 centimeter layer of snow adds additional insulation which can create temperature differentials of up to 20°C between the top and bottom of the snow cover. The base of the heap will thaw and remain unfrozen except for a very limited area around the perimeter of the leach pile.

The test clearly demonstrates that year round leaching of Carmack Copper ore is practical. The heap appears to be adequately insulated by a 1 meter ore layer on top of the emitter system. Normal process heat should be sufficient to maintain a leachate return temperature of approximately 20°C. However, provisions should be made for supplemental heating in a commercial operation. This would permit recycling of the heated solution if electrowinning goes off-line or if there is a long run of exposed pipeline back to the heaps.
